May 2d, I was requested to visit Capt. E—, whose symptoms were very similar to those above stated. The urine, passed frequently in my presence, was turbid on being passed; it was occasionally alkaline, not sensibly so to turmeric, but when tested by litmus reddened by a very weak acid largely diluted; occasionally neutral; on remaining at rest for a time—24 or 30 hours—deposited a muco-purulent deposit, often intermixed with blood. Specific gravity varying from 1·019 to 1·022, but never becoming clear. No urea in excess, but if anything deficient. Earthy bases not superabundant. Exercise, such as walking rather fast, or an unusual distance, causes the voiding of a considerable quantity of blood, which falls to the bottom as a clot, while a portion of the red particles remain uniformly diffused through the urine; and a specimen passed on the 16th instant, and left at rest ever since, now the 28th, exhibits precisely the same appearance, viz. a portion of the red particles still uniformly diffused.

I examined the effects of a saturated solution of tartaric acid in excess in these cases. An effervescence took place; the urine, though clear, became cloudy, and gradually deposited a muddy-looking precipitate, but which evidently had not the crystalline appearance of bitartrate of potass, neither did it form or separate as this salt invariably does when suddenly and artificially precipitated. The precipitate collected, washed, dried, and heated over the spirit-lamp, became black, and deposited charcoal evidently from the decomposition of the tartaric acid. The ash, tested by an acid, feebly effervesced; on being urged by a stronger heat—the blow-pipe in a platinum spoon—it diminished in bulk, and ultimately became white. This white ash, applied to moistened turmeric paper, turned it of a reddish brown. Another portion, dissolved in acetic acid, but feebly diluted with water, without effervescence, and the solution yielded a precipitate when treated with oxalate of ammonia; nor was this precipitate dissolved by even concentrated acetic acid, *however considerable the quantity.* In a word, all the evidence

811.—XXXII.

tended to shew that the tartaric acid had precipitated the earthy tartrates, principally tartrate of lime, and that the proportion of the earthy bases was by no means great. The alkaline bases in these instances, if we except ammonia, seem to have been deficient. The ammonia, too, will perhaps account for the deficiency of urea, as it was probably derived from the conversion of this principle into carbonate of ammonia. It is evident, however, that there is a marked difference in both the sensible and chemical properties of the two specimens of urine in contrast with each other.

In these two cases I endeavoured to render the urine acidulous, by means, first, of hydrochloric acid, and, failing, I conjoined the phosphoric. After, as I conceived, a sufficient trial, and the urine still remaining neutral, I gave the benzoic acid in doses of fifteen grains three times a day. In the case of Capt. E. the urine was rendered acidulous on the third day, and continued so although left exposed for several days; and the benzoic gradually was reduced in dose, and he now feels tolerably well.

In the case of Mr. G., the same effect did not occur for two or three days longer, when I found the urine immediately on being voided acidulous, but becoming neutral in a time varying from 20 to 30 hours. However, the last time I examined this gentleman's urine I found it much improved, although still frequently intermixed with blood in very small proportions, but the intermixture of mucus much greater than natural, although now greatly reduced from what it had been.

From the circumstances just now detailed, I think we have every reason to infer that benzoic acid exerts a greater acidulating agency upon neutral or alkaline urine, than the acids upon which we have hitherto relied for this purpose. Thus the hydrochloric, and the phosphoric, though tried sufficiently, had not the desired effect; but in a comparatively short space of time after the benzoic acid had been administered, the urine in both these cases became acidulous; and exhibited this one of its natural characters the last time I had an opportunity of investigating the matter, and which was on the 23d instant. It is true that as hydrochloric and phos-

2 E

phoric acids had been given in the first instance, and continued at the same time with the benzoic, it may be a matter of question, and indeed one difficult to determine, whether any, and how much, of the acidulation can be justly attributed to each agent.

From the foregoing it is evident that the first case has no value whatever in a therapeutical point of view, but is highly instructive as shewing how easily we might be betrayed into errors, and of serious character. The two latter are of importance, and tend much to corroborate, or rather to confirm, the therapeutical principles laid down by Mr. Ure. No doubt they will excite to farther investigation, while the first will serve as a beacon to guard us against incautious induction, and satisfy us of the true mode of giving a real value to our researches, whether intended as philosophical investigations, or therapeutical facts and observations.

5, St. Vincent Place, City Road,
May 29, 1843.

ILLUSTRATIONS
OF THE
ALLEGED FALLACIES OF
AUSCULTATION, &c.

By H. M. HUGHES, M.D.

(For the *London Medical Gazette*.)

THERE are, perhaps, few, if any, members of the medical profession who would, at the present day, think it proper to assert that the practice of auscultation and percussion had not materially contributed to accuracy of diagnosis in thoracic, and in some forms of abdominal, disease. Facts almost innumerable would be adduced to confute such an opinion. But there are not a few who, while they concede to the stethoscope and plessimeter a limited praise, appear disposed to magnify their occasional failures, and relate, with a measure of exultation, the comparatively rare mistakes of those who take a higher estimate of their importance. Such persons are generally, either not in the habit of employing auscultation in their investigations, or, from physical defects or want of practice, are incapable of fully appreciating its advantages. They may, I think, be divided into those who are too old, or consider themselves too

experienced, to learn, and who, therefore, will not hear;—those who are incapable of distinguishing minute differences of sound and tone, and really cannot hear;—those who never tried to learn, and, consequently, do not expect to hear;—and those who, partly from want of education, and partly from deficiency of tact, combined with some obtuseness of auditory perception, hear imperfectly.

“Ah! Dr. Hughes,” said an old and really experienced practitioner to me, while examining the chest of a medical gentleman in a distant part of Sussex, “I am sorry I have not learned to use this new means of examination; I ought to have done so before, but I cannot do so now.” I gave a very decided opinion that our patient was suffering from acute tuberculous disease of the apex of the right lung, and prognosticated a not very distant fatal termination to his complaint. This opinion was received with kind deference, though opposed to one previously entertained. My senior friend subsequently told me in private that, as our patient had already been in confinement, he feared disease of the brain more than of the lungs. In about two months he died from rapid consumption.

“I really cannot hear it,” said a gentleman whose attention was directed to a particularly well-marked pleuritic rubbing, which was clearly audible by a number of pupils who immediately afterwards examined the patient. This gentleman, however, acknowledged that his ear is far from being delicate in reference to other, and especially as to musical, sounds.

“As to your pericardial sounds,” said another, “I don’t believe a word about them.” “Have you ever heard the rubbing noise which is supposed to have its seat in that membrane?” “No, I never tried.” A case was pointed out to him in which the sound was especially harsh and superficial. He acknowledged it was *strange*, and different from any thing he had heard before. This patient recovered, and, when adhesion had taken place and the sound had disappeared, was again examined by the same individual. Another patient, however, in the wards nearly at the same time, with exactly the same physical signs, died, and was examined after death. The pericardium, covered with rough solid deposit, was shown to

him, and he was convinced, not only of the reality of the sound, but also of the correctness of the usual explanation of its origin. He believed in the existence of a pericardial rubbing; no longer thought it *strange*.

A fellow pupil, now dead, having very considerable talent, but comparatively little experience as an auscultator, and not possessing the advantage of a fine ear, was accustomed, publicly, to dispute the reality of the sound last referred to, which had then been only recently discovered, but which has since proved such an invaluable aid to the diagnosis of pericarditis. But the principal or only reason he was accustomed to assign for his incredulity was that *he* could not distinguish it from the bellows murmur or other sounds arising from diseases of the valves. I am not aware whether his opinions upon this subject were in any respect changed or modified before his death.

The preceding are genuine, and may, perhaps, be regarded as fair examples of persons who, though not actual objectors to, or detractors from, the merits of "physical diagnosis," believe that its importance has been too highly extolled, and its advantages exaggerated.

That opinions founded upon the practice of auscultation and percussion, as upon every other mode of investigation, are liable to error, is of course readily conceded; that mistakes sometimes occur to the most experienced is undeniable; but they are frequently, perhaps generally, attributable either to want of experience or the too hasty conclusions of the auscultator.

To employ these *aids to diagnosis* with advantage, they should be used constantly and for a long period: a protracted education is required: in them, as in other arts, practice is necessary for perfection, and repeated examinations are often indispensable to correctness. Yet the mistakes of the inexperienced are sometimes referred to as the fallacies of the art itself, and opinions, unwillingly given after a single explanation, are advanced as proofs of its imperfections.

Though it may not be correct to say that in all cases, and under all circumstances, the auscultatory or other physical signs should be regarded as the mere handmaids of the general symp-

toms, as many cases might be adduced in which a correct diagnosis has been founded upon the former independently of the latter, yet is it incumbent upon the practical auscultator diligently to weigh every feature, and each attendant circumstance, of the complaint under investigation, and in all cases to exercise his judgment as well as his hands and his ears. The stethoscope and plessimeter should in most cases be regarded as very important adjuvants to the other means of arriving at a correct conclusion as to the nature of a malady, rather than as instruments for their exclusion. Mistakes have perhaps sometimes arisen from neglect of these considerations: the physical indications have been too implicitly trusted, and the history and general symptoms have been too lightly esteemed. Fallacies also sometimes arise from a disregard of the fact, which should ever be borne in mind, and which has been recently forcibly stated by a lecturer on clinical medicine, that physical signs, with very few exceptions indeed, are indicative not of particular diseases, but of physical conditions. Thus metallic tinkling indicates the presence of an admixture of gas and fluid in a circumscribed space, and may exist in pneumothorax, a large vomica, or a distended stomach.

Fallacies are also not unfrequently attributed to auscultation, in consequence of changes taking place in the diseased organ subsequently to the examination, and to the expressed opinion of the physician. After death fluid is found in the pleura, or consolidation of the lung, or a cavity is discovered, the presence of which had not been ascertained, for the simple reason that it did not exist at the time of examination. Rapid changes occurring a short time before death are far from uncommon, and unfounded charges of the fallacies of auscultation in consequence are, I am convinced, not unfrequent.

I shall now relate some cases occurring under my own notice, in which, with due consideration of the history, general symptoms, and physical signs conjoined, fallacies, apparent or real, might have existed, without affecting in the remotest degree the credit of the auscultator.

CASE I.—Disease of the lung; history, symptoms, and some of the physical signs, those of empyema and pneumothorax.

E. G., aged 32, a small woman of light complexion, married, and the mother of several children, was admitted into Guy's Hospital, Oct. 5, 1842. Two years before she had been a patient of the Surrey Dispensary, under my care, suffering from what was believed to be empyema, or at least chronic pleuritic effusion. She had some weeks before I saw her been attacked with pain of the side, which was then enlarged and bulging, quite dull on percussion, and inferiorly afforded no traces of natural respiration. She continued under my care for about a fortnight only, during which she certainly improved considerably by the use of blisters, slight mercurials, and tonics. She then went into the country for two weeks, and continued to improve for two months subsequently. She became pregnant, and during her pregnancy, which terminated in the birth of a living and healthy child, she suddenly expectorated a large quantity of foetid yellow matter. Expectoration of the same kind of matter had continued, and had caused gradually increasing debility up to the date of her admission into the hospital. She was then considerably emaciated; her face was pale, her features contracted, and the expression of her countenance somewhat anxious. She lay upon the back, with considerable inclination to the right side; her cough was not frequent except upon motion, but was constantly induced by turning towards the left side, and was accompanied by an abundant expectoration, which streamed from her mouth almost without effort, and which consisted of a sero-purulent fluid, yellowish, homogeneous, frothless, foetid, and of the consistence and tenacity of thin gruel. She had no pain, and appeared in tolerable spirits, and of a quiet contented disposition. She had never suffered from hæmoptysis, but was occasionally troubled with diarrhoea, and was liable to hectic flushes, especially of the left cheek, and in the afternoon. She perspired considerably at night; and though she continually felt drowsy (perhaps from medicine administered), *she slept but little.*

Physical signs —The entire left side of the chest, both before and behind, afforded very good, perhaps greater than the natural, resonance on percussion; and throughout its whole extent the respiratory murmur, a little increased in intensity, but quite free from rattles or other morbid sounds, was distinctly audible. The right side was considerably altered in form, was flattened below the clavicle, and raised very imperfectly during inspiration. The resonance upon percussion anteriorly was generally less than natural, but in no part could extreme dullness be discovered, while in the inferior lateral region there occasionally, but only occasionally, existed tympanitic resonance. Posteriorly this side was scarcely dull, but not so resonant as the left. Throughout the whole of the upper part of the right side, both before and behind, was distinctly heard a loud and shrill gurgling, possessing at some parts, particularly below the inferior angle of the scapula, a tolerably pure metallic character; while in the lower parts was heard a loud, shrill, and loose mucous rattle. The voice also was loud, shrill, and ringing, throughout the whole of this side, but especially at the upper part. The patient was too feeble to attempt succussion. The sounds of the heart were natural, and were audible in the præcordial region, but were most distinct between the cartilages of the second and third ribs of the right side, where alone the impulse could be felt, and where the apex of the organ appeared constantly to strike the thoracic parietes. She was ordered ten grains of compound chalk powder, with opium, in a draught containing ammonia and gentian, every six hours. A mutton-chop, two eggs, and six ounces of wine daily, and subsequently an opiate enema at night, as the diarrhoea was not effectually checked by the medicine previously prescribed. She obviously improved under this treatment, and appeared to gain flesh; but as she continued to sleep badly at night, half a grain of opium, with ten grains of compound chalk powder, was ordered to be given at bed-time, in addition to her other medicines.

On November 6th Mr. Stocker was called to her on account of a severe pain of the left side, and ordered a

mustard poultice to be applied, and a pill containing antimony, opium, and a grain of calomel, to be given directly, and to be repeated every four hours if the pain continued. The next day the pain was relieved; and as she had no fever, and no increase of cough, but was still troubled with diarrhœa, and too low for physical examination, she was ordered ammonia and decoction of bark, with twelve grains of confection of opium, every six hours, and half a grain of opium if the pain returned. She now became more depressed; she had no cough; her skin was generally moist; and she died rather suddenly during the night of November 10th.

Inspection eleven hours after death.—The head was not opened. Thorax: On raising the sternum the heart was found to occupy nearly its natural situation. The left pleura was slightly adherent inferiorly by tender false membrane, evidently the result of recent pleuritis. The left lung was large, and about its inferior half was of a palish red colour, fleshy and œdematous, from recent pneumonia. The upper half was tolerably healthy, and, as well as the inferior, was free from tubercular deposit. On the right side the lung was so firmly adherent to the costal pleura, except over a small space inferiorly, where there existed only a few old bridges, as not to be detached without tearing away that membrane. The right lung was much contracted; the upper third was of a dark iron-grey colour, dense, and without air, except in that contained in some enlarged bronchial tubes. One or two small cavities existed therein, filled with dirty yellow pus, around which the lung was soft, friable, and uneven. The inferior two-thirds of the lung contained a number of cavities of different sizes, in the midst of a dirty gray-coloured consolidated pulmonary tissue, quite devoid of air. Among these cavities, as they appeared upon an incision being made into the organ, were some evidently produced by the section of greatly dilated bronchial tubes; others, varying in size from a pea to a pullet's egg, communicated freely and by large openings with the bronchial tubes, but were lined with a soft, loose, flocculent, but not decidedly membranous substance, which alone separated them from the pulmonary tissue. These were generally of a

rounded or oval form. One, however, appeared to differ from all the rest: it was situated about the centre of the organ, rather posteriorly; it was of the superficial extent of the palm of the hand, very shallow, and so close to the surface as to be covered only by the thickened pleura, or at most by an exceedingly thin layer of the tissue of the lung, *if indeed any could be proved to exist.* Its internal surface was smooth and polished, crossed by thick bands, and was continuous with the lining of the bronchial tubes, several of which communicated with it by large openings. The whole of these cavities *were quite empty*, excepting those in the upper lobe, which appeared not yet to have opened into the bronchi. Abdomen: The liver was pale, and the right acute edge elongated, coarse, and tumid. The kidneys were firm, and slightly granular; the ovaries hard, wasted, and rugous; and the other organs examined natural.

Upon a review of all the circumstances connected with this rare and very interesting case, it will be observed that almost every thing tended to support the notion that the disease was empyema with pneumothorax. The history and general symptoms in particular appeared alone sufficient to mark the origin and nature of the complaint. The pain of the side, the bulging and immobility of the part affected, the subsequent sudden and copious expectoration of matter, and the excretion of the same for many months, seemed especially to attest the probability of that disorder. The physical signs, though imperfect in some respects, might be supposed not unnaturally to confirm, or certainly not to oppose, the diagnosis derived from the general symptoms. The mis-shapen and contracted parietes, the partial dislocation of the heart, the loud and ringing voice, the shrill metallic gurgling, the occasional tympanitic resonance, were in its favour. It is true that the extended, marked, and continued tympanitic resonance upon percussion, often supposed to be an invariable and almost a necessary sign of pneumothorax, did not exist. But independently of those related by others, I have myself seen, and have notes of, a well-marked case of pneumothorax, in which at no period while the patient remained

under my observation was there even the natural amount of resonance upon percussion. It is also true that the phenomena produced by succussion were not ascertained to exist. These, however, might have been present, though a feeling of humanity towards the suffering and debilitated patient would not permit her attendants to make an attempt to produce them. Upon examination after death, no empyema, no pneumothorax, was discovered; and though the physical signs were admirably and beautifully explained by the physical conditions that were found to exist, and though the history and general symptoms might properly cause under ordinary circumstances those physical signs to be attributed to empyema and pneumothorax, yet might the case be adduced as an illustration of the fallacies of auscultation. In respect to the true morbid anatomy of the disease, as well as to its pathology, different opinions existed. Some believed that all the cavities, of whatever shape and size, were in truth dilated bronchial tubes, and others that they originated in the softening of a diseased lung. My own belief is, that neither opinion was exclusively correct—that both conditions clearly existed; that in fact the case had been one of pleuro-peripneumony, and that it was a genuine example of chronic pneumonia, with softening and dilated bronchial tubes, without a trace of tubercle; and that it is even highly probable that the large superficial cavity, with scarcely any covering but the pleura, and perhaps with that of the costal pleura alone, had been an empyema which had communicated with the bronchial tubes, the air from which had not extended into the general cavity of the pleura, in consequence of the old and firm adhesion of that membrane. It is, however, sufficient for my present purpose to show that the physical state was exactly indicated by the physical signs, that there existed a large cavity containing air, freely communicating with a large bronchial tube immediately under the costal pleura, and that this was clearly indicated by auscultation. Two other circumstances are worthy of notice before closing the remarks upon this interesting case. All the cavities in the lung that opened into tubes, and all the tubes themselves, were found

empty after death, though the expectoration during life had been profuse. The heart, which had been distinctly and constantly felt pulsating between the second and third ribs upon the right of the sternum, drawn over by the contraction of the diseased side, assisted probably by the increased action and development of the left lung, was found after death, and when that lung had collapsed by the admission of air upon the thorax, in its normal position.

[To be continued.]

CASE OF MENINGITIS.

BY CHARLES VINES, Esq.

Surgeon to the Reading Dispensary.

(For the London Medical Gazette.)

THE following case, in which depletion to an unusual extent was necessary, affords also a few other points of interest.

Elizabeth Joseph, æt. 19, a servant, of plethoric habit and nervous temperament, who had enjoyed a good state of health up to June 7th, 1842; was seized at 10 in the morning with rigors, and shortly afterwards with headache and fever. She was visited for the first time at 8 in the evening, and presented the following symptoms. She was in bed lying on her back, and complained of severe lancinating pains in the forehead and back part of the head; the face and neck flushed; slight protrusion and wildness of eyes; pupils dilated and insensible to light; head very hot; carotids and temporal arteries throbbed violently; tongue rather coated, but moist; skin hot and dry; respiration hurried, unusual quickness of hearing and speech; nausea; pulse 130, sharp, contracted, and intermittent; bowels had been open during the day.

Treatment.—Bleeding from the arm in the upright posture. After the removal of 36 ounces of blood faintness was induced, and the symptoms were much relieved. The head to be shaved and an evaporating lotion to be continually applied. To take the following powder directly:—

R. Hydr. Chlorid. gr. vi.; Pulv. Jalap. gr. xv. M. ft. pulv.

After the powder had operated, the pills and mixture as follows:—

R Hydr. Chlorid. ; Pulv. Antim. aa. gr. xij. ; Conf. q. s. ft. pil. vj. Cap. unam 4tâ quâque horâ.

R Liq. Ant. Potas. Tart. 3vj. ; Magn. Sulph. 3ij. ; Aq. Men. sat. ad 3vj. M. ft. mist. Cap. coch. ij. mag. 2dâ quâque horâ, post sing. pil.

The diet to consist of gruel, tea and toast, and water.

8th, 9 A.M.—Had passed a sleepless night, had been restless and incoherent ; all the symptoms as yesterday ; bowels had been open ; no sickness produced by the antimonial mixture ; blood taken yesterday highly buffed and cupped. So long as the faintness induced by the bleeding continued, the symptoms were relieved ; but on reaction taking place, they again recurred.

Ordered another full bleeding, and 30 ounces were taken. To continue the medicines.

9 P.M.—The bleeding relieved the head, as before, about four hours, when the pain returned ; and this evening all the symptoms were aggravated. The pulse had become rapid and thready ; pain in the head excessive ; the blood taken in the morning was cupped, and exhibited the buffy coat. The vein of the arm was again opened, and 16 ounces of blood removed, which relieved the head slightly. Cupping at the back of the neck was then resorted to, and 16 ounces were taken. This last abstraction of blood had a most decided effect over all the symptoms. The pupils immediately acted freely ; the pulse became soft and fell to 90 ; the pain in the head was quite relieved.

To continue the calomel and antimonial mixture, and a blister to be applied to the crown of the head.

9th, 9 A.M.—Had slept well at intervals during the night ; had been quite free from pain ; complained of lightness and giddiness of the head ; pulse 100, fuller, but rather sharp ; respiration less hurried ; pupils natural ; bowels open ; tongue clean ; skin moist ; expressed herself much better.

To continue the medicines.

9 P.M.—The former symptoms had again returned, viz. the quick thready pulse, with pain in the head. Took 12 ounces of blood from the arm.

10th. — Has had no sleep ; been very

restless ; vomiting several times ; suspect improper food was taken yesterday ; pupils dilated and sluggish ; pulse 100 and thready ; spasmodic twitchings of the arms ; pain at the back part of the head ; pain in bowels with tenesmus.

To discontinue the calomel and antimony.

Took 12 ounces of blood from the arm ; directed a mustard poultice to be applied to the bowels, and ordered the following mixture :—

R Potas. Bicarb. 3ij. ; Pulv. Tragac. Co. 3j. ; Sp. Ether Nitr. aa. 3j. ; Aq. Men. sat. 3vj. M. ft. mist. Cap. coch. ij. mag. 4tâ. q. h.

11th.—Has had no sleep ; bowels open twice during the night ; pupils act better ; pulse 90 and soft ; catamenia made its appearance, being a fortnight before the proper period ; pain in head and bowels relieved ; symptoms altogether better.

12th.—Slept five hours during the night ; general condition of the patient improving.

13th.—Slept well ; the bowels confined. Ordered the following mixture :—

R Magnes. Carbon. 3j. ; Magnes. Sulph. 3iij. ; Sp. Ether. Nitr. 3j. ; Aq. Men. sat. ad. 3vj. M. ft. mist. Cap. coch. ij. mag. 4tâ. q. h.

14th.—Passed a good night ; bowels had been open twice ; going on well.

15th.—Going on favourably.

17th.—Passed a sleepless night ; complained of pain in the head and right side ; head hot ; pupils again dilated ; pulse 100, and thready ; appeared strange and incoherent in manner ; countenance vacant ; answered slowly to questions ; skin hot and dry ; bowels confined.

Bled to 16 ounces. To repeat the calomel and antimony. A blister to be applied to the nape of the neck, an evaporating lotion to the head.

18th.—has had no sleep ; symptoms nearly the same as yesterday.

Ordered a blister to be applied to the whole crown of the head.

19th.—Passed a better night ; symptoms generally relieved. From this period a gradual restoration to health took place, and in two months the patient was enabled to resume her former situation. In the course of her recovery, occasional blisters were applied

to the temples and behind the ears, and a due caution observed with regard to diet and the regulation of the bowels.

OBSERVATIONS.—A peculiarity of some importance in the symptoms of this patient was, the occurrence of dilated pupil and insensibility to light at so early a stage of the disease. It cannot be supposed that this amaurotic condition of the eye was produced by effusion, or other more general symptoms of coma would have been present; but we must, I think, infer that it arose from a plethoric or congested condition of the vessels immediately supplying the ophthalmic apparatus exerting an undue pressure on the retina and optic nerve; the origin of this cause being arterial excitement, just as in the first stage of cerebral inflammation, we may have in one case extreme acuteness of the auditory nerve, in another extreme dulness, admitting, I believe, of explanation on similar principles.

Another symptom worthy of notice, was the peculiarly rapid pulse, as though receding from beneath the finger. The abstraction of blood from the nape of the neck appeared to afford much more decided relief than general blood-letting, and would have been repeated but for the strong objection of the patient; and here I refer with great pleasure to the excellent lectures lately delivered by Dr. Burrows before the College of Physicians, in which he has demonstrated that the brain does actually contain more blood at one period than at another, and consequently that local depletion, when properly applied, must have the effect of diminishing vascular plethora, and, as a necessary consequence, vascular pressure within the cranium. In accordance with these views, I would suggest that in severe cases of cerebral congestion, or inflammation, where it is desirable to produce a most decided and speedy effect on the vascular condition of the brain, and where a general blood-letting has failed to effect this important object, that the abstraction of blood by cupping on the vertex of the head, or nape of the neck, is a preferable plan to the application of leeches, or the opening of the temporal artery, the cupping-glass being applied in all cases where practicable to the crown of the head, at the junction of the lambdoidal and sagittal sutures. *It will be remarked in the preceding*

history, that two or three relapses occurred, attributable, I believe, to improper diet; so complete is the sympathy between the head and stomach. The close contiguity of the brain to its investing membrane renders it probable that those cases are rare in which inflammation exists in one tissue without the adjacent one being, to a certain extent, implicated. The hitherto imperfect state of our knowledge in this branch of pathology ought to stimulate us to increased exertion and most attentive observation, in every case that may occur to us. The experienced Dr. Abercrombie, to whom we are so much indebted for our present knowledge of these diseases, confesses that we are often at a loss to distinguish the true origin of the symptoms.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Practical Remarks on Gout, Rheumatic Fever, and Chronic Rheumatism of the Joints, &c. By R. B. TODD, M.D. &c. London, 1843. 12mo. pp. 216.

THIS sensible and judicious work is the substance of the Croonian Lectures delivered this year at the College of Physicians. Dr. Todd's object is to show that rheumatic fever and gout are diseases of the blood; his book, however, is by no means limited to the proof of this proposition, but is full of practical hints.

We are much pleased with the author for insisting on the importance of studying the natural history of disease; without which we cannot assign their due shares to nature and to medicine in its cure.

Some of the points in the following extract are far from universally known.

“The sebaceous glands are not so numerous [as the sudoriferous ones]; they are most abundant in the vicinity of hairs. Their form is that of small vesicular bags, which open by minute orifices into a hair follicle, or quite close to one. When sebaceous matter is suffered to accumulate in these glands, a peculiar disease of the skin is induced, called *acne*, which often shows itself on the face, nose, or forehead, and very frequently on the back;

In a simple form the accumulations are denoted by numerous black points, produced by particles of dust being entangled in the sebaceous matter, which chokes the orifices of the glands. The skin around them will often inflame, and angry pustules result.

Nothing favours the excretion of this sebaceous matter so much as cleanliness and friction. If any additional arguments were wanting to enforce the propriety of adopting means for these purposes, it is derived from the curious, and in some measure humiliating, fact lately discovered by Dr Simon of Berlin, that these glands are the habitat of a parasitic insect, which has been called the *entozoon folliculorum*. This creature is of considerable size, and may exist alone, or in clusters of several, in a single gland. In the perfectly healthy state they are few in number; but when sebaceous matter, their proper food, is suffered to accumulate, they abound. Through the kindness of my friend, Mr. Erasmus Wilson, who has lately read a paper to the Royal Society on their structure and habits, I have been enabled to see the insect alive and had a favourable opportunity of watching its movements, as well as carefully observing its form and structure. Cleanliness and friction remove sebaceous matter, and, therefore, oppose the accumulation of those insects; and the local application of a solution of corrosive sublimate is often very beneficial in removing the points of *acne* which result from the retention of the sebaceous secretion."—p. 84-5.

Austria: its Literary, Scientific, and Medical Institutions. With Notes upon the present State of Science, and a Guide to the Hospitals and Sanatory Establishments of Vienna. By W. R. WILDE, M.R.I.A. &c. Dublin, London, and Edinburgh, 1843. 8vo. pp. 325.

AMONG the subjects treated of by Mr. Wilde, are the present state of science in Vienna; the great General Hospital; public clinical instruction; the young school of Vienna; auscultation, and pathological anatomy; syphilis; the lunatic asylum; midwifery and the lying-in hospital; the foundling hospital; the veterinary institution, and Josephinum Academy; homœopathy, poor laws, and minor hospitals of

Vienna; and the general and medical statistics of the Austrian empire.

The general hospital contains 2,214 beds, and receives from 18,000 to 20,000 patients annually.

The lying-in hospital forms part of the general one, and the mortality in it is quite frightful. Of 4453 women admitted in 1838, no less than 179 died—ought we not to say were put to death? This is a mortality of 1 in 25; in this country 1 in 80 or 100 is the common proportion; but even this is so much greater than occurs in dispensary practice, that it is questionable how far lying-in hospitals can be considered charities. The great size of the one at Vienna, and the fact of its forming part of the colossal general hospital, must tell strongly against the recovery of the patients. Women in child-bed require pure air above all things; and as puerperal fever is, unfortunately, an infectious disease, the only wholesome hospital for their care would be a series of cottages, as was suggested some years ago by Dr. Ferguson.

The tables exhibiting the result of 25,906 deliveries, which Mr. Wilde gives at p. 223, *et seq.*, he supposes to be the most extensive "in British print;" but we think he will find more comprehensive ones at the end of Dr. Merriman's Treatise on Difficult Parturition.

Mr. Wilde's work will be consulted not only by the student who intends to proceed to Vienna, but by the accomplished practitioner who desires to improve the institutions of his own country by culling the best regulations of foreign states.

The British Quarterly Journal of Dental Surgery. Edited by J. ROBINSON, Esq. No. 1. London, March 1843. 8vo. pp. 64. With a Lithograph and Woodcuts.

AMONG the articles in this number we may mention—A review of dental surgery; Successful treatment of irregularity of the central and lateral incisors in an adult, by the editor; Report to the *Académie des Sciences*, Paris, on a memoir by A. Nasmyth, Esq.; Artificial Teeth; On the necessity of a faculty of surgeon-dentists, by J. L. Levison, Esq.; Scale of charges in America; Osseous union of deciduous teeth; A case of complicated double congenital hare-lip, with an excessive

formation and projection of an inter-maxillary bone, by John Martin, Esq.; The process of development of the epithelium; Association of dental surgeons; Mania from decayed teeth; &c.

Mr. Robinson's bold attempt (the first of the kind, we believe, in this country) deserves every encouragement; and, by securing the services of numerous and skilful *collaborateurs*, he will be certain to attain success.

MEDICAL GAZETTE.

CICERO.

THE COLLEGIATE SYSTEM.

ALL who have read the *Pickwick* papers—that is to say, every one—must have been struck with the sayings and doings of certain medical students immortalized in the pages of the great novelist. Unrivalled as he is in his delineations of the more unfavourable phases of London life, he has surpassed himself in the painful fidelity of these medical sketches. After making a slight allowance for the colouring with which the artist enriches the sombre tints of dull reality, what is left is enough to surprise the indifferent reader, and to urge the philanthropist to the mitigation of the evils so picturesquely described. Meantime, while the benevolent satirist attacks the present system—the system of neglect—like a light-armed horseman, the heavy cannon of grave remonstrance and entreaty have been brought against it by other writers. It is satisfactory to think that the combined efforts of these allies have produced some effect, and that the collegiate system will probably be commenced in London this very year. We

have been favoured with some of the details of the new plan, and lose no time in laying them before our readers.

Six houses have been appropriated by the Governors of St. Bartholomew's Hospital, for the purpose of carrying out the Collegiate system. They are all situated in Duke Street, within the hospital walls, and will be finished for the accommodation of twenty-four students, each of whom will have his separate sitting and bed-room. The sets of rooms will be furnished alike, but the rent, of course, will vary in proportion to the distance from the ground. Its precise amount is not yet settled, but it will be less than students usually pay. Now, it has been stated that the average cost of a lodging to a medical pupil in a metropolitan or great provincial town, is about fourteen shillings a week. Assuming this to be pretty near the mark, we should conjecture that the rents for apartments in Duke Street would vary from ten to twenty shillings a week. Moderate as these rents are, they will no doubt, afford a fair return for the outlay: so that the Governors would be justified in thus employing the property of the hospital, even were we to look upon the design merely in the narrow light of a commercial speculation; but when we consider, on the one hand, the noble object which is to be fulfilled, and, on the other, scan the overflowing coffers of St. Bartholomew's Hospital, it would almost be a crime to neglect such an opportunity of benefiting the common weal.

Moreover, a dining-hall, with a kitchen and other offices, will be built in a middle space between the six houses, thus affording a comfortable spot for dining to resident as well as non-resident students; while it is obvious that for the same money it will be easy to give a far better repast than at the chop-houses commonly resorted

to. The bill of fare will probably contain, besides the established dishes, some extra luxuries, like the commons and sizings of a Cambridge dinner. We do not know whether it is intended that each student shall dine separately, after the fashion of a chop-house, or together in the style of a *table-d'hôte*; the latter, if feasible, should be preferred; for the gloomy practice of solitary repasts is one of the most uncomfortable points about English manners. The expenses of lodging and attendance have been carefully computed from the known expenditure of many students living, as they ordinarily do, in lodgings; and both the rent and cost of dinner being brought within those limits, it is pretty clear that the sum total of the comfortable will be less than that of the uncomfortable mode.

Much care will be taken to prevent the frauds so common in lodging-houses,—frauds which, petty though they be, are provoking in themselves, and inconvenient to the purse of the young beginner. The rooms will be attended by laundresses or their analogues, persons of unimpeachable honesty, (and, of course, *anti-Hebes*); and by them breakfast, tea, and small meals, will be served to each man in his own room. As much as is possible, the items of food, drink, coals, candles, &c. will be supplied by persons empowered by the managers of the College; and their accounts, so far as concerns the prices charged, will be watched by the same authorities.

But it is time to quit these household details, and turn to the weightier matters of discipline and superintendence, where more difference of opinion must arise.

Divine service will be performed every morning at eight in the Hospital Church, which is within twenty paces of the College rooms; and the students

will be particularly invited, but not compelled to attend it.

No arrangement has yet been made for the immediate superintendence of the College, nor is the amount of discipline to be exercised yet determined upon. The general opinion is, that there must be a resident tutor, one who by his standing and knowledge should exercise authority, even when silent. Some have suggested that a senior student would be fit for this office; but such a man would soon become either a spy or an accomplice in the frays which he should have checked; and if he did not join with his juniors, they would certainly hate and probably annoy him.

Whatever he is, the Warden (as he will be called) must have educational authority. From the very first he must guide the studies of the resident pupils, and examine them in the progress they have made. He will naturally succeed to the lectureships in the school, or it may, probably, be deemed necessary that he should already hold one as a qualification for the office of Warden.

These matters are still open for discussion, and, indeed, are being discussed at this very time. Had we a vote in the divan, we should certainly hold up hand against the appointment of a senior student as Warden; for this officer should unquestionably be a man who has held a diploma for several years, and who is visibly older than the oldest pupil committed to his charge.

The more difficult question remains, how tight should the reins of discipline be drawn, to observe the happy mean between the irritatingly severe and the uselessly feeble. We may imagine some objector startled at the very name of discipline, and exclaiming—“What! are our sons never to see real life? Is mamma’s apron-string to be indefinitely prolonged into an iron

chain of constant discipline? Instead of fine-spirited men, are we to turn out the prim and bitter progeny of restraint, like so many victims of a dissenting academy?" By no means, Sir Critic; nothing of the kind is contemplated;

Est inter Tanaim quiddam, socerumque Vitelli; There are many resting-places between the Sawyer of the novelist, and the unfavourable specimens of the favoured Caucasian race whom you hint at in your queries. We should anticipate that the discipline at St. Bartholomew's would incline to the side of the agreeable; and though the rigid might call it lax, the lenient would not term it severe. Even if, in the course of years, it should be raised to the pitch of our two antique Universities, this could not be called unreasonably strait-laced, nor one calculated to form harsh puritans, instead of philanthropic citizens of the world.

All these arrangements will be brought into full play, it is hoped, by next October, and there can be no doubt that all which is possible to make the system work well, will be done. A chief mover for this excellent purpose among the hospital authorities is the treasurer, a man of strong common sense, and thoroughly devoted to the hospital and school; a man, in short, of genuine English energy.

"Nil actum reputans, si quid superesset agendum;"

He is cordially seconded by the chaplain, and by all the influential governors; so that we may consider the approaching good to be not merely *in posse*, but almost *in esse*.

CHANGES IN THE HOSPITALS AND SCHOOLS.

MR. STANLEY having resigned his lectureship on anatomy and physiology, it has been determined to adopt the *same division* of lectures as at King's and University Colleges. There will

be no course of demonstrations, but a course of lectures on descriptive and surgical anatomy; and one on general and morbid anatomy and physiology. Mr. Skey has been appointed lecturer on the former, and Mr. James Paget on the latter subject.

Dr. Bright has resigned his office at Guy's Hospital, and Dr. Golding Bird has in consequence become assistant-physician.

Mr. Guthrie has retired from the Westminster, and the death of Mr. Tyrrell occasioned a vacancy at St. Thomas's Hospital, which was filled by the election of Mr. Macmurdo on the 14th.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

I CONCEIVE, as stated in my last letter, that it is only by six or eight apprentices being received into the surgery of a general practitioner, that proper advantages could be afforded to them, or proper time devoted to their studies and superintendence. I proceed to detail the plan by which I consider their instruction could be conducted.

If the practitioner's private practice be extensive, an assistant should be kept, though I do not think it any advantage that the practice should exceed 1000, or 1500 cases yearly, if the surgery is carried on methodically; and perhaps it might be in some measure considered the perquisite of the junior practitioner to receive pupils; and it must be confessed in many instances he would be the most competent instructor in the scientific department.

Supposing, therefore, eight pupils were taken, they might be divided into two classes; one class taking the duties of the surgery, the other confined exclusively to the study. In the surgery, again, the four might alternate morning and afternoon in their duties of dispensing and bookkeeping. Again, the dispensing admits of subdivision into extemporaneous prescriptions, or the putting up of medicines for the patients, and the preparations and prescriptions kept always ready, as the preparations of all tinctures, masses of pills, &c. The book-keeping might be also divided into the posting of the ledger and day-book, and into the proper keeping of the drug-book, registers, &c. &c., and several other small accounts, the detail of which would occupy too much space here. The spare time of the students in the surgery could be occupied in studies of several subjects, that would not suffer by an occasional interruption, as

translations of Latin, German, French, or Greek; the practice of drawing, and readings in the *materia medica*, as in Drs. Pereira's or Thomson's works; and their reading, as well as all prescriptions and entries, should be overlooked by the assistant or master. This division or class of students, on the following week should change places with the other class, and take their place in the study.

The subjects to be prosecuted in the study are such as require the whole and uninterrupted attention, as anatomy and the first principles of medicine; and this species of application could be diversified by a regular time in the laboratory in practising chemical manipulation, taking, perhaps, the 25th section of Faraday for their direction; and in the preparations of all the chemical formulæ in the London Pharmacopœia; while their hours of relaxation, which should not be stinted, might be taxed, if in the country, in the cultivation of the many medical plants, and in the collection of herbs.

The students should be called upon at an early hour every morning, and also every evening, to attend a lecture on a subject connected with their studies, especially on natural philosophy and chemistry, by which the practitioner's time would not be too much interfered with; and early rising, and occupation in the evening, would be useful in a moral view. I consider that instruction by lectures is also essential, because students unused to this method at first cannot learn much by it; and therefore the first lectures in town are often wasted and lost to the pupil. The master would often have opportunities of encouraging the proper employment of the hours of relaxation, by fostering any desire they might evince for any of the collateral sciences, as in the collection of various objects of natural history, geology, and mineralogy, &c., and also by allowing time and procuring masters for other branches, as in drawing, modelling, casting, &c.

I would undertake that by this method, the outline of which is here sketched, and the details of which would be filled out best by each person for himself, that any pupil in three years might be sent to the hospital, having a sound elementary knowledge on the following subjects:—

Elementary and practical chemistry.

Botany—and in this subject considerable progress might be made by the aid of botanical excursions.

Pharmacy—by the actual preparation of all the chemicals, and also by preparing all the extracts, &c. contained in the Pharmacopœia.

Anatomy.—The students could obtain, by the aid of plates and the skeleton, a thorough knowledge of human osteology,

and a good general idea of the situation of all the muscles.

Physiology—the rudiments.

Medicine—the theory, especially as treated in the *Conspectus* of Gregory. As to the practice, though generally considered so essential a part of apprenticeship by non-professional persons, most medical men will agree, that until further advance is made in physiology and the theory of medicines, it would not be of much service. If, however, any one should consider it advisable, a dispensary can be supported for a very small annual cost; and many charitable persons would be induced to lend such establishment their help, when started for legitimate purposes.

Toxicology—the chemical portion practically.

Natural philosophy—the outlines.

I need not add how essential it would be that the master's treatment and conduct towards his pupil should be strictly in accordance with the rules of gentlemanly bearing. Such things having been heard of, it is almost painful to acknowledge it, as a difference made to the apprentice at the table, than which nothing can be more detrimental.

The advantages of a sound scientific instruction of the apprentice would act beneficially, both mentally and morally.

Mentally—because it would begin early to instil industrious and studious habits, and because the pupil would go to town, not only with a sound elementary knowledge, but with a *method of study*; and, to use the exact words of the Apothecaries' Company, the "neglect of regular and systematic study will usually be found to terminate in failure and disappointment;" and it would also, of course, greatly facilitate the labour while at the hospital, and therefore give the greater opportunity of obtaining a better insight into more important matters: and, morally, because it would be no difficult matter to show that the dissipation of medical students on their arrival in London, depends upon the idle habits engendered during servitude, and from the sudden escape from a most rigid confinement to absolute and ungoverned liberty: besides, the previous instruction would give them an immediate interest in all the lectures they are now called upon to attend, and from the first it would place the profession of their own choice in the most pleasing and fascinating light, and it would therefore strengthen their predilection for it, and increase their ardour in its study.

But another point remains, and in the natural order of things should have been first discussed, which is—how is the practitioner at the present day to obtain the six pupils.

It is beyond a doubt that the number of

young persons entering the profession has very considerably diminished during the last few years; and I am sure that in my own neighbourhood there is scarcely one pupil to a dozen practitioners. The current seems to have turned, and is now directed to the professions chiefly of engineers, barristers, solicitors, all which require either no examination, or a very slight one. There is little doubt but the difficulties imposed have acted materially, at least on the young men themselves; I imagine, therefore, by somewhat dignifying the apprentices from the mere dispenser of medicines, to the private pupil, would have some effect in increasing the supply. Nevertheless, I do not doubt there would be some difficulty at first in forming such an establishment, especially with parents who naturally view innovation with suspicion.

I consider, however, that the Apothecaries' Company especially, by whose law it is that apprentices exist, have a right to demand a matriculation. Every member of the profession will cordially join in acknowledgment of the services which they have rendered the profession by their attention to the studies of the licentiates; but the Company have hitherto confined their bye-laws to that period of those studies that commenced after the student's arrival at the hospital; and happy as have been the results already, there cannot be the least doubt an equally beneficial effect would be produced, if the same superintendence was extended to that period of apprenticeship prior to the student's attendance at the hospital. They might test the student's progress by a matriculative examination of a very elementary character, and allow the present curriculum of studies to date from such matriculation. Indeed, when the student is compelled to pass at least two years and a half in the profession before he arrives in town, it is only common justice to ascertain that proper advantages and instruction have been afforded him, and it would be by no means an ill-spent bounty, if some substantial reward could be given to the pupil acquitting himself in the best manner at such examination.

There will be few to deny that education to the extent that I have described would be highly desirable. I trust I have also shown strong reasons why that education should be combined with the sort of knowledge to be obtained only in the surgery of the general practitioner; and that from the pupil's age, and from other grounds, the continuance of medical apprenticeship is expedient. I have also endeavoured to point out how an improved education could be effected, and I leave the method to the consideration of any whom it may concern, whether to the legislature or to the present

authorities, with whose regulations it is perfectly compatible; or, lastly, to any general practitioner who may think well of it, who might adopt it without any alteration whatever even in the present curricula taking place.—I am, sir,

Your obedient servant,
W. H. O. SANKEY.

Margate, June 2, 1843.

DEATH FROM A LARGE DOSE OF SULPHATE OF QUININE.

A MAN 26 years of age, No. 11 Saint Madeline's ward, was affected with acute articular rheumatism; he had been shortly before treated in the Hôtel Dieu for small-pox, and having probably left the hospital too soon was exposed to cold, and contracted acute rheumatism, in consequence of which he was admitted under the care of M. Recamier on the 27th of November; he then laboured under general fever without any complication; the heart, lungs, and head were not implicated; there was derangement of intelligence; no headache; both wrists were very painful and swollen, but the skin was not red; the knees were also painful, but in a less degree; no pain in the hips. The diagnosis was thus stated. *Acute rheumatism of the joints, with fever of medium intensity*; as to the prognosis it was stated that they would probably be of tolerably long duration; that complications were to be expected, such as inflammation of the serous membranes of the ^{thorax}, through nothing of the kind yet existed.

M. Recamier having just witnessed an admirable cure affected in an analogous case, by the administration of sulphate of quinine, to a lady, in private practice, resolved to employ the same treatment in this case. He prescribed the first day three grammes (56½ grains) in twelve papers, one to be taken every hour. No bad effect resulted.

The next day the pains were diminished in the lower extremities, but were more severe in the wrists. On a careful examination of the heart, no bruit de soufflet could be detected, but its pulsations were not quite so distinctly clear as natural.

The second day five grammes (77 grs.) of sulphate of quinine were prescribed; to be taken in the same manner as the first day. The patient had only taken 3½ grammes when he was suddenly attacked with extreme agitation, followed by furious delirium, and death occurred in a few hours.

On dissection the signs of a general and most intense meningitis were discovered; considerable sanguineous effusion of the meninges; penetrated vascularity of the surface of the brain, of which some points,

more intensely inflamed, presented a commencement of softening; the quantity of serum in the ventricles was natural.

While the foregoing case was in progress, a similar but less disastrous one occurred under the care of M. Husson, in the person of a patient affected with symptoms of rheumatism, closely resembling the above mentioned. Six grammes of sulphate of quinine were administered; after the ingestion of the last dose, the patient fell into a state of prostration, rapidly followed by extreme agitation and delirium, to which soon succeeded excessive debility and complete immobility. The pains, however, had disappeared.—*Gaz. des Hopitaux*, Dec. 8, 1842.

LIGATURE OF THE COMMON ILIAC ARTERY.

DR. PEACE, one of the Surgeons of the Pennsylvania Hospital, has recently tied the common iliac artery with success. The operation is stated by the author to have been "a modification of that of Sir A. Cooper, but retaining the great advantage—that of the greater facility of separating safely the peritoneum." He thus describes his operation:—

The patient having had his groin shaved, and placed upon a table of a convenient height, on the morning of the 29th of August, before the medical class, assisted by my colleagues, Drs. Randolph and Norris, and the experience of Dr. J. Rhea Barton, I proceeded to make an incision seven inches in length through the integuments, commencing at a point, on a level with the umbilicus, two inches within and three inches above the anterior superior spinous process of the ilium, and approaching to within an inch of Poupart's ligament, and terminating one half an inch above the external ring; this divided the *arteria ad cutem*, which was twisted by the artery forceps; no ligature was required; next the superficial fascia was divided, then the tendon of the external oblique was exposed, nicked, and with the aid of a director was cut the whole length of the first incision as far inwards as the spermatic cord. There was considerable difficulty in raising up the lower edge of the tendon of the internal oblique and transversalis, owing to the thickening and induration of the surrounding tissues from the pressure of the tumor: this was finally accomplished by means of the handle of the knife, and a careful division of the layers as they presented themselves, until we arrived at the peritoneum, having cut some of the fleshy fibres of the transversalis; the peritoneum was then carefully and with some difficulty detached from

the tumor, which was found to involve a great portion of the external iliac artery; we continued raising the peritoneum till we came to a part of the artery which appeared to be healthy; this was about one-half an inch above the bifurcation of the common iliac. The artery was separated from the vein by the finger nail, and a silk ligature was passed underneath from within outwards, by means of the admirable aneurismal needle of Professor Gibson. Notwithstanding the precautions that we had taken to have the bowels well evacuated, and the length of our first incision, it was some time before we were able to get a view of the curve of the needle still held under the artery, on account of the projection of the tumor and the protrusion of the abdominal contents. Finally, by means of broad, curved steel spatulas, and drawing forward the artery by means of the aneurismal needle that was underneath, we managed to get a view of the common iliac artery, and the iliac vein underneath, on the side of the sacro-vertebral promontory, with the ureter crossing the artery, and attached to the raised peritoneum. The ligature was without the slightest difficulty passed out of the wound by the watch-spring of the needle, and was tied by the tips of the fingers with a simple double knot; both ends of the ligature were allowed to remain hanging together from the wound. Immediately the pulsation of the tumor ceased, and its volume sensibly diminished. The edges of the wound were brought together by three interrupted sutures and adhesive plaster, and dressed with lint spread with cerate, and retained by two adhesives strips. The patient was removed to his bed, placed on his back, his leg slightly raised by a pillow under the knee, his shoulders raised, his body flexed and inclined towards the affected side. The needle was placed under the artery in seventeen minutes, but thirty minutes more were required before the patient was removed to his bed. The ligature came away on the 35th day.—*American Journal*.

WENZEL THE OCULIST.

THIS tradition is current in Vienna:—A lady attached to the court of the empress, becoming blind, was pronounced amaurotic by the medical man called in; her malady continuing to increase, the Baron Wenzel was sent for, and he at once declared it to be cataract, and operated on it with success. So amazed was Maria Theresa at this display of Austrian surgery, that she forthwith established a special lectureship of ophthalmology, and Barth was the first that filled this chair in 1773; and in 1776 he was appointed oculist to Joseph II. He was a

most expert extractor, and there are still several who have witnessed his operations—the invention and use of Beer's knife (that now so generally adopted) is in a great measure due to him, for although his was longer in the blade, and somewhat broader towards the handle, yet it was upon an enlarged scale the same. The objections urged against it, of pricking the nose from the great length of its point, and not cutting itself out (as it is termed) with facility, is now obviated in that introduced by his pupil, Beer. His mode of operating was remarkable; he did not require an assistant, (and was, perhaps, the first oculist who did not), but placing the patient standing in the corner of the room near a window, he opened the lids, and fixing the eye with one hand, he passed his knife through the cornea with the other, as is now so dexterously performed by Mr. Alexander; but, different from that very distinguished oculist, he stood before his patient. It is needless to add that he was ambidexter. He died in 1818; his portrait bespeaks him a man of noble and prepossessing appearance, and his address, added to his acknowledged talents, procured him many admirers.—*Wilde's Austria*.

CASE OF RHEUMATICO-CATARRHAL FEVER

WITH METASTASIS TO THE TOES.

By Dr. LEOPOLD BEER, of Brünn.

THE patient was tall, and eighteen years of age; the prominent symptoms of his protracted fever were weakness, attenuation, sleeplessness, and increasing pain in the legs. In the fourth week of his illness, these pains extended to the soles of the feet, which were sensitive to the touch; their skin, too, was somewhat reddened, hot, and as it were, detached. In the 5th week of his illness, the nails, all of which projected far beyond the toes, degenerated, and were unbearably painful, when pressed towards their roots, sensations which extended as far as the knees. Gradually, and with considerable difficulty, the horn-like points of the nails were pulled off; and first of all dry, and afterwards fluid pus was found under each one. A few days after this operation the pains disappeared, and the patient recovered perfectly.—*Osterr. med. Wochenschr.* and *Schmidt's Jahrb.*

LECTURES

ON THE

THEORY AND PRACTICE OF MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXXI.

On Preternatural Labours. Presentations of the shoulders and superior extremities.

ALL the varieties of preternatural labours have usually been divided into two orders; the first comprehending presentations of the nates and inferior extremities, and the second those in which the shoulder and superior extremities present. Cases in which the back, abdomen, or sides of the foetus present, are so rare, that some practitioners believe it to be almost impossible for them ever to happen at the full period.

In 20,517 cases, delivered in the Maternity of Paris, Madame Boivin states, that no instance of such presentation occurred at the full term of gestation. The representations which have been given by her in the 117th and 118th Plates of her *Memorial de l'Art des Accouchemens*, of presentations of the abdomen and back, were therefore not made from nature; and I can hardly believe that a foetus ever lay within the uterus with his heels and occiput in contact, as you see delineated in the last of these figures. Smellie's 33d table, which exhibits the foetus compressed into a round form, the belly or umbilical region presenting at the os internum, and the funis hanging out of the vagina, is probably also to a great degree an imaginary representation. In the extensive practice of Dr. Merriman and his uncle, amounting together to nearly 20,000 labours, no instance occurred of either of these presentations, except in one or two cases where

812.—XXXII.

the mother had not completed her seventh month of utero gestation; and in these the children passed double through the pelvis. Dr. Hunter says in his MS. Lectures, 1765, "I have read much in authors where the navel is said to present, or, on the contrary, where, on introducing the finger, you feel the middle of the spine. I do not believe there is the possibility of such a thing in nature: the shape of the uterus, pelvis, &c. all deny it." Dr. Denman says, "I do not mention the marks by which the back, belly, or sides might be distinguished, because these, properly speaking, never constitute the presenting part: that is, though they may sometimes be felt, they never advance foremost into the pelvis, in the commencement at least of a labour."

Presentations of the shoulder and superior extremities.—In these difficult and dangerous cases of preternatural labour, usually called cross births, the foetus lies transversely in the uterus, the nates and lower extremities being directed to one ilium, and the head to the other, and the abdomen backward to the spine of the mother, or downward to the os uteri. The thirty-first table of Smellie represents, in a front view of the pelvis, the foetus compressed by the contraction of the uterus into a round form, the fore parts of the former being towards the inferior part of the latter, and one foot and hand fallen down into the vagina. (Exhibiting it.)

The thirty-second table represents, in the same view with the former, the foetus in the contrary position: the breech and fore parts being towards the fundus uteri, the left arm in the vagina, and forearm without the os externum, the shoulder being likewise forced into the os uteri. (See next page.)

The thirty-fourth table shows, in a lateral view of the pelvis, one of the most difficult preternatural cases, the left shoulder, breast, and neck of the foetus presenting, the head reflected over the pubes to the right shoulder and back, and the feet and breech stretched up to the fundus, the uterus contracted at

the same time, in form of a long sheath round the body of the foetus. (See next page.)

In some favourable cases of shoulder and arm presentation, the uterus is widely dilated before the membranes are ruptured and the liquor amnii discharged; and no difficulty is experienced in passing the hand into the uterus, laying hold of the feet, and extracting the child by the operation of turning. If the uterus is not contracting strongly and at short intervals, little resistance is offered to the introduction of the hand, and the delivery may be speedily accomplished with safety both to the mother and child. But if the membranes have burst, the liquor amnii escaped, and the uterus has been contracting firmly upon the child many hours before the operation of turning is attempted, the child is often destroyed by the pressure, and the coats of the uterus exposed to great danger from contusion and laceration in passing up the hand and bringing down the feet. The shoulder and thorax become so strongly impacted in the pelvis, that great force is required to introduce the hand into the

uterus to grasp the feet, and much exertion necessary before the position of the child can be changed.

In other cases of shoulder and arm presentation, the membranes burst and the liquor amnii escapes at the commencement of labour, and the os uteri is rigid and undilated, so that the hand cannot be passed into the uterus after the labour has continued many hours. The difficulty and danger of these cases are greatly increased when the uterus is contracting with violence, and the pelvis is distorted, or a disproportion exists between the child and pelvis from any other cause. The greater number of women, if abandoned to the efforts of nature under these circumstances—the uterus having no power to alter the position of the foetus, would ultimately die undelivered from exhaustion or rupture of the uterus and vagina. Where the pelvis is large, the foetus premature and dead, and the uterine action strong, the child, it is true, has sometimes, where no artificial assistance is afforded, been expelled double, or what has been called by Dr. Denman spontaneous evolution of the

child has taken place. The arm here descends, and the shoulder and thorax are forced lower and lower into the pelvis, and gradually advance by the pains till they escape through the outlet, and the head and other parts soon follow. This expulsion of the fetus double was observed by Puzos, and the proper treatment recommended where it was about to take place. He says, "Si l'enfant plié en deux se précipite dans l'orifice et qu'il s'engage aussitôt les eaux percées, les douleurs continuant de porter en bas, il vaut mieux laisser venir l'enfant dans cette situation, que de faire violence à la matrice pour aller chercher les pieds, l'enfant ne périr pas pour venir de cette façon : il n'ouvre pas non plus une femme

au-delà de l'ordinaire : puisque souvent après les fesses sorties avec les cuisses repliées sur le ventre, la tête a encore peine à franchir ce détroit : quand l'enfant plié en deux à les fesses au passage, il faut le tournée alors le ventre en dessous, mettant les doigts de chaque main dans ses aines, ce qui s'exécute fort aisément, et le dégagement de ses pieds ne donne pas plus de peine." Dr. Denman observed a considerable number of cases of shoulder and arm presentation in which the child was expelled double, and he gave the following account of the process. "As to the manner in which this evolution takes place, I presume that after the long-continued action of the uterus the body of the child is brought into such a

the same time, in form of a long sheath round the body of the foetus. (See next page.)

In some favourable cases of shoulder and arm presentation, the uterus is widely dilated before the membranes are ruptured and the liquor amni discharged, and no difficulty is experienced in passing the hand into the uterus, laying hold of the feet, and extracting the child by the operation of turning. If the uterus is not contracting strongly and at short intervals, little resistance is offered to the introduction of the hand, and the delivery may be speedily accomplished with safety both to the mother and child. But if the membranes have burst, the liquor amni escaped, and the uterus has been contracting firmly upon the child many hours before the operation of turning is attempted, the child is often destroyed by the pressure, and the coats of the uterus exposed to great danger from contusion and laceration in passing up the hand and bringing down the feet. The shoulder and thorax become so strongly impacted in the pelvis, that great force is required to introduce the hand into the

uterus to grasp the feet, and much exertion necessary before the position of the child can be changed.

In other cases of shoulder and arm presentation, the membranes burst and the liquor amni escapes at the commencement of labour, and the os uteri is rigid and undilated, so that the hand cannot be passed into the uterus after the labour has continued many hours. The difficulty and danger of these cases are greatly increased when the uterus is contracting with violence, and the pelvis is distorted, or a disproportion exists between the child and pelvis from any other cause. The greater number of women, if abandoned to the efforts of nature under these circumstances—the uterus having no power to alter the position of the foetus, would ultimately die undelivered from exhaustion or rupture of the uterus and vagina. Where the pelvis is large, the foetus premature and dead, and the uterine action strong, the child, it is true, has sometimes, where no artificial assistance is afforded, been expelled double, or what has been called by Dr. Denman spontaneous evolution of the

child has taken place. The arm here descends, and the shoulder and thorax are forced lower and lower into the pelvis, and gradually advance by the pains till they escape through the outlet, and the head and other parts soon follow. This expulsion of the fetus double was observed by Puzos, and the proper treatment recommended where it was about to take place. He says, "Si l'enfant plié en deux se précipite dans l'orifice et qu'il s'engage aussitôt les yeux percés, les douleurs continuant de porter en bas, il vaut mieux laisser venir l'enfant dans cette situation, que de faire violence à la matrice pour aller chercher les pieds, l'enfant ne périr pas pour venir de cette façon : il n'ouvre pas non plus une femme

au-delà de l'ordinaire : puisque souvent après les fesses sorties avec les cuisses repliées sur le ventre, la tête a encore peine à franchir ce détroit : quand l'enfant plié en deux à les fesses au passage, il faut le tourner alors le ventre en dessous, mettant les doigts de chaque main dans ses aines, ce qui s'exécute fort aisément, et le dégagement de ses pieds ne donne pas plus de peine." Dr. Denman observed a considerable number of cases of shoulder and arm presentation in which the child was expelled double, and he gave the following account of the process. "As to the manner in which this evolution takes place, I presume that after the long-continued action of the uterus the body of the child is brought into such a

compacted state as to receive the full force of every returning action. The body, in its doubled state, being too large to pass through the pelvis, and the uterus, pressing upon its inferior extremities, which are the only parts capable of being moved, they are forced gradually lower, till the body turning as it were upon its own axis, the breech of the child is expelled, as in an original presentation of that part."

Since the publication of Dr. Douglas's essay in 1811, entitled, *An Explanation of the real Process of the "Spontaneous Evolution of the Foetus,"* it has been almost universally admitted that, in these cases, the arm and shoulder do not recede; that the child does not turn upon its axis; and that the nates are not expelled as in an original presentation of that part. The arm, shoulder, and thorax, are first expelled, and the nates and head afterwards. As the term spontaneous evolution is still in common use, and is calculated to convey an erroneous idea of what does actually take place in these cases of preternatural labour, I shall read to you what Dr. Douglas, who first gave a correct explanation of the fact, states on the subject:—"So far as the foregoing detail my observations coincide with those of Dr. Denman and others; but I cannot comprehend how successive repetitions of the same propelling power which forced the child into this situation, should subsequently, at any period, produce a counter effect, causing the shoulder to retreat into the uterus. The fact, however, is, that the shoulder and thorax, thus low and impacted, instead of receding into the uterus, are at each successive pain forced still lower, until the ribs of that side corresponding with the protruded arm press on the perineum, and cause it to assume the same form as it would by the pressure of the forehead in a natural labour. At this period not only the entire of the arm, but the shoulder, can be perceived externally, with the clavicle, lying under the arch of the pubis. By further uterine contractions the ribs are forced more forward, appearing at the os externum as the vertex would in a natural labour; the clavicle having been, by degrees, forced round on the anterior part of the pubis, with the acromion looking towards the mons veneris. But in order to render as clear as possible the successive movements in this astonishing effort of nature, I will endeavour to describe still more precisely the situation of the foetus immediately prior to its expulsion. The entire of it somewhat resembles the larger segment of a circle; the head rests on the pubis internally; the clavicle presses against the pubis externally, with the acromion stretching towards the mons veneris; the arm and shoulder are entirely protruded, with one side of the thorax not only appearing at the

os externum, but partly without it: the lower part of the same side of the trunk presses on the perineum, with the breech either in the hollow of the sacrum, or at the brim of the pelvis, ready to descend into it: and by a few further uterine efforts, the remainder of the trunk with the lower extremities is expelled. And to be still more minutely explanatory in this ultimate stage of the process, I have to state that the breech is not expelled exactly sideways, as the upper part of the trunk had previously been; for during the presence of that pain by which the evolution is completed, there is a twist made, about the centre of the curve, at the lumbar vertebræ, when both buttocks, instead of the side of one of them, are thrown against the perineum, distending it very much: and immediately after the breech, with the lower extremities, issues forth; the upper and back part of it appearing first, as if the back of the child had originally formed the convex, and its front the concave side of the curve."

There is now a premature acephalous foetus upon the table before you, the left arm and shoulder of which presented in labour a few days ago, and the body passed through the pelvis double, in the manner here described; or spontaneous evolution took place. I have repeatedly witnessed the same occurrence where the foetus was premature, and flaccid from putrefaction; and on the 14th August, 1831, I saw a child at the full period expelled in this manner, in a woman who obstinately refused to allow the operation of turning to be performed. The right shoulder and arm presented in that case; and after the labour had continued three days and nights, the child was at last forced through the pelvis doubled up, in a putrid state, the head being flattened, and the viscera of the abdomen pressed through the parietes. It is only in a few rare cases, however, that the delivery is completed in this manner—where an unusual combination of circumstances exists; and it would be improper to calculate upon the occurrence of spontaneous evolution, or allow the possibility of its taking place, to influence the treatment we adopt in cases of arm presentation. It does not occur in cases where the operation of turning is performed with difficulty, and it is not a resource to which, in practice, we ought ever to trust—it ought never to be considered as a substitute for turning. It is now a general rule, established in all countries where midwifery is understood, that in cases of preternatural labour, where the shoulder and superior extremities of the child present, the operation of turning ought to be performed. But the hand must not be forced into the uterus if the orifice is rigid and undilatable; it should be dilated nearly to the size of half a crown piece or more, or the margin ought to be

very thin, soft, and yielding, if it is expanded to a smaller extent than this when turning is attempted. If the os uteri will not admit the extremities of the fingers and thumb in a conical form to be introduced without much force; if it is thick, hard, and unyielding, some delay is necessary that the parts may relax, death being almost always the consequence of thrusting the hand with violence through the orifice of the uterus in a rigid and undilatable condition, whether the membranes be ruptured or not. But as soon as it will admit of the safe introduction of the hand, where you have ascertained that an arm presents, no time should be lost in completing the delivery, otherwise the membranes may give way, the liquor amnii be evacuated, and a case of little difficulty and danger be suddenly converted into one equally hazardous to the mother and child. In all cases of labour, where the first stage is far advanced without the nature of the presentation being positively determined, or a superior extremity is felt through the membranes, the patient should be kept in the horizontal position, that they may not be ruptured; and you should remain in constant attendance upon the patient, and be prepared to interfere the instant the necessity arises.

When the operation of turning is required before the membranes are ruptured, and when the orifice of the uterus is widely dilated, and there are long intervals between the pains, it is accompanied with little difficulty and danger. Having explained to the patient and her relatives the nature of the case, let her lie on the left side near the edge of the bed, with the knees drawn up to the abdomen. Sit down by the side of the bed and quietly take off your coat; lay bare your right arm by turning up the shirt above the elbow, and cover the back of the hand and the whole fore-arm with cold cream, lard, or a solution of soap. Introduce one finger after another into the vagina, and slowly and effectually dilate its orifice. The hand in a conical form, and in a state of half supination, must then be pressed steadily forward with a semi-rotatory motion against the perineum and sides of the passage, till it clears the orifice of the vagina. This should always be done very slowly and gently, as it is accompanied with great pain. Let the hand remain some time in the orifice of the vagina, that it may be fully dilated, and offer no resistance in the subsequent steps of the operation of turning. When the hand has dilated the vagina sufficiently, in the absence of pain gently insinuate the points of the fingers and thumb into the os uteri in a conical form; and if it is not sufficiently open to allow the hand to pass, you must proceed next to use artificial dilatation *here also, very gently and slowly, always stopping as soon as a pain comes on, but not*

withdrawing the fingers altogether at the time from the os uteri. Having succeeded in dilating the part without rupturing the membranes, slide the hand up between the membranes and the anterior part of the uterus into the cavity, and grasp the feet when the membranes give way. Most frequently the membranes burst as the hand is entering the uterus, before it reaches the feet, and the liquor amnii rushes out and is lost, if it is not prevented by pressing the hand forward firmly into the orifice. Never be contented with one foot when it is possible to grasp both; and this can always be done when the liquor amnii has not escaped, and the uterus is not closely contracted around the body of the child. Seize both feet and legs, and when there is no pain, draw them down into the vagina; and as the nates descend through the os uteri, the shoulder and arm will gradually recede or be retracted, and will offer no obstacle to the remaining part of the operation, which should be completed as if the nates and inferior extremities had originally presented, and which has already been very fully described. In actual practice, except in twin cases, the membranes have been ruptured and the liquor amnii is gone, in a great proportion of cases—in about ten to one—long before we are called upon to deliver by turning, and the operation is then a much more serious affair. Sometimes when the os uteri is half dilated, there is an interval of freedom from pain for several hours after the rupture of the membranes, and partial escape of the liquor amnii. Here it is advisable to turn without delay; and the hand can be passed up into the uterus and the feet brought down with little more difficulty than if the membranes had not been ruptured.

The shoulder and arm may present, and the operation of turning be required where the membranes have burst at the commencement of the labour, the liquor amnii has escaped, and the os uteri is rigid, and is not dilated in a sufficient degree to allow the hand to pass. You can learn from experience alone, when there is a probability in such cases of artificially dilating the os uteri without the employment of too much force; it is best to wait patiently, in such a state of the os uteri, till relaxation takes place, before attempting to overcome the resistance, and to obviate the danger of spontaneous laceration of the uterus by venesection and opiates.

A much more difficult case of turning than any of those already described, is that in which the liquor amnii has long been evacuated, the uterus has contracted strongly around the body of the child, and the arm, shoulder, and a part of the thorax, have become firmly impacted in the pelvis. No attempt in such a case should ever be made to force back the presenting part into the uterus, but the hand should be cautiously

ducted to the feet along the arm of the child, and the shoulder pressed aside. It is impossible in all cases to determine positively the position of the child and the side of the uterus to which the feet are directed the hand ought, however, invariably to be passed up between the front of the pelvis and the presenting part of the child, however the trunk and extremities may be situated; and as both hands are frequently required in these cases to turn, it is of no importance whether you employ the right or left first. I believe the two most important rules which you ought to remember in the treatment of these cases are, first, to pass up the hand between the anterior and shallow part of the pelvis, and the presenting part of the child; and secondly, when one hand is rendered powerless by the pressure from the contractions of the uterus, to withdraw this hand and replace it by the other. By the observance of these rules there are few cases, I believe, of arm presentation, in which the operation of turning may not be safely accomplished. It is in rigid and irritable states of the uterus that we encounter the greatest resistance to the introduction of the hand and where these exist in a high degree, recourse should be had to a copious venesection and a large opiate, before the operation is again attempted. Where these means have been vigorously employed, it will rarely be necessary to remove the arm of the child at the shoulder joint, perforate the thorax, and draw it through the pelvis with the crotchet doubled up as in spontaneous evolution.

Sixty-six cases of shoulder and arm presentation have come under my observation since 1823. In a great proportion of these the operation of turning was undertaken in the most unfavourable circumstances, both for the mothers and their children, after the liquor amnii had entirely escaped, and the uterus had not only been contracting for many hours around the child, but repeated unsuccessful efforts had been made to deliver. Seven women died from rupture of the uterus, and three from inflammation of the uterus. Laceration and inflammation of the uterus are therefore the consequences of turning chiefly to be dreaded. Four of these cases of rupture occurred in the practice of other accoucheurs, and three in patients under my own care, and where no great difficulty was experienced, or force employed in turning. The most perplexing cases were those in which there was distortion of the pelvis, with arm presentation; and the most easy and successful, those twin cases in which the superior extremity of the second child presented, and the operation of turning was promptly performed. Edmund Johnson, Esq. has had the kindness to make the following tabular view of the histories of these cases, sixty of which have been recorded in my *Clinical Midwifery*.

A TABULAR VIEW OF SIXTY-SIX CASES OF SHOULDER AND ARM PRESENTATIONS.

October 10, 1823	Arm in vagina; uterus firmly contracting around the child; repeated attempts to turn; uterus ruptured on left side, either from or before operation; foetus escaped through rent, afterwards extracted; none of the ordinary symptoms of ruptured uterus present	Died seven days after delivery; adhesions by lymph around rupture, which, when peeled off, exposed the rent; peritonitis.	
August 1, 1824	Right arm with funis low in the vagina; shoulder and thorax squeezed in brim; liquor amnii escaped; operation of turning performed with difficulty	Died forty-eight hours after from peritonitis.	
October 15, 1824	Right arm, swollen and livid, protruded through the os externum; pelvis distorted; shoulder and thorax wedged in brim; uterus firmly contracted; membranes ruptured four hours; repeated efforts to turn, without success; thorax perforated; arm separated at shoulder; child dragged through the pelvis, doubled up	Recovered.	
Feb. 12, 1827	Triplets; arm of first and second child presented; turned without difficulty; presentation of third natural; all still born	Recovered.	
3			
4			

5	April 9, 1827	Arm presentation; liquor amnii discharged; uterus firmly contracting; turning difficult; child dead	Died from uterine hæmorrhage.
6	May 1, 1827	Left arm presenting, with cord twisted around it; not pulsating; uterus firmly contracted; frequent attempts to turn, without success; thorax perforated, and child extracted	Recovered.
7	May 14, 1827	Presentation of left arm; shoulder and thorax fixed low in pelvis; umbilical cord prolapsed, without pulsation; uterine contractions strong and violent when turning was attempted; thorax perforated and child extracted	Recovered.
8	Dec. 3, 1827	Presentation of arm with head; turning attempted; one foot brought down, and left in vagina a day and a night; distorted pelvis; labour completed by craniotomy; extraction difficult.	Recovered, after severe inflammation of uterus.
9	Dec. 18, 1827	Presentation of arm and funis; os uteri partially dilated, and high up; membranes ruptured three hours; cord pulsating; turning difficult	Recovered.
10	March 25, 1828	Right arm with funis; liquor amnii escaped four hours; slight uterine contraction; operation of turning performed without difficulty; in extracting head the chin hitched over pubis; child dead	Recovered.
11	April 20, 1828	Twins; arm of second child; pains not strong; turning easily performed; one hour between the birth of first and second child; both children alive	Recovered.
12	April 26, 1828	Right arm with funis hanging out of external parts; no pulsation; turning easily performed; placenta retained; rupture of uterus discovered, when placenta was extracted	Died, with delirium and vomiting.
13	June 15, 1828	Left arm with funis; no pulsation; liquor amnii evacuated; strong and violent uterine contractions; tinct. opii employed; turning easily performed	Recovered.
14	August 19, 1828	Right arm; liquor amnii evacuated; no uterine contractions; turning accomplished with great ease; child alive	Recovered; severe inflammation.
15	Sept. 18, 1828	Twins; arm and shoulder of second child protruded through external parts; operation of turning difficult	Recovered.
16	Dec. 15, 1828	Left arm and thorax pressed deeply in pelvis; liquor amnii discharged; strong uterine contractions; V.S. and opiate used with advantage; turning at last performed with ease; child dead	Recovered.
17	Jan. 3, 1829	Presentation of arm; rigid os uteri; pains strong and frequent; thorax perforated; arm divided from trunk; delivery completed with crotchet	Recovered.
18	Jan. 9, 1829	Right arm protruded through os externum; pains slight; turning difficult; child dead	Recovered.
19	May 29, 1829	Presentation of left arm, much swollen; os uteri firmly contracted around shoulder; liquor amnii evacuated; V.S. employed with benefit; turning accomplished with ease; rigors and feeble pulse after operation	Recovered.
20	June 3, 1829	Twins; second child, arm presentation; pains strong; operation of turning not accomplished; arm and shoulder drawn through the outlet of the pelvis, and child delivered doubled up	Recovered.

21	July 28, 1829	Presentation of right arm; membranes ruptured; os uteri dilated; pains few and feeble; operation of turning performed with ease	Recovered.
22	Autumn, 1829	Arm with umbilical cord in vagina three days; would not allow the operation of turning to be tried; complete exhaustion; turning at last effected	Recovered.
23	Nov. 8, 1829	Distorted pelvis; presentation of arm; arm removed by another practitioner, and turning repeatedly attempted; thorax impacted in pelvis; foot grasped with craniotomy forceps, and turning at last effected; head unable to pass through brim; perforated behind ear; delivery completed with crotchet	Died; rupture of orifice and neck of uterus.
24	May 22, 1830	Presentation of left arm; membranes ruptured seven days; irregular uterine contractions; shoulder and part of thorax jammed in brim; turning unable to be performed; arm removed at shoulder; thorax perforated; delivery accomplished with crotchet	Recovered.
25	August 29, 1830	Twins; second child, presentation of arm; membranes entire; uterus in state of rest; first child born four hours previously; turning easily performed; both children alive	Recovered.
26	October 24, 1830	Left arm descended low in vagina; pains very strong, but intervals long; liquor amnii evacuated; turning easily effected; child alive	Recovered.
27	Dec. 4, 1830	Arm low down in vagina; membranes ruptured; great difficulty experienced in turning	Died; rupture of muscular and mucous coats of uterus.
28	June 1831	Twins; arm presentation of second child; membranes entire; turning easily performed; child alive	Recovered.
29	August 14, 1831	Presentation of right arm; would not allow turning to be performed; three days and nights in labour; child putrid, and forced through pelvis doubled up; head flattened; contents of abdomen pressed through parietes	Recovered.
30	Nov. 3, 1831	Presentation of arm; membranes long ruptured; liquor amnii discharged; uterus firmly contracted around child; great difficulty in turning; child dead	Recovered.
31	Dec. 1831	Twins; presentation of arm of second child; membranes entire; no time lost in bringing down the feet; child alive	Recovered.
32	Feb. 1, 1833	Twins; presentation of arm of second child; pelvis large; child small; expelled doubled up; child dead	Recovered.
33	Feb. 13, 1833	Presentation of right arm; membranes ruptured some hours; uterine action suspended; turning easily accomplished; head arrested in brim; delivery completed by crotchet.	Recovered.
34	August 18, 1833	Presentation of arm; useless efforts had been long used to push back arm, and allow head to descend; turning accomplished; child dead	Recovered.
35	October 23, 1833	Twins; arm of second child presented; turning easily effected; child dead; delivery followed by dangerous hæmorrhage	Recovered.

36	Jan. 2, 1834	Presentation of right arm; membranes just ruptured; shoulder and arm low down; turning performed with difficulty; child dead	Recovered.
37	July 14, 1834	Distorted pelvis; premature labour induced; presentation of left arm; turning performed; child dead	Recovered.
38	March 2, 1836	Presentation of left arm and funis, without pulsation; pains feeble; os uteri half dilated; but not rigid; turning easily performed	Recovered.
39	July 31, 1836	Presentation of shoulder; os uteri high up; membranes entire; operation of turning performed with ease; child dead	Recovered.
40	August 2, 1836	Presentation of left arm and large portion of funis; liquor amnii gone; os uteri dilated; pains feeble	Recovered.
41	August 4, 1836	Presentation of left arm; liquor amnii discharged many hours; uterus firmly contracting; child expelled putrid and doubled up	Died; uterine phlebitis and peritonitis
42	Nov. 3, 1836	Presentation of left arm with funis; turning ineffectually attempted; V.S. employed; pains increased; trunk pressed down into brim; turning at last completed with safety; child dead.	Recovered.
43	Nov. 14, 1836	Sudden rupture of membranes; left arm hanging out of external parts, and right arm in upper part of vagina; foot grasped with great difficulty	Recovered.
44	May 24, 1837	Right arm with umbilical cord, not pulsating, hanging out of external parts; many ineffectual efforts had been employed to turn; the operation at last performed	Recovered.
45	Dec. 23, 1837	Presentation of left arm; uterus firmly contracted; operation of turning tried, but failed; opiates used; arm removed from shoulder; uterus contracted on trunk, and caused it to recede, rendering application of crotchet difficult; trunk separated from head; head extracted without much difficulty	Died; laceration of uterus
46	Jan. 18, 1838	Twins; presentation of left arm of second child; liquor amnii evacuated; arm and shoulder thrust to outlet; right arm also descended; turning accomplished with great difficulty; child dead	Récovered.
47	Nov. 6, 1838	First labour; left arm hanging out of vagina; shoulder strongly impacted in brim; os uteri dilated; liquor amnii evacuated; turning completed with difficulty.	Recovered.
48	March 15, 1839	Presentation of right arm and funis, without pulsation; os uteri widely dilated; pains feeble; great difficulty in turning, on account of violent uterine contractions	Recovered.
49	May 24, 1839	Twins; presentation of head and foot of first child; foot brought down with ease; second child natural	Recovered.
50	Sept. 22, 1839	Presentation of right arm and funis; membranes ruptured; os uteri rigid; turning attempted; V.S. and opiates administered; turning again attempted; V.S. repeated, but turning again ineffectual; arm removed at shoulder-joint; child eviscerated; head left in cavity of uterus; head delivered with difficulty by crotchet, on account of rigidity	Died.

21	July 28, 1829	Presentation of right arm; membranes ruptured; os uteri dilated; pains few and feeble; operation of turning performed with ease	Recovered.
22	Autumn, 1829	Arm with umbilical cord in vagina three days; would not allow the operation of turning to be tried; complete exhaustion; turning at last effected	Recovered.
23	Nov. 8, 1829	Distorted pelvis; presentation of arm; arm removed by another practitioner, and turning repeatedly attempted; thorax impacted in pelvis; foot grasped with craniotomy forceps, and turning at last effected; head unable to pass through brim; perforated behind ear; delivery completed with crotchet	Died; rupture of orifice and neck of uterus.
24	May 22, 1830	Presentation of left arm; membranes ruptured seven days; irregular uterine contractions; shoulder and part of thorax jammed in brim; turning unable to be performed; arm removed at shoulder; thorax perforated; delivery accomplished with crotchet	Recovered.
25	August 29, 1830	Twins; second child, presentation of arm; membranes entire; uterus in state of rest; first child born four hours previously; turning easily performed; both children alive	Recovered.
26	October 24, 1830	Left arm descended low in vagina; pains very strong, but intervals long; liquor amnii evacuated; turning easily effected; child alive	Recovered.
27	Dec. 4, 1830	Arm low down in vagina; membranes ruptured; great difficulty experienced in turning	Died; rupture of muscular and mucous coats of uterus.
28	June 1831	Twins; arm presentation of second child; membranes entire; turning easily performed; child alive	Recovered.
29	August 14, 1831	Presentation of right arm; would not allow turning to be performed; three days and nights in labour; child putrid, and forced through pelvis doubled up; head flattened; contents of abdomen pressed through parietes	Recovered.
30	Nov. 3, 1831	Presentation of arm; membranes long ruptured; liquor amnii discharged; uterus firmly contracted around child; great difficulty in turning; child dead	Recovered.
31	Dec. 1831	Twins; presentation of arms of second child; membranes entire, no time lost in bringing down	Recovered.
32	Feb.		

36	Jan. 2, 1834	Presentation of right arm; membranes just ruptured; shoulder and arm low down; turning performed with difficulty; child dead	Recovered.
37	July 14, 1834	Distorted pelvis; premature labour induced; presentation of left arm; turning performed; child dead	Recovered.
38	March 2, 1836	Presentation of left arm and funis, without pulsation; pains feeble; os uteri half dilated; but not rigid; turning easily performed	Recovered.
39	July 31, 1836	Presentation of shoulder; os uteri high up; membranes entire; operation of turning performed with ease; child dead	Recovered.
40	August 2, 1836	Presentation of left arm and large portion of funis; liquor amnii gone; os uteri dilated; pains feeble	Recovered.
41	August 4, 1836	Presentation of left arm; liquor amnii discharged many hours; uterus firmly contracting; child expelled putrid and doubled up	Died; uterine phlebiti and peritonitis
42	Nov. 3, 1836	Presentation of left arm with funis; turning ineffectually attempted; V.S. employed; pains increased; trunk pressed down into brim; turning at last completed with safety; child dead.	Recovered.
43	Nov. 14, 1836	Sudden rupture of membranes; left arm hanging out of external parts, and right arm in upper part of vagina; foot grasped with great difficulty	Recovered.
44	May 24, 1837	Right arm with umbilical cord, not pulsating, hanging out of external parts; many ineffectual efforts had been employed to turn; the operation at last performed	Recovered.
45	Dec. 23, 1837	Presentation of left arm; uterus firmly contracted; operation of turning tried, but failed; opiates used; arm removed from shoulder; uterus contracted on trunk, and caused it to recede, rendering application of crotchet difficult; trunk separated from head; head extracted without much difficulty	Died; laceration of uterus
46	Jan. 18, 1838	Twins; presentation of left arm of second child; liquor amnii evacuated; arm and shoulder thrust to outlet; right arm also descended; turning accomplished with great difficulty; child dead	Récovered.
47	Nov. 6, 1838	First labour; left arm hanging out of vagina; shoulder strongly impacted in brim; os uteri dilated; liquor amnii evacuated; turning completed with difficulty.	Recovered.
48	March 15, 1839	Presentation of right arm and funis, without pulsation; os uteri widely dilated; pains feeble; great difficulty in turning, on account of violent uterine contractions	Recovered.
49	May 24, 1839	Twins; presentation of head and foot of first child; foot brought down with ease; second child natural	Recovered.
50	Sept. 22, 1839	Presentation of right arm and funis; membranes ruptured; os uteri rigid; turning attempted; V.S. and opiates administered; turning again attempted; V.S. repeated, but turning again ineffectual; arm removed at shoulder-joint; child eviscerated; head left in cavity of uterus; head delivered with difficulty by crotchet, on account of rigidity	Died.

51	Nov. 8, 1839	Presentation of left arm ; membranes ruptured ; os uteri fully dilated ; turning favourably performed	Recovered.
52	Dec. 18, 1839	Left arm hanging out of vagina ; uterus firmly contracted around child ; turning accomplished with difficulty, on account of uterine contractions ; great assistance derived from a tape fixed around ankle in this and several other cases	Recovered.
53	Oct. 14, 1840	Presentation of hand with head ; hand pushed back into uterus ; head descended, and case terminated naturally	Recovered.
54	April 1841	Presentation of right arm ; membranes entire ; turning easily performed	Recovered ; uterine inflammation.
55	Aug. 16, 1841	Right arm in vagina ; membranes long ruptured, and uterus contracting ten hours, but not strongly ; turning performed without difficulty ; hand passed between child and part of pelvis, fore finger in ham ; child dead	Recovered.
56	Nov. 24, 1841	Presentation of right arm ; membranes ruptured ; uterus acting forcibly around child ; turning difficult	Recovered.
57	Jan. 19, 1842	Left arm and shoulder fixed in brim ; os uteri partially dilated ; uterus firmly contracting ; membranes ruptured four days ; turning safely completed ; adhesion of placenta ; seized soon after with hæmoptysis	Died ; hæmorrhage from the lungs.
58	June 20, 1842	Twins ; presentation of arm of second ; turned with ease ; two hours elapsed since birth of first child ; child alive	Recovered.
59	August 2, 1842	Presentation of arm, foot, and part of funis ; great difficulty in turning	Recovered.
60	Sept. 8, 1842	Presentation of left arm and funis, without pulsation ; liquor amnii evacuated forty-eight hours ; os uteri very rigid ; uterus contracted firmly on child ; great difficulty in turning, and in getting the shoulders out of the brim and the nates into it	Recovered.
61	Sept. 16, 1842	Liquor amnii discharged twenty-four hours ; an upper extremity in the vagina ; labour pains only a few hours ; both feet brought down into vagina ; version could not be completed till a tape had been passed around the ankles	Recovered.
62	October 25, 1842	Twins ; arm of second presented ; turning easily accomplished ; child alive	Recovered.
63	Nov. 19, 1842	Left arm in vagina ; liquor amnii not completely discharged ; uterus contracts, but not forcibly, around child ; great difficulty in passing the hand into the uterus ; obliged repeatedly to change the hands ; the chief difficulty arose from the head lying on the fore part of the pelvis ; difficulty in turning after the foot had been grasped ; child dead	Recovered.
64	Feb. 16, 1833	Shoulder and arm presenting ; a foot brought down into the vagina, but the version could not be completed ; on putting a tape round the ankle it was accomplished	Recovered.
65	April 31, 1843	Head, arm, and funis, without pulsation ; perforation and extraction with the crotchet	Recovered.
66	April 9, 1843	Child premature ; turned and extracted without much difficulty	Recovered.

CLINICAL LECTURES
ON THE
THEORY & MEDICAL TREATMENT
OF INSANITY,

*Delivered at St. Luke's Hospital,
May 1st, 3d, and 5th.*

BY ALEXANDER JOHN SUTHERLAND.

LECTURE III.

The medical treatment.—The faculty of attention a good test of the amount of insanity.—Caution necessary in estimating the value of a medicine in the treatment of madness.—Of purgatives.—Hellebore.—Opinions of Alex. Trallianus and Oribasius.—The preparations of mercury.—Taraxacum, croton oil, &c.—Emetics; potassio-tartrate of antimony.

IN speaking of the medical treatment of insanity, gentlemen, I feel that I stand the chance either, on the one hand, of dealing too much in generalities; or, on the other hand, of wearying you with details. To avoid this dilemma as far as possible I shall in the present lecture give you only a brief outline of the treatment of the disease, leaving the remainder to be filled up by the cases which I shall hereafter bring under your notice. I have one warning, however, to give you before you draw any conclusion as to the effect of medicine in particular cases; viz. that the patients here are of course under moral as well as medical treatment—I mean the separation from friends; the regular hours and exercise to which they are subject in the hospital; the withdrawal from those heart-rending scenes of privation and misery which have harassed too many before their admission.

The utility of establishing some receptacle for the insane was long ago felt. We find that so early as the sixth century a lunatic asylum (the first which was built) was erected at Jerusalem, for the poor monks whose distempered fanaticism had deprived of reason: here, too probably, the severities of "the Laura," and the stern authority of the abbot, followed them; and the chains under which they sank, and the collars, bracelets, gauntlets, and greaves of massive iron, which confined their emaciated limbs, might possibly have been converted from a means of penance into one of restraint.

In confining my present observations to the medical treatment of insanity, I wish neither to overrate its effects, nor to undervalue the moral treatment, as the one and the other must go hand in hand in order to

insure success. My reason for now speaking only of the former, is, because it is a subject which has from various causes been much neglected.

In the treatment of insanity we must constantly revert to first principles—to those general laws which are our guide in the treatment of other diseases: experience alone teaches us how these laws are to be modified in each particular case, according to the species or stage of the disease, the difference of age and of individual temperament. You must of course bring with you a knowledge of disease learnt at the bedside of the sane patient before you will be able to detect it when it becomes masked by insanity. If you cannot treat symptoms when a sane patient describes them, much less will you be able to treat them in the case of a madman, who either cannot or will not describe them to you. We cannot take too much trouble in endeavouring to separate the real from the imagined pains of the lunatic. Active disease may all at once shew itself; and if the pain which it causes be, without investigation, set down as the effect of imagination, the patient is soon in a condition in which no medicine is of any avail. Our old patients sometimes sink without any apparent cause: they have no cough, no expectoration, no fever, no pain in the chest; they often cannot tell whether they have night-perspiration. When they are examined by percussion, dulness is found over almost every part of the thorax. It is seldom possible in these cases to hear pectoriloquy, as the patient is too weak, or too much lost, to speak; but the respiration is almost inaudible, and they cannot expand the thorax. I need scarcely say that, at the post-mortem examination of such patients, we find the lungs filled with tubercles and vomiceæ. The numerous questions asked of the friends of patients who apply for admission at the Hospital of Siegburg, prove how much trouble is taken in each case; and not without reason. The previous diseases, the habits, even the occupation of the patient, may tend to throw some light upon the method of treatment. Esquirol has well said, "From the gestures, movements, looks, expression, discourse, from shades of difference inappreciable to any one else, the physician often derives the first hint of the treatment which is suitable to each case consigned to his care." Our chief endeavour must be, in the first instance, to ascertain as far as we can the cause of the disease, whether it be moral or physical; we have then to consider what consequences to the general health have ensued. As in the treatment of epilepsy we try to discover whether the disease depends on irritation of the stomach, bowels, uterus, &c., so, in in-

sanity, we must see whether, prior to the attack, there has not been suppression of the catamenia, of the discharge of an old ulcer, or whether an eruption has not suddenly disappeared—whether the patient has at any time been attacked with fever, delirium tremens, gout, and the like.

I advise a systematic arrangement in each case. Observe the state of the pulse and the skin; feel the head; see whether it is hot all over, or in one part only; whether the extremities are cold; whether the tongue is loaded and dry; whether the bowels are open, the urine free, and, if the patient be a female, whether the catamenia are regular. Next observe the breathing, and the action of the heart; pass your hand over the right hypochondrium, and feel whether the liver is enlarged, or whether the abdomen is distended with flatus; and whether there be tenderness about the præcordia. Examine also the beating of the carotids and temporal arteries. When the patient has his head back, and his neckcloth unfastened, you may perhaps see a scar on the throat, which will let you into a secret. The expression of countenance, the complexion, the colour of the conjunctivæ, and the action of the iris, must all be carefully noted. When you are observing the eye, ask the patient whether he sees moats floating before him; and this may lead him to speak of his illusions or hallucinations. When you have exhausted these, ask about his sense of smelling; you may discover, perhaps, that he smells brimstone, and imagines himself lost to all eternity. Now inquire whether his taste is altered; if it be, he may fancy that his friends have conspired to poison him. Then pay attention to the sense of hearing; and lastly, to that of touch. You will now be prepared to draw him into conversation, in order to ascertain whether his emotions are changed, or whether one or more of the faculties of the mind be disordered.

The faculty of attention often serves as a useful test of the amount of insanity. In the commencement of mania the patient will tell you that he cannot read or write, because he cannot apply his mind to any given subject, particularly if the subject be a new one. As the disease progresses the ideas become more and more distracted; he cannot fix his attention for an instant upon the subject matter before him; he is incapable of conversation; he becomes incoherent. On the other hand, the monomaniac, when the disease first appears, is now and then only absorbed in the day-dream of his imagination. As it advances it swallows up, like Aaron's serpent, all the other ideas of his mind, and he is inattentive to every thing else, even to the common decencies of life. As both mania and monomania sink

into dementia, attention becomes more and more weakened, till it is destroyed by a state of complete unconsciousness. Dr. Holland, in his *Medical Notes and Reflections*, p. 239, 1st edition, says, "No principle of practice in mental disorders can probably be successful, which does not recognise their relation to the phenomena of mind in its healthy state;" and he states that some of the more remarkable cases which he has known, "where physical causes of the infirmity did not exist, have been effected really, if not professedly, by a discreet application of this method." It must be confessed that we sometimes meet with cases where there are no physical symptoms to guide us in the employment of remedies, and we are obliged either to trust solely to the moral treatment, or to have recourse to empiricism. If such be based upon rational principles, I see no reason for not adopting it; nor do I understand how we are to advance our art of prescribing in these cases, unless, when all else fails us, we call in this to our aid. Our two rules in applying remedies are, first, to do good; secondly, not to do harm. The scales may hang even between doing nothing and trying a new remedy: indolence always throws her weight in on the side of the former. Some remedies have borne a high reputation in the treatment of insanity, from their success in individual cases; but experience upon a large scale has either proved them to be worthless, or useful only in removing symptoms. No one can be surprised at the reputation which a medicine sometimes acquires as a specific, when he knows the effect which confidence in the prescriber inspires in weak minds. Many of us, I fear, are prone to attribute too much importance to the last prescribed remedy: in the treatment of insanity we cannot be too careful to guard against such an error. In testing the value of a medicine in any disease, more especially in a mental disease, we should never leave out of our consideration the element of time. "Time," as Locke says, "cures some diseases in the mind which reason cannot;" and some too, I may add, which medicine cannot.

It is not the medicine which has produced some effect in this or that case that we are to regard as useful in all cases, but it is that which has produced effects by relieving parallel symptoms in the great majority of cases, that we may expect to derive benefit from, when similar indications present themselves.

Purgatives.—The first class of medicines which claims our attention, as having been used in the treatment of insanity in all ages, are cathartics. The great remedy for insanity among the Greeks was hellebore; its

healing power over this disease had passed into a proverb as early as the time of Aristophanes. It is, however, a mistake to suppose that the ancients employed no other means of cure. Alex. Trallianus employed the bath, warm drinks, bitters; and says that the Armenian stone is better and safer than the hellebore. We have a prescription of his preserved:—

℞ Pieræ, ʒss.; Scammonii, ʒj.; Agarici, Div.; Lapidī Armeniaci, Div.; Caryophyllorum, gr. xx. M. ft. massa.

a certain portion of which was to be taken. This celebrated physician seems also to have had recourse to stratagem when he could not succeed by other means. He gives us the case of a woman who was cured of melancholy in the following manner. The case seems to have been one of monomania (which you have all heard so much of lately). She imagined that she had swallowed a serpent. An emetic was administered, and a little worm was skilfully inserted into what came off her stomach, and she immediately recovered. Nor was moral treatment neglected by him; for he says, "Know that I have cured many by an appeal to ethics rather than pharmacy."

Oribasius gives us minute details as to the manner of preparing and prescribing the hellebore; but he confesses that it should not be given in every case to the infirm and old, and those of a timid disposition. He says, moreover, that a very unpleasant hic-cough followed the administration of this remedy.

Anticyra, as every one knows, was the place most famous for the growth of this plant; so that "naviget Anticyram" became a proverb. When Livius Drusus was seized with madness, he was sent by his physician to Anticyra, where he recovered by means of this ancient specific. One would be inclined to suspect that the sea voyage, and change of air and of scene, did more towards the recovery of the patient than the boasted effects of the hellebore. This drug has, indeed, lost all its popularity. Dr. Cullen and Dr. Perfect speak strongly against the propriety of employing it. I believe that most practitioners are now agreed upon its inefficacy, because we possess much safer and better remedies. Many have been the revolutions which fashion has caused in the treatment of insanity; but the popularity of cathartics has always more or less prevailed, if we may except the latter part of the last, and the beginning of the present century—an age apparently not very famous in its treatment of mental diseases; for we find the following remarks in Dr. Crowther's work:—"Those who superintend the management of mad patients cannot be too attentive to the state of their

bowels. In my practice," he says, "I have witnessed very criminal neglect as to this point. In one case the intestines were so distended that the transverse arch of the colon gave way." These remarks would have been unnecessary, had not some at least of the practitioners of that period neglected the advice of the father of physic, who recommends us to have recourse to purgatives for the cure of melancholy.

It is of no small importance that we should be careful in our selection of our cathartics; it may be that it is necessary to employ merely a laxative; or the case may require stronger measures, sometimes even a hydragogue cathartic.

The importance of making use of these medicines is obvious, from the frequency of constipation as a symptom in insanity and all other head affections, and from the fact of some cases having recovered after a severe diarrhoea. At the time when there were so many rivals for the honour of winning the hand of the Queen, I asked a patient of mine how his suit prospered. He said, "Oh! I have given up the idea of marrying the Queen." I asked him how that happened, and he said that his bowels had been well purged in the morning, and that his ambitious hopes had vanished. Cathartics should be prescribed in insanity for the purpose of emptying the bowels of their vitiated contents, of correcting depraved secretions, of favouring the peristaltic movements of the muscular fibres of the intestines, of calling into aid the sluggish action of the neighbouring viscera, especially the liver, in order that the circulation of the portal system may be relieved; and, above all, to create a copious serous discharge from the exhalant vessels, by which means we create an artificial point of irritation, and thus, as it is usually called, derive from the head.

The preparations of mercury are of the utmost importance in the treatment of insanity, and are perhaps more generally used in this country than those of any other medicine. They are not only useful for their purgative effects, for stimulating the liver and relieving it of the congestion so often found in recent cases, but they are of great service in equalizing the circulation in the capillaries; thus in those cases where, from the heat of head, the injected conjunctivæ, and other symptoms, we have to fear congestion of the cerebral vessels, their use is manifestly indicated. In those cases also where we have reason to suspect incipient paralysis, or even where the disease has begun to develop itself, I have derived much service from the liquor hydrargyri bichloridi, given in ʒss. to ʒij. doses two or three times daily, with occasional purges. The importance of continuing this medicine for a

compacted state as to receive the full force of every returning action. The body, in its doubled state, being too large to pass through the pelvis, and the uterus, pressing upon its inferior extremities, which are the only parts capable of being moved, they are forced gradually lower, till the body turning as it were upon its own axis, the breech of the child is expelled, as in an original presentation of that part."

Since the publication of Dr. Douglas's essay in 1811, entitled, *An Explanation of the real Process of the "Spontaneous Evolution of the Foetus,"* it has been almost universally admitted that, in these cases, the arm and shoulder do not recede; that the child does not turn upon its axis; and that the nates are not expelled as in an original presentation of that part. The arm, shoulder, and thorax, are first expelled, and the nates and head afterwards. As the term spontaneous evolution is still in common use, and is calculated to convey an erroneous idea of what does actually take place in these cases of preternatural labour, I shall read to you what Dr. Douglas, who first gave a correct explanation of the fact, states on the subject:—"So far as the foregoing detail my observations coincide with those of Dr. Denman and others; but I cannot comprehend how successive repetitions of the same propelling power which forced the child into this situation, should subsequently, at any period, produce a counter effect, causing the shoulder to retreat into the uterus. The fact, however, is, that the shoulder and thorax, thus low and impacted, instead of receding into the uterus, are at each successive pain forced still lower, until the ribs of that side corresponding with the protruded arm press on the perineum, and cause it to assume the same form as it would by the pressure of the forehead in a natural labour. At this period not only the entire of the arm, but the shoulder, can be perceived externally, with the clavicle, lying under the arch of the pubis. By further uterine contractions the ribs are forced more forward, appearing at the os externum as the vertex would in a natural labour; the clavicle having been, by degrees, forced round on the anterior part of the pubis, with the acromion looking towards the mons veneris. But in order to render as clear as possible the successive movements in this astonishing effort of nature, I will endeavour to describe still more precisely the situation of the foetus immediately prior to its expulsion. The entire of it somewhat resembles the larger segment of a circle; the head rests on the pubis internally; the clavicle presses against the pubis externally, with the acromion stretching *towards the mons veneris*; the arm and *shoulder are entirely protruded*, with one *side of the thorax not only appearing at the*

os externum, but partly without it; the lower part of the same side of the trunk presses on the perineum, with the breech either in the hollow of the sacrum, or at the brim of the pelvis, ready to descend into it; and by a few further uterine efforts, the remainder of the trunk with the lower extremities is expelled. And to be still more minutely explanatory in this ultimate stage of the process, I have to state that the breech is not expelled exactly sideways, as the upper part of the trunk had previously been; for during the presence of that pain by which the evolution is completed, there is a twist made, about the centre of the curve, at the lumbar vertebræ, when both buttocks, instead of the side of one of them, are thrown against the perineum, distending it very much; and immediately after the breech, with the lower extremities, issues forth; the upper and back part of it appearing first, as if the back of the child had originally formed the convex, and its front the concave side of the curve."

There is now a premature acephalous foetus upon the table before you, the left arm and shoulder of which presented in labour a few days ago, and the body passed through the pelvis double, in the manner here described; or spontaneous evolution took place. I have repeatedly witnessed the same occurrence where the foetus was premature, and flaccid from putrefaction; and on the 14th August, 1831, I saw a child at the full period expelled in this manner, in a woman who obstinately refused to allow the operation of turning to be performed. The right shoulder and arm presented in that case; and after the labour had continued three days and nights, the child was at last forced through the pelvis doubled up, in a putrid state, the head being flattened, and the viscera of the abdomen pressed through the parietes. It is only in a few rare cases, however, that the delivery is completed in this manner—where an unusual combination of circumstances exists; and it would be improper to calculate upon the occurrence of spontaneous evolution, or allow the possibility of its taking place, to influence the treatment we adopt in cases of arm presentation. It does not occur in cases where the operation of turning is performed with difficulty, and it is not a resource to which, in practice, we ought ever to trust—it ought never to be considered as a substitute for turning. It is now a general rule, established in all countries where midwifery is understood, that in cases of preternatural labour, where the shoulder and superior extremities of the child present, the operation of turning ought to be performed. But the hand must not be forced into the uterus if the orifice is rigid and undilatable; it should be dilated nearly to the size of half a crown piece or more, or the margin ought to be

very thin, soft, and yielding, if it is expanded to a smaller extent than this when turning is attempted. If the os uteri will not admit the extremities of the fingers and thumb in a conical form to be introduced without much force; if it is thick, hard, and unyielding, some delay is necessary that the parts may relax, death being almost always the consequence of thrusting the hand with violence through the orifice of the uterus in a rigid and undilatable condition, whether the membranes be ruptured or not. But as soon as it will admit of the safe introduction of the hand, where you have ascertained that an arm presents, no time should be lost in completing the delivery, otherwise the membranes may give way, the liquor amnii be evacuated, and a case of little difficulty and danger be suddenly converted into one equally hazardous to the mother and child. In all cases of labour, where the first stage is far advanced without the nature of the presentation being positively determined, or a superior extremity is felt through the membranes, the patient should be kept in the horizontal position, that they may not be ruptured; and you should remain in constant attendance upon the patient, and be prepared to interfere the instant the necessity arises.

When the operation of turning is required before the membranes are ruptured, and when the orifice of the uterus is widely dilated, and there are long intervals between the pains, it is accompanied with little difficulty and danger. Having explained to the patient and her relatives the nature of the case, let her lie on the left side near the edge of the bed, with the knees drawn up to the abdomen. Sit down by the side of the bed and quietly take off your coat; lay bare your right arm by turning up the shirt above the elbow, and cover the back of the hand and the whole fore-arm with cold cream, lard, or a solution of soap. Introduce one finger after another into the vagina, and slowly and effectually dilate its orifice. The hand in a conical form, and in a state of half supination, must then be pressed steadily forward with a semi-rotatory motion against the perineum and sides of the passage, till it clears the orifice of the vagina. This should always be done very slowly and gently, as it is accompanied with great pain. Let the hand remain some time in the orifice of the vagina, that it may be fully dilated, and offer no resistance in the subsequent steps of the operation of turning. When the hand has dilated the vagina sufficiently, in the absence of pain gently insinuate the points of the fingers and thumb into the os uteri in a conical form; and if it is not sufficiently open to allow the hand to pass, you must proceed next to use artificial dilatation *here also, very gently and slowly, always stopping as soon as a pain comes on, but not*

withdrawing the fingers altogether at the time from the os uteri. Having succeeded in dilating the part without rupturing the membranes, slide the hand up between the membranes and the anterior part of the uterus into the cavity, and grasp the feet when the membranes give way. Most frequently the membranes burst as the hand is entering the uterus, before it reaches the feet, and the liquor amnii rushes out and is lost, if it is not prevented by pressing the hand forward firmly into the orifice. Never be contented with one foot when it is possible to grasp both; and this can always be done when the liquor amnii has not escaped, and the uterus is not closely contracted around the body of the child. Seize both feet and legs, and when there is no pain, draw them down into the vagina; and as the nates descend through the os uteri, the shoulder and arm will gradually recede or be retracted, and will offer no obstacle to the remaining part of the operation, which should be completed as if the nates and inferior extremities had originally presented, and which has already been very fully described. In actual practice, except in twin cases, the membranes have been ruptured and the liquor amnii is gone, in a great proportion of cases—in about ten to one—long before we are called upon to deliver by turning, and the operation is then a much more serious affair. Sometimes when the os uteri is half dilated, there is an interval of freedom from pain for several hours after the rupture of the membranes, and partial escape of the liquor amnii. Here it is advisable to turn without delay; and the hand can be passed up into the uterus and the feet brought down with little more difficulty than if the membranes had not been ruptured.

The shoulder and arm may present, and the operation of turning be required where the membranes have burst at the commencement of the labour, the liquor amnii has escaped, and the os uteri is rigid, and is not dilated in a sufficient degree to allow the hand to pass. You can learn from experience alone, when there is a probability in such cases of artificially dilating the os uteri without the employment of too much force; it is best to wait patiently, in such a state of the os uteri, till relaxation takes place, before attempting to overcome the resistance, and to obviate the danger of spontaneous laceration of the uterus by venesection and opiates.

A much more difficult case of turning than any of those already described, is that in which the liquor amnii has long been evacuated, the uterus has contracted strongly around the body of the child, and the arm, shoulder, and a part of the thorax, have become firmly impacted in the pelvis. No attempt in such a case should ever be made to force back the presenting part into the uterus, but the hand should be cautiously

ducted to the feet along the arm of the child, and the shoulder pressed aside. It is impossible in all cases to determine positively the position of the child and the side of the uterus to which the feet are directed the hand ought, however, invariably to be passed up between the front of the pelvis and the presenting part of the child, however the trunk and extremities may be situated; and as both hands are frequently required in these cases to turn, it is of no importance whether you employ the right or left first. I believe the two most important rules which you ought to remember in the treatment of these cases are, first, to pass up the hand between the anterior and shallow part of the pelvis, and the presenting part of the child; and secondly, when one hand is rendered powerless by the pressure from the contractions of the uterus, to withdraw this hand and replace it by the other. By the observance of these rules there are few cases, I believe, of arm presentation, in which the operation of turning may not be safely accomplished. It is in rigid and irritable states of the uterus that we encounter the greatest resistance to the introduction of the hand and where these exist in a high degree, recourse should be had to a copious venesection and a large opiate, before the operation is again attempted. Where these means have been vigorously employed, it will rarely be necessary to remove the arm of the child at the shoulder joint, perforate the thorax, and draw it through the pelvis with the crotchet doubled up as in spontaneous evolution.

Sixty-six cases of shoulder and arm presentation have come under my observation since 1823. In a great proportion of these the operation of turning was undertaken in the most unfavourable circumstances, both for the mothers and their children, after the liquor amni had entirely escaped, and the uterus had not only been contracting for many hours around the child, but repeated unsuccessful efforts had been made to deliver. Seven women died from rupture of the uterus, and three from inflammation of the uterus. Laceration and inflammation of the uterus are therefore the consequences of turning chiefly to be dreaded. Four of these cases of rupture occurred in the practice of other accoucheurs, and three in patients under my own care, and where no great difficulty was experienced, or force employed in turning. The most perplexing cases were those in which there was distortion of the pelvis, with arm presentation; and the most easy and successful, those twin cases in which the superior extremity of the second child presented, and the operation of turning was promptly performed. Edmund Johnson, Esq. has had the kindness to make the following tabular view of the histories of these cases, sixty of which have been recorded in my *Clinical Midwifery*.

A TABULAR VIEW OF SIXTY-SIX CASES OF SHOULDER AND ARM PRESENTATIONS.

1	October 10, 1823	Arm in vagina; uterus firmly contracting around the child; repeated attempts to turn; uterus ruptured on left side, either from or before operation; fetus escaped through rent, afterwards extracted; none of the ordinary symptoms of ruptured uterus present	Died seven days after delivery; adhesions by lymph around rupture, which, when peeled off, exposed the rent; peritonitis.
2	August 1, 1824	Right arm with funis low in the vagina; shoulder and thorax squeezed in brim; liquor amni escaped; operation of turning performed with difficulty	Died forty-eight hours after from peritonitis.
3	October 15, 1824	Right arm, swollen and livid, protruded through the os externum; pelvis distorted; shoulder and thorax wedged in brim; uterus firmly contracted; membranes ruptured four hours; repeated efforts to turn, without success; thorax perforated; arm separated at shoulder; child dragged through the pelvis, doubled up	Recovered.
4	Feb. 12, 1827	Triples; arm of first and second child presented; turned without difficulty; presentation of third natural; all still born	Recovered.

5	April 9, 1827	Arm presentation; liquor amnii discharged; uterus firmly contracting; turning difficult; child dead	Died from uterine hæmorrhage.
6	May 1, 1827	Left arm presenting, with cord twisted around it; not pulsating; uterus firmly contracted; frequent attempts to turn, without success; thorax perforated, and child extracted	Recovered.
7	May 14, 1827	Presentation of left arm; shoulder and thorax fixed low in pelvis; umbilical cord prolapsed, without pulsation; uterine contractions strong and violent when turning was attempted; thorax perforated and child extracted	Recovered.
8	Dec. 3, 1827	Presentation of arm with head; turning attempted; one foot brought down, and left in vagina a day and a night; distorted pelvis; labour completed by craniotomy; extraction difficult.	Recovered, after severe inflammation of uterus.
9	Dec. 18, 1827	Presentation of arm and funis; os uteri partially dilated, and high up; membranes ruptured three hours; cord pulsating; turning difficult	Recovered.
10	March 25, 1828	Right arm with funis; liquor amnii escaped four hours; slight uterine contraction; operation of turning performed without difficulty; in extracting head the chin hitched over pubis; child dead	Recovered.
11	April 20, 1828	Twins; arm of second child; pains not strong; turning easily performed; one hour between the birth of first and second child; both children alive	Recovered.
12	April 26, 1828	Right arm with funis hanging out of external parts; no pulsation; turning easily performed; placenta retained; rupture of uterus discovered, when placenta was extracted	Died, with delirium and vomiting.
13	June 15, 1828	Left arm with funis; no pulsation; liquor amnii evacuated; strong and violent uterine contractions; tinct. opii employed; turning easily performed	Recovered.
14	August 19, 1828	Right arm; liquor amnii evacuated; no uterine contractions; turning accomplished with great ease; child alive	Recovered; severe inflammation.
15	Sept. 18, 1828	Twins; arm and shoulde of second child protruded through external parts; operation of turning difficult	Recovered.
16	Dec. 15, 1828	Left arm and thorax pressed deeply in pelvis; liquor amnii discharged; strong uterine contractions; V.S. and opiate used with advantage; turning at last performed with ease; child dead	Recovered.
17	Jan. 3, 1829	Presentation of arm; rigid os uteri; pains strong and frequent; thorax perforated; arm divided from trunk; delivery completed with crotchet	Recovered.
18	Jan. 9, 1829	Right arm protruded through os externum; pains slight; turning difficult; child dead	Recovered.
19	May 29, 1829	Presentation of left arm, much swollen; os uteri firmly contracted around shoulder; liquor amnii evacuated; V.S. employed with benefit; turning accomplished with ease; rigors and feeble pulse after operation	Recovered.
20	June 3, 1829	Twins; second child, arm presentation; pains strong; operation of turning not accomplished; arm and shoulder drawn through the outlet of the pelvis, and child delivered doubled up	Recovered.

21	July 28, 1829	Presentation of right arm; membranes ruptured; os uteri dilated; pains few and feeble; operation of turning performed with ease	Recovered.
22	Autumn, 1829	Arm with umbilical cord in vagina three days; would not allow the operation of turning to be tried; complete exhaustion; turning at last effected	Recovered.
23	Nov. 8, 1829	Distorted pelvis; presentation of arm; arm removed by another practitioner, and turning repeatedly attempted; thorax impacted in pelvis; foot grasped with craniotomy forceps, and turning at last effected; head unable to pass through brim; perforated behind ear; delivery completed with crotchet	Died; rupture of orifice and neck of uterus.
24	May 22, 1830	Presentation of left arm; membranes ruptured seven days; irregular uterine contractions; shoulder and part of thorax jammed in brim; turning unable to be performed; arm removed at shoulder; thorax perforated; delivery accomplished with crotchet	Recovered.
25	August 29, 1830	Twins; second child, presentation of arm; membranes entire; uterus in state of rest; first child born four hours previously; turning easily performed; both children alive	Recovered.
26	October 24, 1830	Left arm descended low in vagina; pains very strong, but intervals long; liquor amnii evacuated; turning easily effected; child alive	Recovered.
27	Dec. 4, 1830	Arm low down in vagina; membranes ruptured; great difficulty experienced in turning	Died; rupture of muscular and mucous coats of uterus.
28	June 1831	Twins; arm presentation of second child; membranes entire; turning easily performed; child alive	Recovered.
29	August 14, 1831	Presentation of right arm; would not allow turning to be performed; three days and nights in labour; child putrid, and forced through pelvis doubled up; head flattened; contents of abdomen pressed through parietes	Recovered.
30	Nov. 3, 1831	Presentation of arm; membranes long ruptured; liquor amnii discharged; uterus firmly contracted around child; great difficulty in turning; child dead	Recovered.
31	Dec. 1831	Twins; presentation of arm of second child; membranes entire; no time lost in bringing down the feet; child alive	Recovered.
32	Feb. 1, 1833	Twins; presentation of arm of second child; pelvis large; child small; expelled doubled up; child dead	Recovered.
33	Feb. 13, 1833	Presentation of right arm; membranes ruptured some hours; uterine action suspended; turning easily accomplished; head arrested in brim; delivery completed by crotchet.	Recovered.
34	August 18, 1833	Presentation of arm; useless efforts had been long used to push back arm, and allow head to descend; turning accomplished; child dead	Recovered.
35	October 23, 1833	Twins; arm of second child presented; turning easily effected; child dead; delivery followed by dangerous hæmorrhage	Recovered.

36	Jan. 2, 1834	Presentation of right arm; membranes just ruptured; shoulder and arm low down; turning performed with difficulty; child dead	Recovered.
37	July 14, 1834	Distorted pelvis; premature labour induced; presentation of left arm; turning performed; child dead	Recovered.
38	March 2, 1836	Presentation of left arm and funis, without pulsation; pains feeble; os uteri half dilated; but not rigid; turning easily performed	Recovered.
39	July 31, 1836	Presentation of shoulder; os uteri high up; membranes entire; operation of turning performed with ease; child dead	Recovered.
40	August 2, 1836	Presentation of left arm and large portion of funis; liquor amnii gone; os uteri dilated; pains feeble	Recovered.
41	August 4, 1836	Presentation of left arm; liquor amnii discharged many hours; uterus firmly contracting; child expelled putrid and doubled up	Died; uterine phlebitis and peritonitis
42	Nov. 3, 1836	Presentation of left arm with funis; turning ineffectually attempted; V.S. employed; pains increased; trunk pressed down into brim; turning at last completed with safety; child dead.	Recovered.
43	Nov. 14, 1836	Sudden rupture of membranes; left arm hanging out of external parts, and right arm in upper part of vagina; foot grasped with great difficulty	Recovered.
44	May 24, 1837	Right arm with umbilical cord, not pulsating, hanging out of external parts; many ineffectual efforts had been employed to turn; the operation at last performed	Recovered.
45	Dec. 23, 1837	Presentation of left arm; uterus firmly contracted; operation of turning tried, but failed; opiates used; arm removed from shoulder; uterus contracted on trunk, and caused it to recede, rendering application of crotchet difficult; trunk separated from head; head extracted without much difficulty	Died; laceration of uterus
46	Jan. 18, 1838	Twins; presentation of left arm of second child; liquor amnii evacuated; arm and shoulder thrust to outlet; right arm also descended; turning accomplished with great difficulty; child dead	Récovered.
47	Nov. 6, 1838	First labour; left arm hanging out of vagina; shoulder strongly impacted in brim; os uteri dilated; liquor amnii evacuated; turning completed with difficulty.	Recovered.
48	March 15, 1839	Presentation of right arm and funis, without pulsation; os uteri widely dilated; pains feeble; great difficulty in turning, on account of violent uterine contractions	Recovered.
49	May 24, 1839	Twins; presentation of head and foot of first child; foot brought down with ease; second child natural	Recovered.
50	Sept. 22, 1839	Presentation of right arm and funis; membranes ruptured; os uteri rigid; turning attempted; V.S. and opiates administered; turning again attempted; V.S. repeated, but turning again ineffectual; arm removed at shoulder-joint; child eviscerated; head left in cavity of uterus; head delivered with difficulty by crotchet, on account of rigidity	Died.

found adherent; there was not a drop of fluid to be found therein. And another instance might be hereby added to the so-called fallacies of auscultation. But considerable effusion was predicted, and considerable effusion was found to exist. The general symptoms, as well as the physical signs, might naturally induce the belief that this effusion was partly fluid—it was found solid.

CASE III.—*Pneumonia, with tubercles; rapid and extensive consolidation a few days before death.*

I was, on the 3d of January, 1843, requested to visit a gentleman by Mr. Collambell, of Lambeth, from whom I received the following account of his history and ailments. He was 23 years of age, married, the father of two children; by occupation an engraver on wood, of some celebrity and considerable merit. His mother died of phthisis. Some weeks before, he had been attended by Mr. Collambell for a rather severe attack of hæmoptysis, accompanied by marked dulness of the right side of the chest, and principally affecting, if not wholly confined to, the middle lobe of the lung. The hæmoptysis yielded to treatment; the dulness on percussion, and other signs of pulmonary apoplexy, disappeared almost entirely, and he was prudently advised to go into the country to re-establish his health. While there, according to his own statement, he was again attacked with hæmoptysis, and was treated by nauseants. The after symptoms rendered it probable that the medicine was antimony administered for the cure of pneumonia, the rusty sputa of which had by himself been supposed to prove that he was again suffering from "spitting of blood." After some days he came to town, and again placed himself under the care of Mr. Collambell. I saw him the day after his return. His complexion was fair; his hair long, and black; his breathing was frequent and difficult, rendering it necessary that he should be supported in bed by pillows; his cough was not very frequent; his expectoration frothy, mucous, viscid, generally white, but intermixed with portions of a reddish brown colour; the skin was hot and dry; the tongue moist and not much loaded; the pulse small, feeble, and frequent.

The physical signs were as follows:—The entire right side and the upper part of the left sounded well on percussion, and afforded pure respiratory murmur, only a little increased in its intensity of sound. The whole of the left side was imperfectly raised during inspiration, and the inferior part anteriorly, and all below the scapula posteriorly, were dull upon percussion; affording well marked, but not very fine crepitating rattle at the end of each inspiration, and, below the scapula, decided bronchophony approaching the tone of Punch upon speaking. The patient was considerably depressed in spirits, and very anxious, especially in reference to the probable existence of tubercles in the lungs. After minute examination I felt justified in stating that, whatever might be the probability of their presence arising from other symptoms, I was unable to detect any *physical indication* of their existence.

He was ordered the tartrate of antimony in small but frequently repeated doses, and, as depletion appeared from his debility to be contra-indicated, a succession of blisters to the affected side.

January 9th.—He was represented to have been much lower this morning; but at my visit in the afternoon had considerably improved. The dulness upon percussion had almost disappeared; the bronchophony was no longer audible; the cough had considerably decreased; the affected part of the lung was clearly much more permeable, and the inspiration therein was accompanied with a general muco-crepitating rattle. Just below the heart alone was there a space about as large as the palm of the hand, under which, from the dulness on percussion and the absence of respiratory murmur, or morbid rattles, it appeared probable that the lung was still consolidated. The infra-clavicular, acromial, and scapular regions, were again examined attentively, but afforded no evidence of disease or obstruction. He was still very anxious, weak, and pale; but the skin was still rather hot and dry, and he was ordered to repeat the medicine less frequently, and to persist in the use of the blisters.

I saw him about ten days after this, but discovered little difference in his general or local symptoms. He was now recommended to take a milder tonic, and to continue the blisters.

February 12th.—He had considerably increased difficulty of breathing, and was rather weaker. He had in no respect improved. The muco-crepitating rattle of the left side inferiorly, the dulness and absence of respiration in a small defined portion of the lung, and the absence of the indications of disease in the upper part of both lungs, remained as before. But the tongue was red, and he had some diarrhoea; the pulse as usual was small, frequent, and feeble.

Ordered—Small doses of Hydr. c. Creta and Pulv. Ipec. C. at bed-time, and a mixture containing Compound Chalk powder, Mucilage, and Infusion of Cusparia, during the day.

19th.—No improvement; aphthæ had appeared on the tongue and cheeks, which were red and tender; the diarrhoea continued frequently to trouble him, and though occasionally checked by medicine, materially contributed to exhaust his little remaining strength. His chest was again examined as carefully as his debility would permit. The portion formerly affected therewith presented the same muco-crepitating rattle as before. The part below the heart was still dull, but was now supposed to be breaking down. This at least appeared to be indicated by a peculiarly shrill and resonant mucous rattle being distinctly heard over it. The upper parts of the chest were again carefully examined, and again found to be freely expansible on inspiration, perfectly resonant upon percussion, and free from all morbid sounds, excepting a slight increase of the natural respiratory murmur approaching to puerile respiration. In the lower part of the right lung there was now, however, heard some muco-crepitating rattle.

Ordered—To use a croton oil liniment as a counter-irritant, as the blisters caused considerable inconvenience by stranguary. To take Infusion of Catechu, and aromatic confection with other astringents, and if the diarrhoea should be checked, to replace it with Tr. Ferri Sesquichlorid. and Infusion of Quassia, or some other preparation of iron, should that be found not to agree.

23d.—The diarrhoea continued unchecked; the dyspnoea had considerably increased. The lower parts of the chest presented the same physical signs as before: the upper, in consequence of

the distress caused by the exploration, were not upon this occasion examined. His pulse was now exceedingly small and feeble, and his debility very great. The expectoration, as throughout the complaint, was frothy, mucous, and small in quantity. Sulphate of copper and opium were now recommended to be given in addition to the catechu and aromatic confection, previously ordered by Mr. Collambell, but they were ineffectual in checking the relaxation of the bowels; his dyspnoea gradually increased, and latterly became most distressing, and he expired during the evening of February 27th.

Inspection 84 hours after death, by Mr. Collambell and myself.—Externally considerable emaciation was evident, but there existed no appearance of decomposition. The chest alone was permitted by the friends to be examined. The pericardium contained a few drachms of clear serum. The heart was moderately distended with very dark and nearly fluid blood. It was rather loose, pale and soft in structure, but free from any other marks of disease.

Left side.—The two folds of the pleura were connected by adhesions of different sizes and various characters; some were close and membranous; others soft and opaque; while small portions of semi-transparent lymph were found on other parts of the membrane. The inferior two-thirds of this lung, or thereabouts, were soft, dark, friable, and congested from the receding pneumonia, but were thinly sprinkled throughout with small transparent tubercles. A small portion, about an inch and a half square, at the anterior and inferior part, just below the heart, exactly in the situation indicated by dulness and absence of respiration during life, was consolidated, of a dirty white or fawn-colour, from the infiltration of pus, and contained small cavities partly filled with the same sort of fluid, and communicating with the bronchial tubes. The upper third of this lung was generally very solid, and quite destitute of air, of an iron grey colour, friable, and opaque, but containing a few transparent tubercles interspersed through it, and also many small depôts of well-formed healthy pus, varying in size from a large shot to a small bean. These collections of matter were lodged

in cavities which were of a rounded form, were lined with a fine layer of opaque lymph, were quite filled with the fluid, and appeared to have no communication with the external air. Quite at the apex of the lung was an irregularly shaped cavity, which was broken by the efforts used in tearing away the strong adhesions by which it was connected to the parietes. It appeared to be nearly as large as a pullet's egg, to have walls which were loose, flocculent, and dark-coloured, and to have been multilocular.

Right side.—The upper third of this lung adhered firmly to the ribs, and was in other respects precisely in the same condition as that of the left, excepting that there was no cavity in the apex, but a small one, about the size of an almond, with a smooth lining of semi-purulent lymph, and nearly empty, at the posterior part. The middle lobe contained several defined portions as large as nuts or almonds, of a dirty pale pink colour, firm, friable, dry and airless, probably the remains of the preceding pulmonary apoplexy. With these were commingled masses of grey consolidation of the lung from pneumonia, approaching in character that existing in the apices, but without any purulent depôts. Irregularly distributed between these two specimens of diseased structure were portions of lung perfectly healthy. The inferior lobe of the right side was the least diseased of any part of the lungs. Posteriorly it was dark-coloured from gravitation, but anteriorly was light coloured, dry, soft and crepitant, and contained only a very few transparent tubercles thinly scattered through it.

In the preceding case is presented an example of consolidation of the upper parts of both lungs so extensive and complete as to render a considerable portion of the organs almost perfectly impermeable by air. This consolidation, nevertheless, was not discovered during life. It offers also a very remarkable illustration of some of the supposed fallacies of auscultation. Nothing could be more striking. Those parts of the lungs which afforded during life natural resonance and almost pure respiratory murmur, and were pronounced to be comparatively free from disease, were found after death not only more diseased, with one trifling ex-

ception, than any other part, but impermeable, solid, and suppurating.

The explanation is evident. This disease was not *discovered*, simply because it did not *exist* at the time the exploration of the chest was made. Ten days intervened between the examination of the chest and the death of the individual. During this period his general distress had much increased, his debility from diarrhoea had considerably advanced, and his dyspnoea especially had become gradually but greatly aggravated. During this period, then, this new disease had been set up and had run its course. It did not exist—it may, indeed, be asserted to be physically impossible that it could have existed—at the time of the preceding examination. Even if this, however, were not true, it would appear incredible that a portion of the lung not so large as the palm of the hand, in a more difficult position for examination and detection, should be constantly pronounced to be consolidated, till it was stated, only a few days before death, to be breaking down and forming cavities, and should be afterwards found exactly in the situation, and precisely in the condition that had been predicted, and yet that this far more extensive and obvious disease should have remained undiscovered. The case, then, was an instance of rapid consolidation of the lung, with purulent deposits, occurring in a scrofulous subject a short time before death. Such rapid changes are, I am convinced, especially in persons of bad constitution, by no means unfrequent. Thus a person, not many weeks since, was admitted into the hospital, the duration of whose entire illness was not more than eleven days, but upon the examination of whose body after death the middle lobe of the right lung was found not only perfectly consolidated, but softened, and of a dirty fawn colour, from the infiltration of pus, the consequence of an active but low form of pneumonia. Thus also it arises that cavities are sometimes found where none had been predicted; that large caverns are exposed to view, where small abscesses were supposed to exist; and that consolidations and effusions are discovered after death which had not been prognosticated during the life of the patient.

REFLECTIONS
ON THE
INFLUENCES OF COLD UPON THE
LIVING BODY.

BY T. WILKINSON KING.

*Admitted effects ; chemical ; vital —
Safety valve—Heat depends on many
functions — Five effects of cold —
States of Nerves—Congestion—Delay
of functions ; reaction ; irregular—
Diathesis ; fever ; wasting ; irrita-
tion.*

AT a time when cold and cold water are becoming so much reputed among the ignorant and the careless, it may not be unacceptable to many to find an attempt made towards determining the medical value of these agents. We hope to be able, in a small degree, to correct the received doctrines relative to the subject of cold, but it is not so much our intention to treat of it systematically as to prepare the way for other considerations.

We cannot but observe that the compiled notices concerning cold appear to us to comprise much that is erroneous and unsatisfactory, especially in the way of theory.

There does not appear to be any cause of disease so well appreciated or so generally admitted as cold. We do not mean that its agency is understood, but merely that authors and observers of all kinds, and in all places, attribute the rise and modification of the greatest variety of affections to the influence of cold, and to us it seems almost impossible, medically, to attach too much importance to the study of the agent in question.

"The theories of sympathy and of associated motions are hardly adequate to an explanation of the phenomena of torpor from cold. There must here, as in other cases, be a regular series of events, a succession of antecedents and consequents in the relation of cause and effect, from the first to the last event, which it is the business of philosophy to discover and enumerate. The narration is still incomplete, from

* In respect of principles, these thoughts are, in part, a repetition of what has been elsewhere advanced. In respect of illustration, they are left somewhat deficient, to avoid repeating more. We may refer generally to former papers in this journal, and in the Guy's Hospital Reports, and particularly to one in the latter, On Variable Disorders.

defective facts and limited observation. Some links of the chain, however, are perhaps within our reach. The terminations of the sanguiferous system on the surface of the body have their action immediately diminished by the local abstraction of caloric*." Thus wrote a highly intelligent physician, Dr. G. Kellie, of Leith, near forty years since. It is little to his reproach that the existing knowledge and doctrines did not enable him to extend his reflections with much greater success. With reference to severe cold, he argued farther thus:—"The whole series of changes, from the first torpor of the skin and lungs to the complete suspension of the voluntary powers, may be connected and illustrated by the theory (of pulmonic sympathy and influence); if, as there is some reason to conjecture, *the blood suffer changes at the cutaneous surface* similar to those it undergoes in the lungs—if there be a co-operation of the functions of these two organs in freeing the blood from carbon, hydrocarbonate, or carbonic acid."

The words in italics have our concurrence, but, as will be seen, we do not accompany the physiologist to the conclusion. Dr. K. quotes a particularly happy apology from the Essay on the Sublime and Beautiful:—"A theory founded on experiment, and not assumed, is always good for so much as it explains. Our inability to push it indefinitely is no argument at all against it. This inability may be owing to our ignorance of some necessary mediums—to a want of proper application—to many other causes besides a defect in the principles we employ."

When we see how much chemical reactions are influenced by temperature, and observe that the functions of vegetable life are similarly controlled, we may well conclude that there is no more important subject in medicine than that of the influence of temperature on the animal body. Temperature or heat must be a main element in every process of health and disease, and in the operation of every remedy.

Chemistry shows us very clearly that water is at least a triple compound of oxygen, hydrogen, and matter of heat: thus it is, we must remember, that heat

* See the Edinburgh Medical and Surgical Journal, vol. i. p. 308. 1805.

is one of the essential elements of the blood and animal tissues. The degree and variations of temperature of a living part are necessary consequences of its nutrient functions, and when we have considered the heat which is indispensable to the integrity of the part, our next great concern probably should be with the temperature which disturbs the function of the part, and finally the functions of the body generally. In all this, however, the caloric evolved may be considered chiefly as an index of the more material changes by which it is eliminated.

With reference to the influence of cold, we should not neglect to consider what is best known with regard to the temperature of our bodies.

Thus it is highly important to remember that all parts have their own natural and pretty definite proportions of heat. The following is probably a well-observed instance:—In the month of July, the left ventricle itself was about 103° Fah., its blood a little less, and so successively less and less, the right ventricle and its blood, and then the mouth and rectum, the hands, the groin and axillæ, the cheeks, the feet, and the surface of the hypochondria exposed, on which the thermometer stood at 95°.

In the main, the *heat of the body decreases towards the surface*; there is a difference of three or four degrees between the layers half an inch deep on the chest, legs, and arms, and the muscles an inch and a half deeper. Other circumstances modify this statement.

Parts are warm in proportion to their depth, central situation, vascular supply, and immediate vascular activity.

When the artery of a limb is compressed, the heat of the whole limb begins immediately, though slowly, to decline, and on removing the obstruction, so soon the temperature begins to rise*.

On the approach of summer, or the like, while the thermometer is rising from 60° to 80°, the heat of our bodies is rising from 90° to 100°, and so that of birds from 100° to 110°.

Again, we find it a general law, *that*

* See an explanation of the changes after tying arteries, in a paper "On the Open State of the *Ductus Arteriosus* after Birth," by T. W. King, *London and Edinburgh Monthly Journal of Medical Science*, July 1842.

to raise or lower the temperature of any one part is to do the same by the rest. Put one hand in water at 110°, and in a short time it and all the remotest parts will gain 1° of heat. With one hand in iced water, the opposite one will pretty speedily lose 9° or 10°. These are facts of the utmost importance, and of the most constant use in our reflections on health and disease, prophylactics and remedies*.

It is a remarkable fact that the temperature of warm-blooded animals follows very closely in inverse proportion to the degree of safety-valve-function attributed to each; that is, in direct proportion to the force and precision of the general circulation†. The temperature of the body seems in most cases to be in proportion to the frequency of the pulse.

Harvey put a ligature on the arm until the veins were distended, and then cooled the limb down considerably, and he found that suddenly relaxing the ligature produced a deep sense of cold in the thorax. This may seem a rude experiment, yet it cannot but have its fellow in every-day life, and the most valuable corollaries depend on it. It is in vain to impute all delay of secretions and the like to mere obstructions of nervous influence; cooling the blood is a certain means of retarding all capillary functions. Subsequent reactions are the necessary result of such retardations. If the reaction be general and equal, it is salutary, but if it be only partial, it can scarcely fail to be excessive and mischievous. It has been very commonly advanced that the respiratory function is that which especially and almost exclusively regulates the heat of the body, but we should not forget that the supplies of digestion are equally essential. We make this remark, however, chiefly for the sake of a more general observation, that the condition of the blood and its function are dependent on many organs, and that we must be careful not to impute an undue share of uses to any particular organ, however essential it may be in some one respect.

The function of respiration is no

* See the article *Animal Heat*, in the *Cyclopedia of Anatomy and Physiology*.

† Vide *Accounts of the Safety Valve-function in the Heart of Man and Warm-blooded Animals*, by T. W. King, *Guy's Hospital Reports*, Nos. 4 and 11.

doubt essential to the processes of circulation, nutrition, and evolution of heat, but the full development of many functions (as to a series of animals) is scarcely less indispensable than that of respiration. We have nothing which serves to prove that the highest grade of respiratory function could of itself be equal to any useful end.

Medically, the influence of cold seems to demand a threefold consideration. We have to seek for the explanation of its morbid agency, of its curative actions, and of its peculiar influence in regulating the functions of the body, as we observe them changing with the advance of winter, or a visit to colder climates. Thus, we find a physiological, a pathological, and a therapeutic series of views, which require distinct investigation, but it may for the present suffice, if we are enabled, by reference to these various points indiscriminately, to establish more accurate notions of the influence of cold generally.

It is desirable to consider, but not easy to decide, how far cold may operate locally. It does not seem to affect the feet, or the neck and arms; yet a disordered tooth, or perhaps a chronic laryngitis, are directly disturbed by it. We do not imagine that if half a dozen square inches of the subclavicular space were alone exposed to cold air, that this would particularly affect the lung; but in the case of a skin disease, or an ophthalmia, the case seems different.

Cold directly applied may affect any organ, and especially if it be already weak. Remote cold, as at the feet, may affect any organ, but especially the weak one; as the lung, or the eye, as in the case of rheumatism or headache. Some nodes seem to be the effect of direct cold; chilblains, also, and the cutaneous irritation of the winter's evening.

Cold extremities are to be considered as general indications both of the influence of external things and of the internal dispositions. They are the first marked indications; but we do not think it wise to impute disorder to this local affection, without admitting that the surface as well as the system has been at the same time much more generally affected. The patient may complain of having had cold feet; but the physician must conclude that the

cold has operated almost over the whole surface.

The first great effect of the application of cold to the surface of the body is, to diminish the vitality, or rather nutrition of the part. The consequences of this result will be various, according to the degree, extent, and the duration of the cold, and according to the powers of resistance which the individual may possess. Five different changes at least demand attention,—

1st, as affecting the state of the surface;

2dly, with regard to superficial local reaction;

3dly, the simple determination of blood to the interior;

4thly, the depression of functions generally; and

5thly, the determination of active functions generally, or in particular parts, by reaction.

Dr. Copland, the focus of authorities, observes (Dictionary, p. 355), "*The primary effects of the abstraction of heat from a part, to the extent of producing a decided sensation of cold, appear to be exerted upon the nervous system, whose sensibility and vital manifestations it lowers, and, when excessive, entirely annihilates.*" Now we do not deny this statement, yet we believe that the partial view it affords is a great and prevalent error. The concomitant effects on the blood and capillaries, as independent organs (suppose frost-bite superadded to old paralysis), are much more essential local changes; and there is reason to suppose that the effects of cold on the mass of the blood are of the first consequence, independently of all the nervous functions. Some may infer with Mr. Travers that the blood-globule has its own peculiar nervous organization, which is susceptible of disturbance or irritation; but even this is an insufficient evasion, for it is a much more certain and not less important fact, that the chemical or material organization of the blood is the subject of disorder, and a cause of diseases.

Cold applied to a part in some intensity operates very much as a slow or steady pressure; the nutrition of the capillaries, &c. is suspended or disturbed, and subsequently they yield more than adjacent vessels to the distending blood. By this their reparation is effected, and their strength

restored, so that they resume their natural calibre; and in this manner, so far as the local changes are independent, we see merely decline of capillary function, reaction, and restoration, occurring as natural and simple sequents and consequences.

The application of cold in syncope is possibly a simple transfer of blood; or is there here nervous agency in addition?

The salutary effects of cold belong to the study of therapeutics; and amongst medical authors the use of cold has had strong advocates. I shall but briefly reflect on its mode of operation. Topical cold reduces inflammation, and seems often admissible; but the more the inflammation is healthful, the less it needs to be cut short; while the more it is morbid, the less it is safe to subdue it. Applied to the head in cases of brain affection, cold is generally sanctioned; in erysipelas of the scalp it is mostly prohibited. Certainly the most frequent known explanation of metastasis is by the action of cold. Sponging the surface of the chest is only equal to any equally free ablution; it may be harmless, refreshing, or fatal.

The *cold bath* is said to be in many cases invigorating; and it may be pretty evident that the glow which it induces must tend to the freer nutrition of the skin, if it be not rather an absolute index of the augmented nutritive process. The general ease of body, sense of health, "feeling light," as it is called, are indications of the internal functions being at least free from oppression. But what is to be inferred from all this? May we conclude more than this, that a well nourished skin, able to resist casual impressions of cold, may thus sometimes be obtained? whilst the means often fail or prove pernicious; and the desired object is not less surely promoted by the warm or tepid bath, frictions, or common exercise. Cold, frictions, and even heat, applied generally, with judgment, are all calculated to produce a free nutrition of the surface, which may be regarded as equally salutary in itself, however produced. It is in vain, however, to promote this state at the expense of other organs; and, of course, it is still more in vain to expect such a result while general wasting is in progress. Nutrition of

the skin can only be promoted while the proper materials prevail in the blood. If it be an object to be desired, it would appear that friction offers the simplest means of insuring cutaneous nourishment. The use of warmth, while it excites superficial actions, is more calculated, according to experience, to facilitate many functions, both nutrient and secretory, or even to induce wasting. The application of cold, however judicious, may not be free from danger; its advantages seem to depend on moderating (retarding and perhaps equalizing) the internal functions. So far it would seem to resemble the medicines which retard excretion, and add force to the circulation.

A gentleman informed us that he was in the habit of accelerating his circulation to a considerable degree before taking his seat on or in a coach, and he believed that thus he was better and longer able to resist the cold while inactive. In this we conceive he may have judged rightly, and especially, supposing as a contrast the case of one taking his place after a long period of rest. The general action of the system, free distribution of the blood, and evolution of heat, would take time to subside. Our approval is not to be understood of a state of perspiration, by which, with evaporation, the body is rapidly cooled down, nor will it apply to that exercise which may produce any material waste of the circulatory fluids, for under such circumstances protracted exposure would find the body too rapidly becoming exhausted of its nutrient and calorific materials. If cold could be made to effect the simple purposes of abating perspirations and cutaneous loss, we might easily understand the advantage. This object, however, in delicate persons, is at least of doubtful security. Long-continued cold is out of the question. The most transitory cold may be tried with but little risk. The safest mode of cooling the surface is by exercise in the air with light clothing; for, while the first equalizes the functions of the body, the latter tends to moderate them; but even this attempt, in our own experience, requires much caution. It is sometimes scarcely necessary that more than a small part of the frame be partially clothed to produce more effect than is healthful or safe. With respect

to exercise it should be remembered likewise that it not only tends to regulate all functions, but first favours the nutrition of a great part of the body, and so prepares matters for excretion (to stimulate excretories), and even induce freer digestion.

Cold applied generally to the surface to a limited degree, when the body is sufficiently vigorous, scarcely seems to produce a decrease of activity. It may be that the sudden impediment leads at once to a commensurate reaction of the capillaries of the skin. Hence the glow after immersions, &c. But these pleasing effects are not constant, and the man who has enjoyed a bath in the morning may take severe mischief by cold in the evening. This indicates conclusively the grand point on which all our medical reflections must turn; namely, the constitution or state of the individual concerned. One takes cold, another does not. One and the same exposure shall produce, in so many different persons, catarrh, pleuritis, and rheumatism,—strumous, fibrinous, serous, and purulent effusions. It is little to say, that age, sex, and habits, help to decide these results. Relapse and metastasis will often find their explanation in a similar way.

The simple determination of blood to the interior of the body, which is so commonly adverted to as a mischievous effect of external cold, does not seem in itself competent to disturb any organ in particular, nor is it in fact equal to any thing beyond that of simple repletion. If all the other causes of diarrhoea, local and general, exist, external cold may readily induce it, or reproduce it when it has just subsided; but, under ordinary healthy circumstances, the so-called inward congestion from sudden cold is only adequate to the common effects of repletion, such as a fuller and more active heart, deeper respiration, and more free secretion and nutrition of the deeper organs generally. That some even tender frames may endure exposure and inactivity with impunity, is possibly true, yet not without many limitations. The appearance of tender health may depend on exposures; both it and the impunity may be deceitful, or only temporary; and, at the best, it would seem that the powers of resisting and of maintaining a general equipoise of the animal functions, under great dif-

ficulties, is the ultimate limit of health and safety.

That the material diminution of the superficial functions of nutrition or secretion, &c. will leave more to be disposed of by other actions, we need not stay to explain; yet we should recollect that the pathological irregularities of this compensatory process deserve much attention. One organ is already more prone to excitement perhaps; the individual more prone to concoct the stimulus of one particular secreting organ, or even to determine specific deposits, as tubercle or pus. It is not only certain that cold may arrest the functions of the skin, but, by diminishing the temperature of the whole mass of the circulating fluids, we cannot but conclude that all the nutritive and depurative functions are, in a definite measure, impeded, and perhaps still farther perverted; and hence it follows that difficulty must be expected, both generally and locally, in various degrees, according to the quantity of heat abstracted, and to the sufferer's natural powers. The fatal sleep from cold is not mere narcotism, but rather to be compared to hybernation. It is an increasing retardation of all functions, beginning at the surface. Dr. Marshall Hall concluded from experiment that hybernants presented but insensible degrees between ordinary sleep and the deepest hybernation. The torpor of tropic reptiles, and of fish in mud, seems analogous: one animal may be frozen, and another dried up, and still be capable of renewed life. In what other ways cold may affect the system must remain to be seen elsewhere.

It may illustrate our reflections, to consider how, by degrees, all the organs may adapt themselves to a low diet, stimuli, or excesses; and thus it is with regard to the depression of functions which a cold climate may induce. All nature shews a rapid and full development of life in warm regions, and tardy evolutions in cold climates. Excessive heat brings on premature decay, and a cool region tends to moderate actions and longevity; but still much depends on the peculiar disposition of individuals.

It cannot be denied that many persons in health suffer nothing from exposure of very severe kinds; and perhaps it is true that a very transitory,

though severe, application of cold is mostly harmless even to the delicate; but to these last the effect of any continued cold, though at the time unperceived, is very generally pernicious: hence one great advantage of warm climates to persons in delicate health.

Dr. James Blundell and others have recommended the free use of cold in cases of dangerous uterine hæmorrhage; and it must be admitted that facts are brought forward which seem both to justify and uphold this practice in various analogous cases. We offer no decided opinion on the merits of such a plan of treatment, but we hold that some reserve is imperatively called for. Oozing of blood from a mucous surface, the open veins of a relaxed uterus, or tangible perforation of an artery, surely demand different methods. The constitution, and also the instant condition of the patient, involve particular considerations. We cannot question the fact, that cold may arrest the catamenia, or any other secretion, and the administration of warmth may restore the function. The spontaneous arrest of epistaxis is so constant, that cold is hardly proved to have any decided effect. The circumstances of inflammatory hæmorrhage, as from the bowels, would seem strictly to contra-indicate the use of cold.

The case of bleeding from the most minute vessels is probably that in which the sudden stoppage of blood by remote cold is most likely to be effected.

Some attribute almost as much harm pathologically to warmth as to cold, but we think not justly. External warmth promotes much superficial capillary activity and secretion; and thus it frees the internal functions, and perhaps even enervates. A person with catarrhal affection of the chest, well clothed or active, goes into the cold air in the upright posture with comfort; and this even increases for hours, especially if perhaps there is some excretory diminution of the circulating fluids, and not an increase, as by renewed meals. Subsequently he returns to his warm room and comfortable meal, and he sits or reclines inertly; upon which a general increase of vascularfulness and activity, and local obstruction and secretion, commences and pro-

ceeds, until the general secretions have disburthened the circulation, and he is again at ease by a partial restoration of the balance. This exposition applies in a manner to a great variety of chronic disorders, such as discharges, rheumatism, strictures, and skin disorders. With us capillary distension comprises the chief mystery of *spasmodic* stricture, the proper name for which we conceive to be transitory, or transitory aggravation of, stricture.

A great variety of pains, catarrhs, inflammations, and fevers, are said to arise from cold, and doubtless, where the vigour is wanting to resist, external cold greatly disturbs the balance of the circulation, and obstructs both the superficial secretions and deeper functions. A person affected with any variable chronic discharge, which is excited by every little cause of disturbance to which the body is exposed, seems in a great measure exempt from fevers and phlegmasiæ; but the case is widely different if the habitual discharge becomes arrested.

We think we have often sufficiently noticed, that chronic disorder, repeatedly aggravated by cold or the like, is often attended by a short train of febrile symptoms, which the local excitement seems to carry off.

Now we may suppose that one in strong health may throw off the effects of severe exposure by a simple and general reaction, yet not without loss or waste; and may we not still farther suppose, that such causes of decline, and similar but less complete restorative eliminations, often repeated, may be among the substantial causes of febrile and inflammatory attacks? These are not always to be attributed to "a cold," without previous disorder. How universal and just is the idea of an accumulating morbid cause; and is not temperature as much an imaginable cause of deteriorations as a supposititious state of the air?

All men readily draw inferences from the appearance of emaciation; but we do not know of any reflections which pretend to give a rational account of the wasting body, and of its connection with different morbid states. We may endeavour to clear up the approaches of this important topic; and it is perhaps some recommendation of our attempt to say, that our observations

have been corroborated by personal experience, as well as by some experimental attention to the subject of declining health in former periods.

It is not necessary to dwell on the effects of deficient food, or simply impeded nutrition, nor on the palpable results of wasting discharges, yet it is desirable to state here that the considerations which remain are calculated to define and limit the application of the above mentioned causes. Asthma imposing abstinence, the functional or organic impediments to digestion, excesses or anxiety, are more or less intelligible causes of marasmus. The influences of cold are occasionally evident also.

A delicate patient is heard to say, "It is a matter of surprise to my friends every year, that, while others grow thinner and feebler during the hottest weather, I invariably grow larger and stronger." And the medical observer will hardly fail to call to mind cases of wasting which have recurred almost as regularly as the winter season. We know that susceptible infants, convalescents, and the aged, waste with cold, and fatten with warmth. This, as a general remark, is amply corroborated in different climates. The mortality among infants in France is great in proportion as the season or the "department" is cold. The deaths in foundling hospitals, where scarcely one in 19, 27, and 37 are reared, we attribute greatly to the want of warmth and comfort. If any thing like 5 out of 6 of our poor infants are cut off (see Underwood), has cold no share in the result? It is notorious that young infants flourish in the tropics, and also many delicate and aged. To such person each successive exposure, though only to moderate cold, and for a short time, without ample care, clothing, and activity, is speedily followed by languors, and perhaps pains, catarrhs, cutaneous itching, and, unless suppressed, often perspiration; and also by irregular digestion, turbid urine, some falling off of the hair, &c. These, all or in part, may occur without any consciousness of the cause, and pass off in twenty-four hours, and be renewed still more rapidly. Half a family only eat more heartily after sitting in a cold church; the rest become weary and restless, complain of

aching legs and feet, and fall asleep. Repeated relapses of this kind, however little the effects are manifested, and however little the causes are suspected, are a common source of wasting and decline.

We do not dispute that cold, proportioned to the powers of endurance, may often invigorate, as there are doubtless instances in which high temperatures accelerate the functions of secretion to the wasting of the body; but those who, setting aside the natural prejudices of a vigorous body, carefully look into the progress of declining health, with or without the presence of chronic disease, will, we are assured, find reason to accuse cold as a morbid cause alike of declines, relapses, and aggravations, and also of those new and fatal seizures which cut short many obstinate diseases.

These reflections are offered to the reader as rational though feeble suggestions on a difficult and neglected subject. Many points have been passed over to render them brief; and some conclusions to which these views tend are for the present omitted, to avoid offence. Our object has been to regard the effects of cold as a form of irritation or disturbance, both local and general. We hope to strengthen and extend these remarks, by examining the subject of heat in a somewhat similar manner.

36, Bedford Square.

REMARKS ON MESMERISM.

BY GEORGE SOUTHAM,

Surgeon to the Salford and Pendleton Royal Dispensary, Manchester.

(For the Medical Gazette.)

[Concluded from p. 354.]

SLEEP appears to be one of the most frequent effects of mesmerism. It has been produced in different degrees, from slight drowsiness to profound stupor; in some instances accompanied with an exalted state, or partial suspension of sensation, thought, and voluntary motion, giving rise to somnambulism or ecstasy in those of ardent imagination. Such effects are similar to the various conditions of natural sleep, which, when perfect, is characterised by the senses ceasing to perceive external

impressions, the ideas and emotions being suspended, and the will no longer controlling the voluntary movement; when imperfect dreaming and somnambulism arise, from the conception of ideas by the mind not entirely ceasing, one portion of the mental faculties remaining awake when the rest are asleep: with this addition in somnambulism, that the voluntary muscles, and generally one or more of the senses, are called into activity. In ordinary cases, sleep is induced by mental and corporeal fatigue, but it is not necessary that all the functions of the body and mind should be equally exposed to exhaustion; for such is the power of association and habit, that when one organ or faculty experiences fatigue, the others participate in the same condition; thus the body becomes drowsy from study, and the mind by corporeal exertion*. When sleep is partial (which is frequently the case if produced artificially), this association of the functions of the body and mind does not take place, and some of the senses, or particular sets of the muscles, are awake while the rest are asleep. For instance, if we look steadily at an object for a length of time, the whole field of vision becomes darkened; and if the object is placed in such a position that the action of the levator† muscles of the eyelids are powerfully excited, closure of them is induced‡. Temporary blindness will be the only consequence, if the faculties of the mind and the voluntary actions have not participated in the drowsiness; but generally a tendency to sleep arises in some of them, from having been indirectly influenced in the operation, or from having sustained a degree of exhaustion in consequence of their share of the nervous energy being contributed to the support of the organ which has been the object of attention. This experiment, regarded as a striking proof of the mesmeric power, depends on the concentration of the sensorial

energy on the organ of vision, and its gradual exhaustion by constantly directing the attention to the part; on the same principle as the blind and the dumb acquire occasionally such an extraordinary acuteness of touch, that it is apt to be mistaken for the faculties of hearing and seeing. The withdrawal of this energy, under the influence of mental motion, from the external senses, produces insensibility to pain and outward impressions, just as intense reverie on abstract subjects renders the individual almost dead to every thing around him—as in the well-known examples of Archimedes and Sir Isaac Newton.

Every practitioner of experience knows with what activity similar influences operate in persons of excitable dispositions, especially where the balance and harmony of the functions of life have been weakened from previous disease. Some forms of dyspepsia, affections of the respiratory and circulating organs, are frequently aggravated by the continual direction of the mind towards them, which ultimately proves the most troublesome part of the complaint. The same powers are still more active in those nervous diseases which more peculiarly belong to females, who, as Hunter observes, “being less acquainted with the real properties of natural things, are more apt to imagine preternatural ones; and their reasoning powers not being so strong, they indulge the actions of the mind more, and allow it to take possession of the body*.” Thus hysterical attacks are frequently brought on by the mere expectation of them, in addition to the morbid state of the system, which originally caused the disorder. In fact, as Müller remarks, “any state of the body which is conceived to be approaching, and which is expected with perfect confidence and certainty of its occurrence, will be very prone to ensue as the mere result of that idea, if it do not lie without the bounds of possibility†.” In illustration of such phenomena, he mentions a case detailed by Pictet in the German translation of Sir H. Davy’s *Researches on Nitrous Oxide*. “A young lady wished to inspire this intoxicating gas, but in order to test the power of the imagination, common atmospheric air was given to her, instead of the nitrous oxide.

* Mason Good’s *Study of Medicine*, vol. iii.

† Dr. M. Hall “believes the levator palpebræ, and perhaps the four recti muscles of the eye, to be, of all the muscles of the animal frame, the most purely cerebral, or voluntary, and unendowed with fibres from the excito-motory system. When awake volition raises the eyelid. During sleep, the excito-motory property induces constant contraction of the orbicularis, as it does of the other sphincters.”—*Diseases and Derangements of the Nervous System*, 1841.

‡ The success of this experiment is much facilitated by the remarkable association which exists between the actions of the eyelids and the iris.

* Works edited by Palmer, vol. i. p. 360.

† *Elements of Physiology*, vol. ii.

She had scarcely taken two or three inspirations of it, when she fell into a state of syncope, which she had never suffered previously." Few examples, however, are more conclusive than those observed in some mesmeric patients, which frequently border on the marvellous. Elizabeth O'Key, obedient to every wish of her master, was told by him that nickel was capable of retaining and transmitting the magnetic fluid in an extraordinary degree, but that lead possessed no such virtues: accordingly when nickel was produced, and a few passes made, she was thrown into one of her fits of ecstatic delirium. It need scarcely be remarked that these alleged magnetic properties of nickel have been very satisfactorily refuted*. Kluge says, that such is the wonderful sympathy between the magnetiser and the patient, that he has known the latter to vomit and be purged in consequence of medicine which the former had taken. Whenever he put pepper on his tongue, or drank wine, the patient could taste these things distinctly on her palate; and I have seen a person suffering from deafness, who, whilst in the mesmeric sleep, imagined she heard the tick of a watch, which was found afterwards not to have been going.

The idea that a structural defect will certainly be removed by a particular remedy, has sometimes increased the organic actions of the part to such a degree as to remove the disease†; hence the miraculous cures said to have been performed by our kings laying their hands upon persons afflicted with scrofula, and other wonderful effects worked by the numerous empirical remedies which have been in vogue at different periods; but the ingenious and simple experiments of Dr. Haygarth‡ on the tractors, have satisfactorily explained the virtues of such agents, and proved that their success depends chiefly on the power of transferring the nervous energy from one part of the body to another, under the influence of an excited imagination.

The epidemic nature of certain forms of insanity, and of those remarkable convulsive diseases formerly so prevalent in Scotland, America, and the continent, may be accounted for on the

same principles; and the facility with which the latter appear to have been propagated amongst a crowd, shows that much of the success of Mesmer and his followers is owing to the public exhibitions, and the other imposing means they have adopted.

On this subject, the French commissioners*, after observing how considerable the effects were which isolated patients exhibited, stated that even in the public process, the crises do not commence in less than the space of two hours. They further remark, that the impressions are communicated from one to another, and reinforced in the same manner as the impressions which are made by theatrical representations. "The applause by which the emotions of individuals at the banquet are announced, occasions a general emotion, which every one partakes in the degree in which he is susceptible. The same observation has been made in armies upon a day of battle, where the enthusiasm of courage, as well as the impressions of terror, are propagated with so amazing rapidity. The drum, the sound of the military musical instruments, the noise of the cannon, the musketry, the shouts of the army, and the general disorder, impress the organs and exalt the imagination in the same degree. In this equilibrium of inebriation, the external manifestation of a single sensation immediately becomes universal: it hurries the soldiers to the charge, or it determines them to fly. In a numerous assembly, individuals are more subjected than on other occasions to their senses and imaginations, and less capable of consulting and obeying the dictates of reason. Hence the origin of that religious frenzy which formerly affected so powerfully both the minds and bodies of the enthusiasts of the *Cevennes*; and hence the acts of insanity into which public bodies are apt to be hurried in times of political revolution.

Magnetism, then, or rather the operations of the imagination, are equally discoverable at the theatre, in the camp, and in all numerous assemblies, as at the banquet; acting, indeed, by different means, but producing similar effects†."

‡ On the Imagination as a Cause and as a Cure of Disorders of the Body. London, 1800.

These observations lead me to notice phreno-mesmerism.

The influence of the will over the train of thought being suspended in sleep, we ascribe to the objects of imagination a real and present existence, similar to those of perception when awake. In dreaming, then, some of the faculties, as the will, perception, and judgment, being in a state of torpidity, whilst the memory and imagination are active, the mind becomes crowded with ideas, which, in the absence of the governing powers, are in most instances subject to the laws of association, and occur with more or less irregularity according to the cause which gives rise to them. Generally, dreams consist of the simplest forms of ideas and emotions; but when they are caused by any train of thought or reasoning which has had a certain persistency in the mind whilst awake, they are produced with greater regularity and vividness.

Further, particular ideas may be associated with certain bodily sensations: a person feeling himself in an uneasy position in bed fancies he is tied down, or that he is falling from a precipice: another, having a bottle of hot water applied to his feet, dreamt that he was making a journey to the top of Mount Etna, and found that the heat of the ground was almost insupportable. Dr. Reid relates of himself, that the dressing applied after a blister on his head having become ruffled so as to produce considerable uneasiness, he dreamt of falling into the hands of savages, and being scalped by them; and every one who is in the habit of dreaming will remember similar instances in his own person.

Moreover, dreaming and somnambulism can be produced in some persons by whispering into their ears when they are asleep. An interesting case of this description is alluded to by Dr. Abercrombie, on the authority of Dr. Gregory. "The subject of it was an officer in the expedition to Louisburg, in 1758, who had this peculiarity in so remarkable a degree, that his companions in the transport were in the constant habit of amusing themselves at his expense. They could produce in him any kind of dream by whispering into his ear, especially if this was done by a friend with whose voice he

was familiar. At one time they conducted him through the whole progress of a quarrel, which ended in a duel; and when the parties were supposed to be met, a pistol was put into his hand, which he fired, and was awakened by the report. On another occasion, they found him asleep on the top of a locker, or bunker, in the cabin, when they made him believe that he had fallen overboard, and exhorted him to save himself by swimming. He immediately imitated all the motions of swimming. They then told him that a shark was pursuing him, and entreated him to dive for his life. He instantly did so with such force as to throw himself entirely from the locker upon the cabin floor, by which he was much bruised and awakened, of course. After the landing of the army at Louisburgh, his friends found him one day asleep in his tent, and evidently much annoyed by the cannonading. They then made him believe that he was engaged, when he expressed great fear, and showed an evident disposition to run away. Against this they remonstrated, but, at the same time, they increased his fears by imitating the groans of the wounded and the dying; and when he asked, as he often did, who was down, they named his particular friends. At last, they told him that the man next himself in the line had fallen, when he instantly sprung from his bed, rushed out of the tent, and was roused from his danger and his dream together by falling over the tent-ropes. A remarkable circumstance in this case was, that after these experiments, he had no distinct recollection of his dreams, but only a confused feeling of oppression or fatigue; and he used to tell his friends that he was sure they had been playing some trick upon him*."

Similar cases have been related by Smellie in his *Natural History*, and by Beattie in his *Moral and Critical Dissertations*.

It is evident, therefore, that there are some individuals, accustomed to dreaming, in whom the slightest suggestion, or bodily impression, is sufficient to call into action a certain train of ideas; and those who have watched the experiments of the phreno-mesmerists cannot but admit that they

* *Inquiries concerning the Intellectual Powers*, page 262, Edin. Rev.

depend on similar principles; with this addition, that by associating a particular set of ideas with a certain bodily impression, they may be renewed on other occasions by the mere repetition of the impression. Accordingly, they have associated the different faculties and propensities with impressions on the corresponding phrenological organs; and the remarkable facility and precision with which they appear to be renewed, when once formed, have led the "men of skulls" to regard these phenomena as indisputable facts in favour of phrenology. Unfortunately, their experiments were confined to the phrenological organs: had they extended their inquiries, they would have discovered that benevolence, veneration, self-esteem, &c. might have been as easily associated with corresponding places on the foot, or any other part of the body, as on the head.

Malebranche said, "that to become a philosopher we must see clearly; but to be endued with faith, we must believe blindly:" and certainly, from the recent acts of the phrenologists, it would appear that having discovered their inability to bring their general views into accordance with known facts, they have wandered into the paths of mysticism, and brought to the aid of their science "some dim and disfigured images of truth," which have been ascribed to supernatural powers.

With regard to the reputed advantages of mesmerism, it has been asserted that such a degree of insensibility can be produced under its influence that individuals have undergone severe operations without feeling pain.

Ordinary sensation, it is well known, is frequently suspended from mental emotion, and from disease. We have no means of ascertaining the limit beyond which absence of feeling does not extend; but when such a condition occurs in an extreme degree, it generally arises from some morbid state of the nervous system; and as we have seen that several of these formidable affections are produced by mesmerism, we may infer that any remarkable insensibility to pain can only exist as a symptom of disease.

There is little probability of it possessing any salutary effects (although we are told that it is an infallible cure for most intractable complaints); for a power so energetic in exciting disease

can scarcely be expected to have any remedial virtues. If its application could be limited to the production of sleep, or to regulating the supply of nervous energy, it might, under the influence of faith, be successful in the cure of those affections arising from, or modified by, imaginary causes.

CONTRIBUTIONS

TO

ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

Some Remarks on the Structure and Arrangement of the Spinal Arachnoid.

A FEW years ago I published in the MEDICAL GAZETTE a translation of a memoir, by Arnold, on the Membranes of the Brain and Spinal Marrow; to the translation I added a commentary. My chief object was to point out to anatomists the existence and the peculiarities of a tissue subjacent to the arachnoid (sub-arachnoid tissue), connecting that membrane to the pia mater as well cerebral as spinal. 2. To explain my reasons for differing with M. Magendie in respect to those "communications" he supposes to exist between the fourth ventricle (cerebellar) and the general sub-arachnoid space. And, 3. To describe the true nature of that membrane which invests the cerebral and cerebellar ventricles (ventricular membrane) and the surfaces of the convolutions of the brain where they oppose each other. These observations I now make from memory, not having the memoir before me, but I believe that these were the points at which I chiefly aimed.

Since then, some additional observations on the arrangement and structure of the spinal sub-arachnoid tissue have been made by an anatomical writer who, though evidently young and but recently in the field, has already, by the remarkable clearness of his descriptions, earned for himself a reputation which must be lasting. The observations to which I allude are contained in a foot-note to the admirable descriptive work of Mr. Viner Ellis. They are not put forward as his own, but described as having been furnished him by an old and much esteemed friend of mine, Dr. Sharpey; they refer

to an anatomical structure to which, for many years, I had occasionally given a good deal of attention, and bestowed on its examination a good deal of labour. Surprised at the discrepancy between us, I repeated with, if possible, still greater care, my previous observations. To avoid every chance of error, I requested my assistants to repeat the dissections. I next made them, in presence of large classes of students. After reading to them the various passages alluded to as occurring in Mr. Ellis's work, and finding that hitherto I have met with nothing to alter my previous description of this membranous structure, which, by the by, simply accords with the usual descriptions of others, I now venture to submit the matter in dispute to my brother anatomists and physiologists: the ultimate structure of these important membranes can scarcely be too frequently examined*.

Mr. Ellis's text is as follows:—"Dissection of the Spinal Cord." "A small portion of the cord is to be cut off, and the dura mater, having been laid open both before and behind, placed in water, with the dura mater pinned out on a piece of board, and with the posterior surface uppermost. If air be gently blown beneath the visceral layer of the arachnoid, the sub-arachnoid space is perceived, and it is found to be divided into a right and left portion by a septum extending along it."—P. 150.

As a lecturer on anatomy for nearly twenty years, and the conductor of large practical classes, I have been much in the habit of laying open the spinal column with the view of demonstrating the structures to classes and to individuals. Now, what I have observed having a reference to the passage just quoted is simply this, confining my remarks as strictly as I can to the *dorsal* aspect (posterior of Mr. Ellis) of the spinal marrow and its membranes. I am quite within bounds when I say that I have opened and examined the spinal marrow and its membranes, or caused it to be opened and examined in my presence, at least a hundred times.

* When I commenced these observations I was in hopes of putting my hand on the "Translation of Arnold, with a Commentary," already referred to; it was published, so far as I can recollect, in the GAZETTE (perhaps in the Lancet) some four or five years ago, but I have failed in putting my hand on the volume, so that I am compelled reluctantly to quote it from memory.

On laying open the spinal column in the usual way, by removing the arches of all the vertebræ from the atlas to the last sacral, and incising cautiously the dura mater, the visceral layer of the arachnoid presents itself. This generally adheres by a few points here and there to the parietal layer, an arrangement which I once thought might have some remote connexion with the speculations of Goethe, Frank, Oken, Dumeril, and De Blainville, but which were supported neither by comparative dissections nor by abnormal structures. If the visceral layer of the arachnoid be now punctured, and a blow-pipe introduced into the sub-arachnoid space, air may be blown in with the greatest ease, so as to fill large portions of this space, of some inches in length, and extending quite across the medulla, or, in other words, from side to side: the examination of the same aspect of the membrane under water gives precisely the same result. Thus the septum has no existence as a complete septum; its existence as an incomplete one I think extremely doubtful. It is worthy of remark, that neither M. Cruveilhier*, nor the learned authors of the *Encyclopédie Anatomique*, now in the course of publication, make the slightest mention of this septum on the dorsal aspect of the spinal arachnoid, nor, indeed, on any other. This is negative evidence, it is true, but of an important kind in a matter of this sort. M. Magendie's opinions must be known to these anatomists. To their works I shall afterwards return; in the meantime, I may remark, that although varieties in the connexions of the visceral layer of the arachnoid (on its dorsal aspect) with the proper membrane of the medulla are occasionally met with, they amount to nothing more than the adhesion of the two membranes to each other at more numerous points by a fine filamentous and sometimes fibrous-looking tissue. Mr. Ellis continues—

"The sub-arachnoid space is much larger in the lower than in the upper part of the cord; it contains the sub-arachnoid fluid, and is divided, as Magendie has shown, by a partition along the middle line, and it communicates with the interior of the brain by the aperture in the fourth ventricle, as proved by Magendie. Dr. Sharpey

considers this space to be lined by a thin membrane, that (which?) he describes as a loose serous sac; this is reflected around the cord by its visceral layer, and on the arachnoid by its parietal; it is separable from the arachnoid, and it may be raised with care, as a thin membrane, from the cord, roots of the nerves, and ligamentum dentatum. He suggests, also, that the portion extending along the posterior part of the space is formed by a reflection of this thin membrane inwards to the cord; that the sub-arachnoid fluid is secreted by this, and contained in it; and that it is continued into the ventricles of the brain, which it lines, by the aperture of the fourth ventricle into the posterior sub-arachnoid space of the brain,"—pages 150 and 151. Again, at page 14 of the same volume, "This space (the posterior sub-arachnoid space) situated between the medulla oblongata and the hemispheres of the cerebellum, is wider before than behind, and communicates in front with the anterior space by the side of the medulla and pons; on the sides and behind with the under surface of the cerebellum, and below with the large sub-arachnoid space of the spinal canal. When this space is opened, the aperture of the fourth ventricle is exposed. By this aperture the cavities of the interior of the brain communicate with the sub-arachnoid spaces both of the brain and of the medulla; and Dr. Sharpey thinks it probable that the membrane which he considers to line the interior of the sub-arachnoid space of the medulla is continued into the cavities of the brain by this opening."

In a foot-note is added—"We might conceive this membrane (the internal arachnoid), to be prolonged from the external arachnoid by the canal of Bichat into the interior of the ventricles, after lining them to be continued through the opening of the fourth ventricle into the so-called sub-arachnoid space, which it lines, being applied to the surface of the spinal cord, the nerves, and the ligamentum dentatum on the one hand, and on the other to the surface of the external sac of the arachnoid; the two by their mutual adhesion forming the loose arachnoid."

Now if it be meant by the above passage that the arachnoid membrane transmits into the interior of the brain by the great cerebral fissure, a mem-

branous sac lining the ventricles, then it will be quite unnecessary for me to say one word in refutation of an opinion already proved false in all our elementary works; a statement involving in fact a physical impossibility: but the passage no doubt admits of another meaning, namely, that a serous sac lining the ventricles passes through the fissure of Bichat to communicate with the sub-arachnoid space there, and through the fourth ventricle, to communicate at the anterior spinal sub-arachnoid space. Now this assertion equally involves a physical impossibility, or nearly so.

Before venturing to offer any critical remarks on the passages now quoted, I shall first beg the reader to remember what I said regarding the disposition of the spinal arachnoid, as high at least as the lower extremity of the medulla oblongata observed on its *dorsal aspect*; secondly, I shall state the result of several dissections of that portion of the arachnoid extending from the point until fairly traced over the cerebellum; thirdly, the dissection of the arachnoid and its space on the anterior or ventral aspect of the spinal marrow; fourthly, the distribution of the arachnoid with reference to the cerebral anfractuosities, and the great posterior cerebral fissure, so called, of Bichat, so well described by Veselius and Galen; and lastly, I shall compare these dissections with the passages just quoted from Mr. Ellis's work.

1st. We have seen that in the vast majority of dissections air may be blown into the posterior sub-arachnoid spinal space freely; that there exists no septum here; that the points of adhesion between the visceral layer of the arachnoid and the proper covering of the medulla spinalis are extremely few. Now trace the arachnoid upwards towards the medulla oblongata and cerebellum, and it will be found that the parietal layer of the arachnoid generally adheres with sufficient firmness towards the lower end of the medulla oblongata as to prevent the passage of air upwards into that large sub-arachnoid space formed by the sudden passage of the arachnoid across to the cerebellum, leaving thus a large space immediately behind the fourth ventricle. If the arachnoid be very cautiously opened where it forms the posterior wall of this space, another membrane will be found either close to

it, or separated by a considerable quantity of filamentous tissue: this membrane I believe to be a layer of the pia mater, or proper membrane of the medulla spinalis and oblongata, which quits the medulla along a line more or less distant from the margins of the calamus to reach the cerebellum by a nearer point: it varies in its position, and often seems to be merged in that deeper layer of the spinal neurilemma which, approaching the aortic margins of the calamus, passes from these to the vermiform process, and aided by the valves of Tarin completely shuts in the fourth ventricle behind, cutting off all communication between the fourth ventricle and the posterior sub-arachnoid space. The "opening," then, of Magendie must be generally artificial. I say generally, because that a deficiency should occasionally exist in the pia mater as it shuts in the ventricle is neither impossible nor improbable. But if any additional serous sac exists exterior to the arachnoid in this space, communicating at this point with the interior of the ventricles, it can only do so by forcing its way through a real barrier which the pia mater presents against the escape of the ventricular fluid into the posterior sub-arachnoid space. This fact I have verified over and over again, and I find it constantly proved by every case of chronic hydrocephalus internus.

No mention is made of any septum in the posterior sub-arachnoid space; the internal arachnoid, as it is called, seems to commence in the interior of the ventricles whose walls it lines, communicating with the sub-arachnoid spaces chiefly at two points: 1st, at the great cerebral fissure; 2d, at the pretended foramen of Magendie. Now at the great cerebral fissure there exists a physical obstacle to such a communication, which is this: the cerebral pia mater as it passes from one edge of the fissure to the other, shuts it closely in; it adheres, in fact, (as it does to the edges of the convolutions) to each edge firmly, passing from one to the other, and in passing transmits into the interior of the brain two distinct processes, namely, the excessively delicate ventricular lining, and secondly, the tela choridea and choroid plexuses. These structural arrangements were pointed out in my Commentary on Arnold. Thus it is physically impossible that any serous

sac can pass across the brain by the wall of the ventricles, as described in Mr. Ellis's work. The ventricular lining is in fact a layer of the pia mater, and the ventricular cavities are excluded from all communication with the sub-arachnoid space by the firm adhesions of the same membrane at the margins of the great openings into the interior of the brain, viz. the great cerebral fissure, and the fourth ventricle: the prolongation of the vascular layer of the same membrane, under the name of choroid plexuses, contributes to shut up the openings.

I promised to return, thirdly, to the dissection of the arachnoid membrane, and sub-arachnoid space on the ventral aspect of the cord; and, unquestionably here, great varieties exist.

A very common arrangement is a loose adhesion of the visceral layer of the arachnoid to the pia mater, so that on blowing up the space by introducing the blow-pipe, the arrangement was found to be very similar to that on the dorsal aspect. Sometimes, on the contrary, the space is crowded with filamentous tissue to such an extent, and at the same time so short and dense, as to prevent the passage of the air amongst its meshes for any great distance at least, although considerable force be used. Now between these extremes every variety exists, and it has not unfrequently happened that four or five specimens examined in succession with a view to determine this very question, have presented each of them structures quite dissimilar to the others. To look for a serous sac here was quite out of the question; supposing it to exist in some cases (which is not impossible). Mr. Ellis has omitted mentioning how it terminates upwards.

I find that I had promised to compare these dissections with the statement in Mr. Ellis's text; but perhaps the reader had better do this for himself. Much, no doubt, remains still to be inquired into with respect to these membranes; I shall be happy to repeat the dissections with any anatomist situated within a convenient distance. It were easy for me to extend these notes, by pointing out several contradictory passages in the generally very clear and eminently descriptive work of M. Cruveilhier; but this is unnecessary. The work was published in 1835, and in a new edition they may not be

found. My object is not criticism; merely truth.

In conclusion, it only remains that I should notice, with surprise, the extremely meagre and imperfect account of these structures which has just appeared in the "Encyclopédie Anatomique," a work leading necessarily to great expectations, as well from the celebrity of its translator, M. Jordan, as from the host of distinguished and original contributors to the work, and more especially from the celebrity of that high name, Valentin, attached especially to the volume containing the "Neurologie."

ON THE
CIRCULATION IN ACARDIAC
FŒTUSES.

To the Editor of the Medical Gazette.

SIR,

IN the last number of Dr. Cormack's Monthly Journal of Medical Science is an article by Dr. Marshall Hall, on the circulation in *acardiac* fœtuses; from which article it appears that Dr. Hall is of opinion, that the propulsion of the blood through the hepatic and general systems of an *acardiac* fœtus is effected by the heart of the perfect fœtus, by which the *acardiac* one is usually, if not invariably, accompanied. Now, before we give credence to so extraordinary a doctrine as this—that the heart of one fœtus can propel the blood through the two distinct systems which compose the circulation of another and *acardiac* one—Dr. Hall should prove to us that the heart of a perfect fœtus is capable of propelling the blood through *both its own systems*; that is, through the hepatic system as well as the general. By *hepatic system* I mean the *roots* of the umbilical vein in the placenta (and of which roots the placenta chiefly and essentially consists), the *trunk* of the umbilical vein, the *branches* of the umbilical vein in the liver, the *portal plexuses*, and the *hepatic veins*. By the term *general system*, I mean the heart and all the other vessels, arteries, and veins, except the *spleno-hepatic* vein. There is no *pulmonary system* before birth; for owing to the communication, first, between the two auricles by means of the foramen ovale, and secondly, between the

pulmonary artery and aorta by the ductus arteriosus, the pulmonary vessels are only a part of the general system.

I confess, sir, I should much like to see what sort of facts and arguments Dr. Marshall Hall could adduce in support of the present all but universal opinion, that it is the heart which propels the blood through the liver both before birth and after. It may seem somewhat heretical, and indeed presumptuous, in me, to call in question the truth of so venerable a doctrine; but it so happens that I am acquainted with a simple fact, which, in my mind, clearly proves it to be erroneous. That fact is, that more blood enters the heart by the hepatic veins *before* birth than is propelled through the umbilical arteries; and, *after* birth, than is propelled through the cæliac and mesenteric arteries. Now for the left ventricle to be able to propel the blood through the liver after birth, it would be necessary for it to be able, by propelling a certain quantity, say one ounce, through the cæliac and mesenteric arteries, to displace and drive out of the portal vein, and propel through the portal plexuses and hepatic veins, a *greater* quantity, say ten drachms; and again, for the fœtal ventricles to propel the blood from the placenta through the umbilical vein and fœtal liver into the fœtal auricles, it would be necessary for them to be able, by propelling a certain quantity through the long and tortuous umbilical arteries, also to effect the propulsion of a *greater* quantity through the vessels of the hepatic system; that is, through the roots, trunk, and branches of the umbilical vein, the portal plexuses, and hepatic veins. If this be *possible*, if the heart *can* propel the blood through the liver either before birth or after (much more the heart of one fœtus propel the blood through the hepatic and general systems of another fœtus!) it is not true that a power cannot overcome a resistance greater than itself; for the heart must do so—must always be performing a physical impossibility from the very moment of its formation.

It is evident that more blood *does* pass through the umbilical vein than through the umbilical arteries; for if as much was continually being returned from the fœtus to the placenta, by the umbilical arteries as passes

from the placenta to the foetus by the umbilical vein, it is clear nothing could be *deposited* in the foetus; and, as *ex nihilo nihil fit*, how could the development of the foetus then be effected? That more blood passes through the hepatic veins into the heart after birth than is propelled through the cæliac and mesenteric arteries, is indubitably true, because all the fluids taken into the stomach pass through the gastric and duodenal veins into the splenic vein, and so *through* the liver into the heart; and not, as most of us have been taught, through the thoracic duct and *behind* the liver, through the chest, into the neck! I have no doubt in my own mind that even the nutrient juices derived from the solids pass from the digestive tube through the hepatic system into the pulmonary, and not through the trunk of what are called the absorbents. I must state, however, that I ask no one else to believe this. I am by no means desirous of undermining the present physiological creed as to the office of the *thoracic duct*. Nevertheless, I am prepared to defend my own opinion against any one who may feel disposed to advocate the aforesaid creed, either in your pages or elsewhere.

But, to return to Dr. Hall and the acardiac foetuses. Will that physiologist deny the truth of the fact which I have adduced—that more blood does pass through the liver before birth than is propelled through the umbilical arteries, and after birth than is propelled through the cæliac and mesenteric arteries? And if he will not deny its truth, and I think he cannot, will he oblige me by endeavouring, in his next paper concerning acardiac foetuses, to reconcile that particular fact with his present views concerning the circulation?

In conclusion I may state, that I entirely concur with Dr. Hall in the opinion that the capillaries have nothing whatever to do with the propulsion of the blood through the veins. I cannot conceive any thing to be more evident and certain, than that they must necessarily retard its motion, and that such retardation is proportionate to their length and minuteness. I am very far, however, from agreeing with Dr. Hall and others in the belief that the heart is the sole agent in the propulsion of the blood. I admit the

right ventricle propels the blood through the lungs, and the left through all other parts and organs except the liver; but with the propulsion of the blood through that organ, I hold the heart has nothing whatever to do, either before birth or after. The hepatic system is always a distinct, perfect, and independent system; and the two veins, of which the spleen and placenta are essentially only the roots, perform in that system, the one before birth, and the other after, the triple function of recipient cavity or auricle, propulsive agent or ventricle, and afferent vessel or artery. Of each of those two veins it may be said, "*tria conjuncta in uno*;" for each is an auricle, a ventricle, and an artery, although a vein.—I am, sir,

Your obedient servant,

JOHN JACKSON.

June 10, 1843.

ON THE
TISSUE UPON WHICH THE RE-
MOTE* ACTION OF POISONS IS
EXERTED.

By W. WATES, M.D.

(For the London Medical Gazette.)

Our ignorance regarding the *modus operandi* of the agents we daily use in the treatment of disease has ever been the fertile source of false theories; has given rise to the bitter, because hitherto unanswered taunt of the empiric and sceptic; has proved a stumbling-block to the pharmacologist at the outset of his task, and is the acknowledged opprobrium of our whole profession. To endeavour to do away with this is the object with which the following remarks are made.

* In order that no misconception may arise regarding the position in the chain of sequence which the phenomena induced by poisons, acting on the organised frame, occupy, to which the term remote applies, I copy from Dr. Copland's Dictionary of Medicine, page 558, par. 8, the meaning that word is understood by nosologists to convey; in which it is used throughout the following remarks.

"The division, however, which has been most generally adopted is into remote and proximate or immediate, according to their relation to the disease occasioned by them: the remote being the first in the chain of causation, the proximate or immediate those early changes which they effect in the economy, and which constitute the primary condition of the disease, or, in other words, the pathological states arising directly from the operation of the remote agents."

It has been observed, that we never can know how our medicines act, and, therefore, that it is almost vain to attempt the research: but this, I apprehend, is nothing more than pleading ignorance as a plea for idleness. Whilst the laws which regulate all the various constituents of the universe amongst themselves are gradually being discriminated and fixed, is there any just reason why those by which the effects of agents upon the human frame are produced should remain undefined? I believe not: nor would they so long have been misunderstood, if the same strict rules had been applied in the reasonings based upon the observations made upon the latter, as have been upon those made upon the former. Medical writers have been too apt to permit the opinions springing from a few imperfect observations to colour the results of their investigations, which have been made, though perhaps not intentionally, to prove certain hypotheses, instead simply of defining the strict relations of cause and effect between certain phenomena.

In order that my mind might be as little swayed as possible by any particular theory, I determined, whilst making the investigation into the *modus operandi* of medical agents and poisons, not to make any experiments myself, but to take those executed by men of acknowledged skill and observation; and by collating them, to endeavour to deduce the various points in which they agree; hoping that thus I might be enabled to lay down some of the laws which they obey in such a way as that they might become fixed data in our reasonings, and prove sure starting-points for fresh research.

Perhaps no little confusion upon this subject has arisen from the mind of the student not fully comprehending what is included under the expression "the action of poisons." In it are necessarily implied the capability, 1st, in the agent to produce an impression upon the organ to which it is applied: 2d, of that organ for receiving that particular impression: and 3d, of the organ impressed to manifest its being acted upon by the impression created by the agent.

The first of these relates to the individual properties of each poison, and as they are universally conceded I shall not stop here to notice them, but

pass on to the consideration of the second and third divisions of the subject. In discussing the former of these two propositions, the question to be first determined is, "upon what tissue are the remote actions of poisons exerted."

No point has been more debated than this, and each succeeding writer seems to have enveloped the matter in greater mystery than he found it, and none more so than Messrs. Morgan and Addison, whose "Essay on Poisons" is written in such an obscure style, that it is almost impossible clearly to understand the meaning they wish it to convey.

Much, if not all, the difficulty met with in determining this most essential part of the inquiry, has arisen from the remote effects of the poison being entirely overlooked, and from the proximate effects, or pathological states, the consequence of the remote action, having been mistaken for them. For instance, some poisons are said to exert their remote action upon the brain, and others upon the heart, the spine, and lungs respectively, because the organs present symptoms of derangement of their functions when a poison is introduced into the system. Yet it will be seen that those very poisons still produce their full effects upon the system, when the particular organ it is supposed to have its remote action confined to, either is removed from the body, or when the chain of communication between the part poisoned and it is destroyed. Yet that organ, when present, is indisputably affected, and the question arises, does the poison act remotely on it, or are they the proximate effects of the poison which it exhibits? This we will now proceed to examine.

What, then, is the tissue remotely acted upon by poisons?

It is admitted on all hands that poisons have the power of affecting the system in two ways. One, in which the impression is not transmitted beyond the part to which it is primarily applied, and in which the general powers of life manifest no symptoms of partaking in any, or to a very slight degree, in the effect of the agent; the other, in which the proximate effects of the remote action of the poison are such as shew that the whole system is affected. The former is the local, the latter the general action of poisons; each consequent upon the remote action.

Several organs are said, by various authors, to be the seat of the remote action; as the brain, the spinal cord, the heart, the lungs, the liver, the stomach; and the blood itself is classed along with them.

Dr. Christison, in his work on Poisons*, says, "poisons are commonly, but I conceive erroneously, said to affect remotely the general system. A few of them, such as arsenic and mercury, do, indeed, appear to affect a great number of the organs of the body. But by much the larger proportion seem, on the contrary, to act on one or more organs only, not on the general system."

The brain is supposed by many to be the organ remotely acted upon by certain poisons, and among those that hold this opinion may be enumerated Christison, Brodie, and Magendie. I imagine Messrs. Morgan and Addison entertain the same opinion, but am not certain, although I have carefully perused their "Essay" three or four times, and have collated the various passages. I shall therefore give them the benefit of the doubt.

Under the head "remote action," at page 19 of his most valuable work, Dr. Christison writes: "A great number of the poisons now under consideration act upon the brain. The most decided proof of such an action is the nature of the symptoms, which are, convulsions, giddiness, delirium, palsy, coma. All narcotic poisons act on the brain, and most narcotico-acrids too; but very frequently other organs are acted on at the same time, in particular the spine, and heart."

Sir B. Brodie, as quoted by Morgan and Addison, at pages 21 and 31 of their Essay, infers from his experiments that the brain was affected when death was produced by hydrocyanic acid, and by ticunas. Magendie, also, is represented by the same writers (at page 40) as supposing that the brain is the organ remotely impressed by the action of poisons.

As it will avoid repetition, I shall here introduce the opinions of those who contend for a remote action upon the spinal cord, either in connection with, or independent of, a similar action upon the brain, and also those which advocate the remote action upon the heart, lungs, and blood, and then consider the evidence which affects them.

* 3d edition, p. 17.

"It has been maintained by some, that all poisons which have a remote action exert it through the medium of the brain; but it does not apply well to those which act on remote organs, such as the heart or spine, without causing any sensible symptom referrible to the head. The infusion of tobacco paralyses the heart, and nux vomica irritates the spine, without causing any disorder of the mind: which could scarcely happen through the medium of the brain*."

"Few poisons act specifically upon the spinal cord. The only species, indeed, which are known to possess such an action, are nux vomica, the other species of plants which, like it, contain strychnia, and the false angustura bark. Their action on the spine is quite independent of any action on the brain, if indeed such action exist at all, for when the spinal cord is separated from the brain by dividing the medulla oblongata, the effects on the muscles supplied by the spinal cord are produced as usual. Many poisons which act on the brain also act on the spinal cord."†

"Some very interesting experiments were made by Emmert with this poison (false angustura bark), to show that it acts upon the spine directly, and not on that organ through the medium of the brain."‡

Of the remote action upon the heart.—"Of the poisons which act remotely through a sympathy of distant parts with an organic injury of the textures directly acted on, many appear to act sympathetically on the heart alone."§

"Some poisons of this kind act chiefly if not solely on the heart. The best examples are infusions of tobacco, and upas antiar."§

Dr. Christison also places the active principle found in hemlock by Geiger, on his authority, in the list of poisons which act remotely upon the heart, either alone or in conjunction with other organs: together with arsenic, and oxalic acid, on the authority of Dr. Campbell, Dr. Coindet, and himself.*

The remote action on the lungs.—Regarding the lungs being the seat of the remote action of poisons little is

* Christison on Poisons, p. 19.

† Ibid. p. 19.

‡ Ibid. p. 807.

§ Ibid. p. 17.

§ Ibid. p. 17-18.

* Ibid. p. 18.

known. Dr. Christison writing on it says, "other poisons act upon the lungs: but we are not acquainted with any which act on them alone."* Magendie found that in poisoning with tartar emetic, the lungs are commonly inflamed, and sometimes hepatised. Mr. Smith, and M. Orfila, both remarked similar signs of pulmonary inflammation in animals poisoned with corrosive sublimate. But these poisons produce important effects on the organs likewise.

These remarks, like the others, are included under the head of "remote action" of poisons, in Dr. Christison's work.

Before I enter upon the consideration of each of the above remote actions, I will make an observation regarding the capability of organs in general to receive and to transmit impressions caused by external agents, of whatever nature they may be.

It is a general law throughout nature that particular functions have each a structure specially constructed for its performance, and that function is alone capable of being produced by its own particular organ: further, each portion of the frame is capable of receiving such impressions only as are calculated to act upon its peculiar structure. In conformity with this law, the brain is constituted for reasoning upon impressions created by external agents acting upon the extremities of, and transmitted by, the cerebro-spinal nerves, and has for its sole function the formation of ideas of external objects from the impressions thus transmitted, and is in nowise necessarily connected with the control or regulation of the functions of organic life. The same remark applies to the spinal cord; its function is to receive impressions created by external objects, and to react upon those organs, whose function is to be in relation with, and to be exercised upon, the external objects creating the impression. Therefore, the cords of communication between the object impressing, and the brain, or spinal cord remotely impressed, are constituted for appreciating and transmitting external forms and properties alone.

As poisons do not differ essentially in their external qualities from other substances which are perfectly inno-

uous, it will not surprise us to find that these organs (the brain and spinal cord), having functions in connection with the nature of external objects only, are not in any way necessarily connected with the remote reception of the impressions created by substances whose capability of action is quite independent of their external properties.

I shall now proceed to shew that, in conformity with this law—

1st. Poisons do not act when applied to the cut surface of the brain, spinal cord, or to the cut extremities of cerebro-spinal nerves.

2d. Poisons do act when the nervous connexion between the brain and the part inoculated is destroyed by division of the spinal-cord.

3d. Poisons do not act when the inoculated part is connected with the trunk cerebro-spinal nerves alone.

4th. Poisons continue to act though the cerebro-spinal nerves supplying the inoculated part be divided.

1st. Poisons do not act when applied directly to the cut surface of the brain, spinal cord, or cerebro-spinal nerves.

Dr. Copland, speaking on this subject, says, "for when the poison has been applied to the cerebro-spinal nerves, it has been found by Orfila, Fontana, and others, to have no further operation, or even less than when applied to other tissues*." Again: "The celebrated and accurate experiments made by Fontana on the venom of the viper, and ticunas, can be justly estimated only in accordance with this view, for when those substances were applied to the cerebro-spinal nerves, no more rapid effect was produced than when applied upon any other tissue; but when injected into the veins, the result was almost instantaneous." In another work† he says:—"It may be concluded from this that the opinion of many physiologists, that poisons act mortally when they are applied to these parts of the nervous system" (i. e. the brain, spinal marrow, and cerebro-spinal nerves), "are not well founded, and are devoid of direct proofs."

On the same point Dr. Christison writes‡—"The experiments of Emmert,

* Dictionary of Practical Medicine, vol. 1, page 194, par. 141.

† Appendix to Richerand's Physiology, 3d edition, p. 599, par. 14.

‡ On Poisons, 3d edition, p. 697.

* Christison on Poisons, p. 18.

Coullon, and Krimur, shew that it (dilute hydrocyanic acid), has no effect when applied to the trunks or cut extremities of the nerves, or to a fissure made in the brain or spinal marrow; and that its action is not prevented by previously dividing the nerves;" and again,* "as to the nervous tissue, it is a singular fact, and well worthy of mention, that the poisons which appear to act on the sentient extremities of the nerves, on the brain and spine, do not act at all on the cut surface of the brain or nerves, or upon any part of the course of the latter. This has been proved with respect to hydrocyanic acid, opium, strychnia, and all active narcotics."

Messrs. Morgan and Addison made the following experiment, to shew the same thing†. "The brain of another rabbit of the same age and condition" (as one previously poisoned), "was then laid bare, and a small portion of the cerebrum sliced off horizontally; in the surface thus exposed a portion of woorara, of the same size as that used in the experiment on the first rabbit, was inserted, the greatest care being taken to prevent its contact with any part except the brain itself. After an interval of three quarters of an hour had elapsed from the time of the inoculation, the animal was, from motives of humanity, destroyed; but during the whole of that time not the slightest symptoms of the effect of the poison upon the system was observed; the animal under excitement leaping about the room as usual."

Dr. Christison‡ remarks that "some poisons retain their action although the brain be removed," though he does not give the experiment, or the authority upon which the statement is based.

2d. Poisons do act when the nervous connection between the brain and the part inoculated is destroyed by division of the cord.

Widemeyer relates the following experiment. "In a dog the spinal cord was divided at the top of the loins, so that no movements took place when the hind legs were pricked; hydrocyanic acid being then introduced into a wound in the left hind leg, symptoms of poisoning commenced in one minute, and

the hind legs were affected with convulsions as well as the fore legs."*

"In a second frog we divided the spinal marrow below the origin of the tracheal plexus, and applied strychnine as before. The anterior extremities became tetanic first, after an interval of twenty minutes, and the posterior extremities became tetanic after an interval of fifty minutes."†

"Emmert found that poisoning took place in an animal in whose hind leg the extract of false angustura bark had been inserted, and in whom the spinal cord had been severed in the loins; and in others, where the medulla oblongata was cut across, and artificial respiration kept up, the usual symptoms were produced over the whole body by the administration of it internally or externally."‡

"The spinal marrow of a half-grown rabbit was divided; the leg was inoculated with strong prussic acid; the animal died in three minutes after the introduction of the poison, this being the usual period of time in which that poison was found to operate upon these animals under common circumstances, when introduced into the same part.§"

3d. Poisons do not act, when the inoculated part is connected with the trunk by cerebro-spinal nerves alone.

"A fact somewhat analogous has been established by the same experimentalist (Emmert) in regard to the woorara; he found that it does not act when introduced into the limb of any animal connected to the body by nerves alone."||

Mr. Brodie "tied a tape half an inch wide round the thigh of a rabbit, excluding the sciatic nerve, and although the leg was wounded, and poisoned with ticunas, yet no sensible effect was produced at the end of an hour from the operation; after this interval of time had elapsed, the ligature was removed, and in twenty minutes the rabbit was found motionless and insensible¶."

"A. Herr observed the same results in a corresponding experiment made with hydrocyanic acid and strychnine on frogs: the thigh of a frog was divided

except the nerves, and the artery was tied; then ticunas poison was applied to the foot, without any effect on the system following.*"

"In another rabbit of the same age a ligature was tied round the leg to the careful exclusion of the sciatic nerve; six drops of prussic acid were then applied to a wound in the foot of the strangulated limb, and without producing the slightest possible effect,"† though a rabbit had just previously been killed with four drops of the same acid.

These four experiments, and all similar ones, are open to some objection, which I shall not notice here, but when I come to consider the circumstances which modify the action of poisons I shall advert to them.

4th. Poisons continue to act though the cerebro-spinal nerves supplying the inoculated part be divided.

To shew this the following experiment by Sir B. Brodie is quoted from Morgan and Addison.

"The axillary plexus of a rabbit is next divided, and the same poison" (woorara), "is inserted into the limb which produced death in the usual period of time‡."

"Next, many poisons act with unimpaired rapidity when the nerves supplying the part to which they have been applied have been previously divided, or even when the part is attached to the body by arteries and veins only. Dr. Monro *secundus* proved this with regard to opium; the same fact has been extended by Mr. Brodie and Professor Emmert to woorara; by Magendie to nux vomica; by Coullon to hydrocyanic acid; by Charret to opium; and by Coindet and myself to dilute oxalic acid."§

§ Ibid. p. 29.

§ Christison on Poisons, p. 9.

of mutual assurance, as suggested in our last number but one, and strongly recommended by us to the members of our hard-working and ill-paid profession, is the consideration of the qualities, the conduct, and the circumstances which wisdom suggests, or experience proves, conduce to success or failure, to honour or discredit, in a professional career.

We need not do more than advert to those general principles of morality, beyond the limits of which all praise however flattering, all wealth however abounding, falls lamentably short of true success. These principles, if they have not been firmly inculcated during early youth, while the mind is receiving that imperceptible direction in favour of good which sound early education can alone afford, must be taught in the more exciting and violent methods which it is the office of the preacher to use: for to his office is often reserved the arresting that tendency to evil, which seems natural to man, and the bringing, by all the energies at his command, the distorted mind and perverted faculties to an upright and becoming direction. Setting aside these general principles, we would consider our subject within the more special limits of professional ethics, and examine some of the circumstances which seem most frequently to have caused success or failure.

The following advice has been given to a candidate for success at the bar:—"Spend your patrimony, the larger the better, as elegantly, indeed, but as completely as you can. Marry an heiress, and spend her fortune also; and when your necessities shall have made you industrious, your knowledge of mankind will enable you to make a profitable use of the connections you have formed." This counsel, which has much of the brilliant profligacy of Lord Chesterfield, or the broad satire of Dean Swift, has of course this capital disadvantage, that if deliberately

acted on it would make a man a scoundrel, and if found by experience to be true, it would be needless. At forty, every man is a fool or a physician, well acquainted with his own mental as well as bodily infirmities; but to this degree, "in nature's good old college," there is no admission *ad eundem*. All the terms must be rigorously kept; the diploma cannot be obtained, like some recently advertised, "for fifty pounds without absence from practice, or thirty-five pounds with two months' residence abroad, including travel through the most delightful part of Europe,"—in company, of course, with the intelligent advertiser. The graduate in self-knowledge—the most difficult of arts—will often have to say with Crabbe—

"We've trod the maze of error round,
Long wandering in each devious glade;
And when the torch of truth is found,
It only shows us where we strayed.
Light for ourselves, what is it worth
When we no more our way can chuse?
To others when we hold it forth,
They in their turn the boon refuse."

But the advice above given is brilliant—

"Se non è vero, è ben trovato,"

and not a few have acted and will act on it. But it scarcely is good for our profession, whatever it may be for the law. Seriousness, not occasional but habitual; earnestness, not affected but real, are useful in securing the confidence of the sick, and indispensable in the studies which prepare us for practice: and if the unvarying liveliness of a mercurial temperament, seems, in some instances, to have been a prime element of professional success, we may rely on it that such unwearied cheerfulness has only lightened the labours of conscientious activity; that it has been kept up by a consciousness of duties performed, not used as a substitute for duties neglected. Of those who can set the table in a roar, how many can leave it at the calls of duty?

Those who are dissatisfied with their position and success are too apt to throw the whole blame on outward

circumstances, when the fault has been mainly in their own conduct. This would be a mere harmless vent for their wrath or repinings, did it not too often tempt them to seek in a change of place or of circumstances that success which can only be fairly expected from a change of conduct. Now of all defects in education, that is the greatest which omits instruction in the art of bearing and suffering. Man's burden of work and trouble is to be borne steadily up the hill of life, and those who are perpetually stopping to shift it, or perpetually seeking less wearisome roads than the direct one, will find themselves, towards the close of the day, hardly less wearied, though far less advanced, than steadier travellers, whom they will have the mortification to see resting while they continue toiling. We certainly do see some of our fellow travellers carry burdens of needless bulk, and in a very awkward manner, which makes us long to give them a hint or a hand for diminishing the weight, or for its better adjustment; but such sturdy fellows do get along surprisingly, and we cease to wonder at their contempt of advice and interference when we see the progress they have made. The old apprenticeship system, and the old school drudgery, had some useful qualities, and produced some useful results, which we may be very thankful if we find secured by the "reading-made-easy" plans so largely tried of late years. The whole advantage of skilled labour, which makes a man and his work so valuable in the eyes of the Benthamite political economist (and not of him only), is forfeited by perpetually shifting from one pursuit or one place to another. The fact of having aimed, and missed an object, is a good reason for aiming again and again, till we hit it, and making their dinners depend upon their success—as is sometimes practised towards young savages, who are

to live by their bow and arrow — may furnish a useful hint for more civilized education. The encroaching sea of Holland—the lagoons of Venice—the frost and the thaw, the swamp and the torrent, at St. Petersburg—all the physical disadvantages which great nations have overcome, have not caused a mere worthless expenditure of toil and treasure; they have been occasions of discipline,—they are crabbed passages in the national grammar, invented seemingly for the mere vexation of pupils, but which once diligently mastered, enable nations not only to correct their early mistakes — their “nonsense versés”—but to write for themselves on the pages of history those great world epics which will, for ever be remembered and quoted, however dimly or traditionally.

Diligent labour, patient application, repeated trials after repeated failures, must be, sooner or later, the portion of all who would win success in any department of life: the object makes no difference in the means required, though it may make a fearful one in the reward earned. The applause of the postur-master, or the blessings which follow the philanthropist, can be won in no other way, though circumstances, talents, taste, or even education, may determine our lot, or direct our choice.

It is often complained that a devotion to science is ill rewarded; this may be true in appearance, but is false in fact. Pure science does not contend for the same objects, nor seek the same rewards, as art or skill. It must be fed and clothed, indeed, but of material outward gains it can receive but little more. Its market value is often not found out till after the death of the inventor, when, with the aid of art, it has been wrought into forms and patterns which men admire, wish for, and find useful or pleasant; but has science, therefore, no rewards? ask the earnest cultivator of physiology, of comparative anatomy,

of mechanics, mathematics, or others, for his cash estimate of his labour of love. When he requires to use some art as a bread-winner, he will be all the better workman for being a scientific one, and his science may thus procure him better wages, but he will live by his art, and for skill in this he must labour like other arts men, and will receive the arts-man's reward, and no other. Men agree to deal at certain or uncertain prices, for law, physic, and divinity, for they want justice, health, and piety; but these, the several professors do not pretend to sell.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

June 13, 1843.

THE PRESIDENT IN THE CHAIR.

On the Characters and Structural Peculiarities of a group of Morbid Growths in which cancerous affections are included. By DR. HODGKIN.

THIS paper was in continuation of a subject which had already been brought before the society on a former occasion by the same writer.

After describing the different appearances revealed by the improved microscopes of the present day, the author endeavoured to connect the nucleated cells, which Müller has shewn to exist in these structures, with the production of those compound cysts which were described in the former paper, and pointed out as affording the type of the adventitious structures referred to.

The following are the conclusions which the author is desirous of drawing from the observations contained in the paper:—

1st. The unrestricted confirmation of the views contained in the former paper as to the existence of the type of compound serous cysts in the adventitious structures referred to. The author had not only found it in man, but in several of the inferior species of mammalia, and in birds. Several able observers had, on examination, coincided with his views, and he mentioned the late Professor Delpech, and the present Professor Rokitanski, having personally informed him of their having, independently, been induced to adopt his views.

2d. That the microscopic examination of these tissues, though extremely interesting, does not furnish perfectly conclusive tests of any particular form of adventitious structure to which a specimen may belong, but

that it demonstrates the application of the nucleated cell theory, whilst it is fatal to that of cancerous matter being formed in the blood and eliminated at the spots at which the tumors become manifest. It therefore furnishes an important argument in favour of operation, though other practical considerations require to be attended to before operation is decided on.

3rd. That to have a complete view of the mode of production of these structures, we must combine the cell theory of Schwann and Müller, the coagulation principle which the author had previously suggested, and the process of organization investigated by Mr. Kiernan — three stages of development which appear to occur in the order just enumerated; and that none of the phenomena, taken singly, is an adequate test of malignancy, which, as stated in his first paper, must be regarded as the sum of several characters.

4th. That chemical analysis, though extremely important and interesting, affords an imperfect and inadequate criterion, as the principles concerned may vary or be changed in the progress of development.

5th. That, in operating for the removal of a tumor of this class, it is extremely important to leave behind none of those minute cysts which often form granules in the surrounding cellular membrane, though it may appear in other respects perfectly healthy. This appears to be a mode of extension of the disease independent of inflammation.

6th. That experience teaches us that the infiltrated form of these diseases occurs in the structures in the neighbourhood of the purely adventitious growth, when these structures have been the seat of inflammation, and that the chances of success from operation are consequently infinitely diminished when such surrounding inflammation has taken place. The presence of the peculiar matter of the disease in the interior of vessels appears to be one of the modes in which infiltration, the result of inflammation, exhibits itself, and is, therefore, not a valid argument in favour of the pre-existence of such matter in the circulating blood.

On the Nature of the Ossification of Encysted Tumors. By JOHN DALRYMPLE, Esq. Assistant-Surgeon to the London Ophthalmic Hospital.

The author removed from the upper eyelid of a patient an encysted tumor, about the size of a pea, which was found to consist of concentric layers of hard earthy material. Upon examining the structure by the microscope, he found that the layers were composed of epithelium scales closely agglutinated together; but instead of the usual transparent and thin lamina, with its central nucleus, they were thickened and hard, and

contained granular earthy molecules, which could be removed by immersion in weak muriatic acid. No amorphous earthy deposit existed around or among the scales, which were opaque, of a light brown colour, with a clear and large central nucleus. Having added some observations on the microscopic appearances of other encysted tumors, the author concluded by noticing shortly the difference between the origin of proper ossific growths and that of the tumor described by him. Accompanying the paper was a drawing which exhibited the epithelium scales of which the tumor consisted, with the granular earthy material disseminated through them.

On the Varieties, Causes, Pathology, and Treatment, of the Inflammatory Affections of the Retina. By EDWARD OCTAVIUS HOCKEN, M.D.

After some general remarks on the frequency of retinitis occurring as a secondary affection consequent on other diseased conditions of the eye, the author drew attention to three tables, which shewed the relative numbers of cases of idiopathic inflammation of the retina, met with in three large Eye Infirmaries during several years. According to the records of the West of England Eye Infirmary, there were 20 cases of retinitis in 3,926 patients admitted for various ophthalmic diseases during four years. Of these, 6 were acute, 9 chronic, and 5 not specified. Combining with these the results of the Glasgow Eye Infirmary, and the London Ophthalmic Hospital tables, the author found that acute retinitis only occurred once in every 1755 cases of other diseases of the eye; and this corresponded with his own experience: that the proportion of sub-acute cases was 1 in every 500; and that of chronic cases 1 in 330. He then proceeded, in accordance with the title of his paper, to make observations on the pathology and treatment of the different forms of retinitis, and illustrated his views with the details of some cases.

On the Presence of Spermatozoa in the fluid of Common Hydrocele. By E. A. LLOYD, Esq. Assistant-Surgeon to St. Bartholomew's Hospital, and Surgeon to Christ's Hospital. [In a letter to the President.]

The object of the author was to announce the fact, that in two cases of common hydrocele, in which he examined the fluid withdrawn by tapping, by the microscope, he found numerous spermatozoa. The first case occurred in the early part of last winter. Subsequently to that, in the course of a few weeks, he examined the fluid in four other cases, but without finding any animalcules in them. Three months ago, the second case

occurred. The patient was 63 years of age, and had been operated on previously for hydrocele, about fifteen times. Sixteen ounces of a greenish yellow fluid, so albuminous as to be quite adhesive, were drawn off. The author counted forty of these microscopical beings in one drop of this fluid. Some of the animalcules were observed to retain their power of motion for three hours after the fluid had been withdrawn. Blood-globules, transparent cysts, and small granular bodies, also portions of epithelium, or what much resembled it, were likewise found in the fluid. The author concluded by mentioning that since the last case he has examined the fluid of many hydroceles, but had not met with spermatozoa in any of them.

The next and last meeting of the season will be held on Tuesday, the 27th inst.

FELLOWES' CLINICAL PRIZE REPORTS.

BY ALFRED J. TAPSON.

University College Hospital, 1842.

[Continued from p. 394.]

CASE XII.—*Measles in an adult; the characteristic eruption abundant; coryza; slight sore-throat; bronchitis, and a copious peculiar expectoration, much like that of phthisis, &c. Treated by mercury, saline draughts, tartar emetic, &c.*

SUSAN HENRY, æt. 29, admitted May 16, 1842, under Dr. Taylor. Conformation moderate; black hair, and rather dark complexion. Has been married twice, and had two children, and is now in the fourth month of pregnancy. Her habits have been regular. During the last few months she has not been able to get sufficient food. Lives in Sussex Street, in a dry, but confined, situation. Her mother died seven years ago of consumption; her father is living and well.

She has been subject to a cough in the winter, and slight expectoration, for the last six years; also has occasionally suffered from mild attacks of rheumatism, and has usually had an attack of colic about twice a year for five years. Has never had measles, and is not aware that she has been exposed to it now; has not seen any one with it.

The *present attack* commenced on the 10th inst. with chills alternating with flushes of heat, pain in the back and in the limbs, headache, sickness, and vomiting, faintness, and general weakness. On the 12th, these symptoms had increased, and she noticed a few red spots on the back of the right hand. On the 13th, there were more of the spots

on both hands and on the feet. At this time she felt so ill that she kept her bed; her throat was sore, and she had a cough; the eyes and nose were also sore, and discharged a thin fluid; she fainted once or twice, and was very feverish. On the 14th, the eruption appeared on the knees and elbows, and then on the thighs: on the 15th, on the abdomen, and she believes also on the face at this time. She has been very sick, and vomited repeatedly almost from the commencement; and the soreness of the throat, and running of the eyes and nose, sneezing, &c. have increased. She has had no medical advice, nor has she taken any medicine.

The *present symptoms* are as follows:—The skin feels rather hot and dry; there is an abundant eruption on the face, hands, feet, elbows, and knees, and some, also, on the chest and arms, but it is most abundant on the joints; she says it has been worse on the feet and knees than it is at present. The eruption consists of slightly elevated papulæ, which are confluent in those parts where they are most numerous, and the patches are chiefly semicircular or crescentic; the colour is dull, red, not at all vivid, and disappears on pressure. The face is rather swelled; the tongue is tremulous when protruded, and is covered with an uniform dirty-white fur; the throat feels sore, she says, and the mucous membrane of the fauces, uvula, and back part of the pharynx, is rather redder than natural, but not much swollen. She is very thirsty; has headache and running from the nose and eyes; the conjunctivæ are not inflamed, and the pulse is 108, moderate in volume and force; the breathing is very quick (54 respirations in a minute), but probably is quickened by temporary excitement. She has a hacking cough, which troubles her very much during the night, and is attended with a good deal of thick, frothy, mucous expectoration, similar to that of acute bronchitis. The bowels are rather relaxed, being open three or four times a day, and the evacuations watery; she has had slight pain in the bowels at times, and there is some tenderness on pressure, limited to the right iliac region. The urine is rather scanty, natural in colour, acid reaction, and contains a flocculent deposit of the phosphates; it is not albuminous.

Physical signs.—There is no morbid sound heard with the respiration; the vesicular murmur is somewhat rougher than natural, and there is a slight murmur heard with the first sound of the heart at the apex.

℞ Pulv. Hydrarg. c. Cretâ. gr. v., ter sumend. Low diet. To be kept cool and quiet.

May 17th.—Has not slept during the

night; the skin still feels hot (it is 104° F. in the bend of the elbow), and she complains of itching very much. The eruption is increased on the chest and back, but is somewhat faded on the face, hands, and arms; the redness here is of a more purplish tinge, and more diffused; the crescentic patches are still distinct. The running at the eyes and nose is not diminished, but the eyes are suffused and too sensitive of the light; headache and soreness of the throat less. Breathing much less rapid, only 28 respirations in a minute; she, however, feels more oppressed. The respiratory murmur is too rough, and there is a little sonorous rhonchus; the cough is troublesome; the expectoration contains some thick opaque masses; pulse 112, full, and rather firm. The lips are dry and cracked; the tongue congested and indented at the edges; the papillæ much enlarged; the fur on it is rather brownish along the middle; thirst considerable. Bowels open seven or eight times since yesterday, and the abdomen feels tender on pressure, especially in the hypogastric region; the urine rather scanty and dark coloured, and contains a cloud of mucus.

R. Acidi Tartarici, 3ij. ; Sodæ Sesquicarb. 3ij. ; Aquæ, f3viij. M. f. Mist. ; Sum. cochl. tria magna. 2da. vel. 3tiâ qq. horâ.

18th.—Did not sleep well, in consequence of her breathing being oppressed, but now feels much easier. The skin is warm and rather moist; the eruption is almost gone from the hands, arms, and face, and also is faded somewhat on the chest, but is pretty red on the lower parts of the body and the legs; very little itching to-day; no coryza or sneezing. The cough is rather less troublesome, and the expectoration freer and more abundant; it is a mixture of mucus and of opaque separate masses of a yellowish green colour; it is of a loose character, and altogether very like the expectoration of phthisis. When first expectorated it is of a pale yellowish white colour, homogeneous, and almost gelatinous in consistence, but after standing a little while it separates into a thin nearly transparent mucus, and the masses above mentioned, which sink to the bottom of the vessel. The gums are a little tender to the touch. Has no pain anywhere, but there is some tenderness on pressure in the epigastric and umbilical regions, and during the night she had several sharp pains in the abdomen, which were relieved by vomiting; pulse 96, moderately full; bowels open; urine increased in quantity, reaction acid, sp. grav. 1027; it contains a copious pale brown sediment of the phosphates, and when heated and nitric acid added, a flaky precipitate of albumen is produced.

Cont. Med.

Milk, half a pint daily.

19th.—Slept much better; breathing easier; the rash nearly gone from the whole body except the legs and back. The gums feel more tender and the teeth rather loose; tongue pale; pulse 82, not so full as it was; she feels rather weaker.

Omittantur pulveres.

20th.—The rash quite gone, except from the lower part of the back; no soreness of the throat, and the cough has been very troublesome during the night; the expectoration rather less in quantity, but the appearance is much the same as on the 18th. The respiratory murmur is rough both anteriorly and posteriorly; not otherwise morbid; the sound on percussion is the same on both sides—tolerably clear; pulse 80; bowels open; urine neutral in reaction, not albuminous.

R. Antim. Potassio Tart. gr. 4. Mist. Camph. f3iss. f. haust. 6tis horis sum.

21st.—The cough, she says, is harder and more frequent, and the expectoration less; there has been considerable running from the nose during the night, and she has perspired very much; has no pain in the chest; tongue covered with a white fur; pulse 78, soft, but moderately full. The medicine griped and purged her two or three times, and also made her vomit three times.

23d.—The eruption is completely gone, and there is a slight exfoliation of the cuticle over the arms and face, but it does not appear to be general over the body. The cough is not at all better; the expectoration is about the same in quantity and in appearance; the fluid part of it is almost transparent, like mucus; the respiratory murmur is still rough, and is accompanied with a sonorous rhonchus. The medicine has not made her sick since the 21st.

Emplast. Canth. pectori applic.

R. Antim. Potassio Tart. gr. 4; Tinct. Camph. Co. ʒxx. ; Mist. Camph. f3j. ft. haust. 4tâ. qq. horâ sum.

Milk, a pint daily.

25th.—The blister relieved the chest and cough considerably; there is still a good deal of expectoration, and it is mixed with frothy mucus.

Bread, a pound daily.

27th.—The breathing is more free and cough less troublesome; she still expectorates the same mixed kind of matter, and to-day it is slightly tinged with florid blood; the respiratory murmur is less rough, and no sonorous rhonchus can be heard.

30th.—Cough is now quite gone; she feels rather weak, but in every other respect is quite well.

Discharged cured.

REMARKS.—The above account of the mode of attack, and of the symptoms on the patient's admission, readily leads to a correct diagnosis as to the nature of the disease. It commenced on the 10th instant, with the usual symptoms of fever, which were followed on the 12th by the appearance of an eruption, coming out successively on the hands, feet, arms, legs, abdomen, face, back, &c., and continuing to come out on the back till the 17th, at which time it was commencing to fade on the parts where it had appeared first. By the 21st it had disappeared entirely from the whole body; so that it lasted in each part about four or five days, and terminated in partial desquamation of the cuticle on the arms and face.

It was clearly, therefore, an eruptive fever; and the only doubt that could exist was, whether it was rubeola or scarlatina. The eruption appeared on the third day of the fever; but this would not help in the diagnosis between these two diseases, as it usually appears on the second in scarlatina, and fourth in rubeola. Again, there was some soreness of the throat, but it was inconsiderable in amount, and was conjoined with a catarrhal affection of the mucous membrane of the eyes, nose, and bronchi, which almost always occurs in rubeola, and not often in scarlatina. But leaving these comparatively unimportant points, the dull or purplish red colour of the eruption appeared at first sight quite characteristic of rubeola; the eruption was in small slightly elevated spots, which manifested a great tendency to arrange themselves in small crescentic or semilunar patches, leaving the intermediate skin of the natural colour.

There are some points in the case deserving a rather particular notice: thus—1st. There was an almost universal affection of the mucous membranes: that of the eyes, nose, and bronchial tubes, discharged a great quantity of mucous secretion; that of the mouth was also probably affected in some way, causing the tumid flabby appearance of the tongue, &c.; that of the alimentary canal was also affected, giving rise to the diarrhoea that existed almost from the first, and most likely also to the pain and tenderness of the abdomen, and lastly, very probably a few of the changes in the urine were due to some affection of the mucous lining of the urinary passages. Of these mucous membranes, that which lines the nasal passages, &c. is especially apt to be affected in the early stages of the disease; whereas the bronchial and alimentary mucous membranes are more likely to be affected at the decline of the eruption, at which time inflammatory complications are most common.

2d. The expectoration presented a very remarkable appearance: at first it was little else than simple frothy mucus, as in bronchitis, but it very soon acquired the peculiar appearance described in the report of the 18th inst., at which time it bore so striking a resemblance to the expectoration of phthisis, that in itself it would create in most persons' mind a very strong suspicion of the existence of that disease. Dr. Taylor, however, stated at the time in the ward, and also subsequently in his clinical lecture on the case, that Chomel had noticed this resemblance between the expectoration of measles in adults and that of phthisis, and said they could only be distinguished by the fluid portion being of a whitish colour in measles, and not in phthisis: in this case, though the expectoration had at first a decidedly whitish colour, yet the fluid portion which separated on standing was not white (*vide report*). We presume that Chomel in the above statement does not include the microscopical characters, for these, surely, must be different in the two cases.

3d. The urine underwent several changes at different periods of the disease; it contained a good deal of mucus on several occasions: in the earlier part of the disease there was an excess of the phosphates, and shortly after this a considerable excess of the lithates, and also a small quantity of albumen. This has been mentioned by Becquerel as a common occurrence in fevers generally, and is attributed by him to the congestive state of the kidneys produced by the fever; and in such a case as measles, where the functions of the skin must be materially interfered with, we can easily believe that congestion would be likely to arise in these organs: but at the same time we are much inclined to attribute the presence of the albumen in this case to the influence of the mercury on the system, rather than to the fever. How mercury causes it we do not know, whether by its operation on the solids, or, what is more probable, by altering the constitution of the blood; but that it does cause it we have seen instances where it was given in rheumatism, and in all the albumen appeared in the urine just at the time the influence of the mercury on the system was evidenced by the tenderness of the gums, and in these cases, as here, the presence of the albumen could not be detected more than one or two days. Further, we have not found albumen in those cases of rheumatism where mercury has not been given, so that we can hardly ascribe it to the rheumatism itself.

The cause of the disease was, no doubt, contagion, though the patient believed she had not been exposed to it in any way; and she was predisposed to any contagious dis-

ease in consequence of being in a weak state from poor living ; and besides, she had never had the measles, which, in itself, is almost a predisposing cause, considering how few, comparatively, escape measles altogether.

The treatment of measles is generally very simple, but little being required beyond watching for any complications that may arise, so as to be able to attack them at their very onset. This patient was given small doses of the Pulv. Hydrarg. c. Cretà so as slightly to affect the gums ; she was also ordered low diet, and to be kept quiet and cool, and some saline draughts. Under this treatment the fever and eruption passed off in about the usual time without any serious complication having arisen. There was a tendency to bronchitis from the first, and it increased after the decline of the eruption, but was soon removed by a blister and antimonial draughts, and the cough and expectoration had quite ceased before she left the hospital.

HOW TO MAKE LEECHES BITE.

THE leech which it is intended to apply is to be thrown into a saucer containing fresh beer, and is to be left there till it begins to be quite lively. When it has moved about in the vessel for a few moments, it is to be quickly taken out and applied. This method will rarely disappoint expectation, and even dull leeches, and those which have been used not long before, will do their duty. It will be seen with astonishment how quickly they bite. — *Weitenweber's Beitr.*, and *Schmidt's Jahrb.*

CAT'S MINT.

The *Nepeta cataria* of Linnæus is recommended by Dr. Guastamacchia as a sovereign remedy for tooth-ache, whether it proceeds from catching cold, or from caries. The leaves of the plant are placed between the affected tooth and the opposite one ; this causes a copious flow of saliva, and in two or three minutes the most violent pains are relieved. If the patients cannot keep the leaves in contact with the diseased tooth, they must chew them, and the object is equally attained by the flow of saliva thus excited.—*Filiatre Sebezio*, and *Schmidt's Jahrb.*

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, June 15, 1843.
T. Hawksley.—H. Chambers, Donington, Lincolnshire.—J. Wade, London.—W. Clayton, Hull.—E. Lawford, Leighton Buzzard.—H. Hill, Worcester.—F. Forwood, London.—R. E. Lutley, Wiveliscombe, Somersetshire.—J. Boodell, Tiverton, Devonshire.

ROYAL COLLEGE OF SURGEONS.
LIST OF GENTLEMEN ADMITTED MEMBERS.
Friday, June 16, 1843.
J. B. Langley.—E. Bullock.—J. Hooper.—P. M'Intyre.—H. Nathan.—S. M. Marshall.—G. Royde.—T. L. Henley.—J. Warwick.—J. Duke.—A. Kidd.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending Saturday, June 10, 1843.

Small Pox	10
Measles	29

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXXII.

*On Presentations of the Umbilical Cord,
and Labours with two or more Children.*

THE umbilical cord may present along with the head, nates, or extremities of the child. Dr. Saxtorph has collected together, from various authors, 292 cases of prolapsus of the cord, in 212 of which the head presented; in 41, the head and extremities; in 5, the nates; in 20, the feet; and in 12, the arm or shoulder. Of 116,277 labours, the funis presented 480 times, being about 1 in 242. Dr. Churchill states, from nearly the same sources, that prolapsus of the cord, in Britain, occurred 226 times in 47,377 cases, or about 1 in 209½; in France, 82 times in 36,621 cases, or about 1 in 446½; in Germany, 93 times in 14,514 cases, or about 1 in 156. Putting the whole of these together, we have 98,512 cases of labour, and 401 examples of prolapsed cord, or about 1 in 245½. Of 355 of these cases, 220 children were born dead, and there is no difficulty in explaining the cause of this great mortality. The cord is sometimes felt through the membranes, pulsating in the progress of the first stage of labour, but when they burst, and the liquor amnii flows out, a portion of the cord passes through the os uteri into the vagina, or out of the external parts, and is exposed to more or less pressure from the head of the child as the labour advances. The vessels of the cord continue to beat for some time, but their pulsations gradually

become more and more feeble, and at last entirely cease, if the compression is great and long continued. The circulation of the foetal blood through the placenta is interrupted—the necessary changes in it are not effected by the maternal blood—and the consequence is the death of the child before its expulsion, by a process similar in all respects to asphyxia after birth. In the operation of turning, the child is not unfrequently destroyed by unavoidable compression of the cord with the hand, when it has not escaped from the uterus, and been exposed to the cold air; and the same occasionally takes place in the vagina, from the pressure of the nates or head interrupting the circulation in its vessels. It is generally believed that the child is exposed to much greater danger when the cord descends in the anterior than in the posterior part of the pelvis. Some children appear to perish much more quickly than others, from prolapsus of the funis. In the last case of this kind which has come under my observation, the membranes were ruptured, and a great part of the liquor amnii discharged at the commencement of the labour, and a long coil of the cord immediately after passed into the vagina; but though the labour continued for eight or ten hours, and the vessels must have been subjected to great pressure from the head in the pelvis, yet the child was born alive by the natural efforts. It seemed more advisable to trust to these, than to any of the means hereafter described. If the circulation in the cord be arrested for a few seconds only in some children, they cannot be made to breathe after birth, while in others, even when the blood has almost entirely for some time ceased to flow through the vessels—at least, has been so feeble that it could scarcely be felt—respiration has been established readily on exposure to the air.

Prolapsus of the cord has been observed, like other preternatural presentations, to occur repeatedly in the same persons in

successive pregnancies, and where no satisfactory cause could be assigned for the occurrence. Sudden rupture of the membranes, and escape of a great quantity of liquor amnii; unusual length of the cord; attachment of the placenta to the inferior part of the uterus, and the cord terminating in its lower margin; irregular shape, or irregular action of the uterus; unfavourable position of the trunk and extremities of the child; the death of the child and distortion of the pelvis, have all been considered causes of presentation of the umbilical cord, and probably may, in certain cases, assist in producing the accident.

I regret being obliged unreservedly to acknowledge that no generally successful plan of treatment has yet been discovered for prolapsus of the cord. If it does not pulsate, the child is dead, and the case should be treated as if the cord had not descended before the child: the condition of the mother alone is then to be considered.

If a shoulder or arm presentation is complicated with prolapsus of the cord, the operation of turning should be performed as soon as the circumstances of the case will permit, and compression of the cord be avoided as much as possible. Should the cord pass down before the nates or lower extremities, the rules which have been already pointed out for the treatment of cases referred to this order of preternatural labours should be strictly observed, and the condition of the umbilical arteries closely watched. If we could by any means contrive to effect a reduction of the portion of prolapsed cord, or push it back into the uterus above the head, and retain it there till the head had passed through the os uteri, or completely distended it, or if we could by any means hasten the delivery, the danger to which the child is exposed would evidently be averted. The whole hand must be introduced into the vagina, and not the fingers merely, if you would succeed in reducing the cord. This I have found to be the case in actual practice, and I am persuaded there is no other method upon which any dependence can be placed. "It has been proposed," says Dr. Merriman, "to carry the cord upon the points of the fingers, or upon a forked piece of cane or whalebone, through the os uteri and above the head of the child, so as to prevent the funis being pressed upon as the head descends through the pelvis. But this expedient has been often found to fail, for upon withdrawing the fingers, or the forked stick, the funis usually sinks again into the vagina." Dr. Aitkin says, "that a grooved piece of ivory tied on the edge of the point of the lever, to retain and carry the cord, returns it with certainty." But many of Aitkin's recommendations are very fanciful. Dr.

Mackenzie informed Dr. Denman of another method which he had tried. "Instead of attempting to replace the descended funis in the common way, he brought down as much more of it as would come with ease, and then enclosed the whole mass in a small bag made of soft leather, gently drawn together with a string, like the mouth of a purse. The whole of the descended funis, enclosed in this way, was conveniently returned, and remained beyond the head of the child till this was expelled; and the bag containing the funis having escaped compression, the child was born living." But he very ingeniously told me, that he had afterwards made several other trials in the same manner without success. Dr. Denman does not, however, state whether a pitchfork, or the fingers, or what other means, were employed on these occasions to push up into the uterus the piece of cord tied in the soft leather bag. "Many years ago," says Dr. Denman, "Mr. Croft also informed me of a method which he had successfully used in these cases. When he had in vain attempted to replace the funis in the common way, he carried up the descended part beyond the head till he met with the limb of the child—suppose the leg or arm. On this he suspended the funis, and then withdrawing his hand, suffered the labour to proceed in the natural way." Mr. Croft met with other cases in which he had been equally successful in suspending the funis over the limbs of the child. "There may be much of accident in the success of these different methods," observes Dr. Denman, who had sagacity enough to know their real value, "but I should believe, whenever it may have been thought necessary to introduce the hand into the uterus, that it would be found more expedient to complete the business by turning the child and delivering by the feet." "Dr. Davis recommends an instrument," says Dr. Merriman, "consisting of a thin plate of flat elastic steel, gently curved, and fixed into a wooden handle. Near the point are two or three small apertures; through these apertures it is proposed to pass, by means of a needle, sufficiently strong threads, and to connect by these threads the prolapsed funis to the instrument, and then to remove the funis out of the way of confusion by carrying the point of the instrument above the head of the child." Dr. Merriman does not inform us of the number of cases in which Dr. D. Davis succeeded by this instrument in removing the funis out of the way of confusion, but merely observes, that "any of the foregoing methods which appear practicable in particular cases may be attempted, but there is reason to fear they will frequently fail."

In 1835, Dr. Michaelis, of Kiel, published

some Observations, in a German journal, on the Reposition of the Umbilical Cord, and recommended the hand, or an elastic catheter with a silk ligature, to be employed for this purpose. The following is the account of Dr. Michaelis's method of treatment, contained in the 1st Vol. of the British and Foreign Medical Review. "From what has been stated, reposition of the cord consists in carrying it above that circular portion of the uterus which is contracted over the presenting part. The reposition of the cord may be effected by the hand, or by means of an elastic catheter and ligature. In replacing the cord by the means of the hand alone, Dr. Michaelis remarks that we shall effect this more readily by merely insinuating the hand between the head and the uterus, and gradually passing it further round the head, pushing the cord before it; in this manner we do not require to rupture the membranes where we have felt the cord before the liquor amnii has escaped—a point of considerable importance. The reposition by means of the catheter is effected by passing a silk ligature, doubled, along a stout elastic catheter from 12 to 16 inches in length, so that the loop comes out at the upper extremity; the catheter is introduced into the vagina, and the ligature is passed through the coil of umbilical cord, and again brought down to the os externum. A stilet, with a wooden handle, is introduced, and its point passed out at its upper orifice, and the loop of the ligature hung upon it; it is then drawn back into the catheter, and pushed up to the end. The operator has now only to pull down the ends of the ligature, passing the catheter up to the cord, which now becomes securely fixed to its extremity. When the reposition has been effected, he has merely to withdraw the stilet; the cord is instantly disengaged. To prevent any injury, &c. the ligature should be brought away first, and then the catheter."

"Dr. Michaelis has recorded eleven cases of prolapsus of the cord where it has been returned by the above means, in nine of which the child was born alive. In three cases the arm presented also, which was replaced, and the head brought down; in two of these the child was born alive." This is the first time I ever read or heard of the reposition of the cord being attempted before the rupture of the membranes and escape of the liquor amnii. Nothing but mischief could possibly result from "insinuating the hand between the head and the uterus, and gradually passing it further round the head, pushing the cord before it," before the rupture of the membranes. The most important part of the treatment in cases of funis presentations is to preserve the membranes entire as long as possible. Let me entreat you, therefore, to avoid all inter-

ference at this period, for the cord is never exposed to dangerous compression before the membranes are ruptured and the liquor amnii is discharged. I should have thought the catheter and ligature, and stilet with wooden handle, as here recommended to be employed in the reposition of the cord, would be the best means you could possibly adopt for putting the cord into "the way of confusion." But not only is the cord here stated to have been replaced by this awkward contrivance, and nine out of eleven children saved, but in three cases of arm-presentation *the arm is replaced, and the head brought down*, and in two of these the child was born alive.

In the Dublin Lying-in Hospital, the practice which Dr. Collins found of most benefit in cases of presentation of the umbilical cord was keeping it up with great diligence with the fingers, assisted often by a piece of sponge. "It is quite impossible, however," he says, "in the majority of cases, to succeed in this way in protecting the funis from pressure, as it is no sooner returned, than we find it forced down in another direction. We tried in a few instances to return the funis completely into the uterus, by passing a piece of soft twine through a long gum elastic catheter, so as to retain the funis exactly at its extremity, and when thus fixed a strong copper wire was introduced into the catheter in order to render it sufficiently firm to carry up the cord; when elevated as far as practicable by these means, the wire was withdrawn, and the catheter retained in its position during the subsequent expulsion of the child. With this contrivance there was not a sufficient number of trials, as it was but a short time previous to my retiring from the hospital that this expedient was had recourse to." "The total number of cases of prolapsus of the umbilical cord, met with by Dr. Collins, was 97; of these, 24 children were born alive; none of the mothers sustained any injury in the delivery. 12 of the 97 occurred in twin cases; and in 7 of the 12 it was the cord of the second child. Nine occurred where the feet presented (not including two met with in twin children), which was in the proportion of one in every 14 of such presentations; two only, where the breech presented, which was in the proportion of 1 in every 121 of such presentations—this approaches nearly the proportional average in all deliveries, which is one in 171½; four occurred where the shoulder or arm presented—this is in the proportion of 1 in 9 of such presentations. Seven occurred where the hand came down with the head. Seven of the 97 children were born putrid; three of the 97 were premature births, viz. two at the 7th, and one at the 8th month."

Without attempting to press up the pro-

lapsed portion of cord above the head, it has been recommended to place the cord towards one of the sacro-iliac synchondroses, with the view of diminishing the danger of compression. As there is no angle in the gravid uterus corresponding with either sacro-iliac synchondrosis in the dried pelvis, little good would probably be effected by any such attempt to remove the funis out of the way of compression.

Where the head has descended into the pelvis sufficiently low for the application of the short forceps, and the pulsations of the cord are becoming weak and indistinct, there can be no doubt about the propriety of delivering as expeditiously as possible with the forceps; the misfortune is, however, in the greater number of cases of this description, that the child has been destroyed by the pressure before the head is within reach of the instrument, and it can seldom be applied till the child is dead. In two cases Dr. Merriman succeeded by means of the forceps in bringing the children alive.

The operation of turning has been had recourse to in many cases of presentation of the umbilical cord, and in some instances with success, the child's life having been preserved, and the mother having escaped all injury. Guillemeau, Portal, Mauriceau, Giffard, Chapman, and Smellie, and the most eminent practitioners of all countries, before the commencement of the present century, delivered by turning the child in most of these cases, and sometimes they did so when they knew that the child was dead, and when it would have been better practice to have perforated the head and extracted it with the crotchet. In some cases there can be no doubt that the child's life has been saved by the operation of turning, and that the mother has not been injured, but in the reports of the greater number of such cases there is little or nothing stated respecting the mothers' recovery. In 33 cases of prolapsus of the funis recorded by Mauriceau, who was more successful in the treatment of these cases than any other practitioner, he delivered by turning 19 times, and all the children were born alive except one, and most of the women were uninjured. Of 21 cases related by Giffard, in a great proportion of which, if not in all, the operation of turning was performed, or his extractor employed, 17 of the children were born dead; and how many of the women recovered it is impossible to tell, as he does not state. Had Giffard's cases been all left to nature, the probability is a much greater number of the children would have been born alive, and the women would have escaped the danger to which they were exposed by the operation of turning. The following passage proves, I think, that Giffard must have left some cases of prolapsus to nature. "If you cannot return

the navel-string, and there retain it, you ought as soon as possible to turn the child, although it presents with the head, and bring it by the feet, unless it is sunk very low into the vagina, and that a few pains will protrude it." "If the navel-string comes down" says Smellie, "by the child's head, and the pulsation is felt in the arteries, there is a necessity for turning without loss of time; for unless the head advances fast, and the delivery is quick, the circulation in the vessels will be entirely obstructed, and the child consequently perish. If the head is low in the pelvis, the forceps may be successfully used: no doubt, if the pelvis is very narrow, or the head too large, it would be wrong to turn; in that case we ought to try if we can possibly raise the head so as to reduce the funis above it, and after that let the labour go on: but if the waters are all gone, and a large portion of the funis falls down, it is impossible to raise it, so as to keep it up, even although we could easily raise the head; because as one part of the funis is pushed up with the fingers, another part falls down and evades the reduction: and to raise it up to the side and not above the head, will be to no purpose: when a little only jets down at the side, of the head, our endeavours will be for the most part be unsuccessful." In the ninth case, related at p. 255, vol. 3, the head and funis presented, and the membranes were ruptured: he tried to pass the cord above the head, but finding as he pushed up the different folds of the funis they again descended, he turned. "When the head is not uncommonly large," he observes upon this case, "nor the pelvis narrow, this method of delivery seems most advisable to save the life of the child, for unless a very small part of the funis is come down, it seldom can be slipped up so high as to prevent the pressure of the head, and obstruction of the circulating fluids in the vessels of the cord."

Where you have reason to anticipate any difficulty in turning, and even in cases where the uterus is dilated, the membranes unruptured, and the parts relaxed, and every thing tempts you to turn, you had better abstain from all interference in this way. Preserve the membranes entire as long as possible; and when the cord descends after their rupture, pass the whole hand into the vagina, and force it above the head, and if this fails, use the forceps, or then leave the case to nature. If it is a first child, and the os uteri is rigid and only partially dilated, and the contractions are strong, you can do no good by attempting to turn; you will not save the child, and you may rupture the uterus when you least expect to do so. "As to turning," says Dr. Collins, "the risk to the mother is in the majority of cases so great as to forbid

its employment, nor do I think the practitioner justified by the circumstances in so greatly hazarding his patient's life."

On labours with two or more children.

Dr. Churchill states that we find among British practitioners, in 161,042 cases of labour, 2477 cases of twins, or about 1 in 69, and 36 cases of triplets, or 1 in 4473. Among French practitioners, in 36,570 cases, 332 cases of twins, or about 1 in 110, and 6 of triplets, or 1 in 6,095. Among German practitioners, in 251,386 cases, 2,967 cases of twins, or about 1 in 84, and 35 of triplets, or about 1 in 7,185. Taking the whole we have 448,998 cases and 5,776 of twins, or 1 in 77½, and 77 cases of triplets, or 1 in 5,831. The statistics of the British Lying-in Hospital, which was instituted in 1749, are not included in the above statement. Since the institution of this hospital, 35,978 women have been delivered, and 36,401 children born. Four hundred and twenty-three had twins, and one three boys. The proportion of boys to girls born in this hospital is about 18 to 17; of still births, about 1 in 25; and women having had twins, about 1 to 85. I have seen only two cases of triplets during the last 16 years, and neither of them occurred in this hospital. The proportional number of women giving birth to twins, appears, according to Dr. Collins' report, to be much greater in Ireland than in any other country of Europe from which authentic records have been obtained. In France, he says, there is 1 twin case in every 95 births; in Germany 1 in 80; in England 1 in 92; in Scotland 1 in 95; in Ireland 1 in every 62. Of 129,172 women delivered in the Lying-in Hospital of Dublin, 2062 gave birth to twins; 29 of the 129,172 produced 3 at each birth, which is in the proportion of 1 in 4450. One only gave birth to four. Of 697 cases of twins collected by Dr. Churchill, 417 children of the 1394 died, or about 1 in 3½; and out of 12 cases of triplets, i. e. 36 children, 11 were lost, or 1 in 3. A considerable number were premature and still born, and some putrid at birth.

Women are exposed to much greater risk who give birth to twins than those who are delivered of one child; and the danger is produced chiefly by the over-distension of the uterus during pregnancy, the preternatural presentation of one or of both the children, and the occurrence of hæmorrhage from the want of uterine contraction after the separation and expulsion of the placentæ. Inflammation of the deep-seated structures of the uterus, especially the veins, not unfrequently proves fatal to women who have been delivered of twins. We seldom discover before the birth of the first child that there is a second or third in the uterus.

By the stethoscope it has sometimes been ascertained, from the remarkable difference in the action of the two hearts. I have never from auscultation been absolutely certain of the existence of twins before the commencement of labour; but in some cases, from the great size and unusual shape of the abdomen, the peculiar movements described, and the irregularity and feebleness of the pains after labour has begun and continued many hours, I have suspected there were twins, and my suspicions have been well founded. But I must admit that all these symptoms are sometimes fallacious, and that women often feel confident from these and other symptoms that they will have twins, when they bear only one child.

It is in our power, and it is our duty, in all cases to ascertain with certainty, after the expulsion of the first child, if there be a second within the uterus. The small size of the first child often leads us to suspect that there is another, before the hand is applied over the abdomen, and the head, nates, or some part of the second child, is felt through the parietes. If the uterus contains a second child, it is still large, hard, and unequal; the uterus still fills the epigastrium, at least reaches considerably above the umbilicus. I have been repeatedly called to deliver a second child where there was nothing within the uterus but a great placenta. In all cases, therefore, you will not trust to the application of the hand over the abdomen, but make an internal examination; not merely for the purpose of determining whether there is a second child, but, if there is, to ascertain the nature of the presentation. Put the umbilical cord of the first child upon the stretch, and pass along it two fingers of the right hand, and if there is a second child you will feel the second bag of membranes, and discover whether the head, the nates, the extremities, or funis present. It is necessary to inform the nurse of the fact.

The following figure from Smellie gives a front view of twins in the beginning of labour, the anterior parts being removed as in most of the preceding figures. The uterus is stretched with the membranes and liquor amnii. The two placentas are represented adhering to the posterior part of the uterus, the two foetuses lying before them: one with its head in a proper position at the inferior part of the uterus, and the other situated preternaturally, with the head to the fundus; the bodies of each are here entangled in their proper funis.

When the nates or inferior extremities of the second child present, the binder should be applied firmly round the abdomen, some stimulant should be given, and some time allowed for the uterus to contract. At the end of an hour, or even earlier, if the pains

do not return, rupture the membranes, tighten the binder, and bring down the lower extremities, and deliver the child in the manner already described when the nates present. No good can in any case be produced by allowing the child to remain longer in the uterus than an hour after the birth of the first.

If a shoulder or superior extremity of the second child presents, proceed immediately to perform the operation of turning, which is easy and safe both for the mother and child, if you pass up the hand into the uterus, before the membranes are ruptured.

In twin cases, where the head of the second child presents, apply the binder, rupture the membranes, and the uterus will *obably* contract upon the child and expel

it without any artificial assistance. If, however, the labour has been very protracted, and there is great exhaustion, and some risk lest the natural powers should be insufficient for the delivery of the second child, I am disposed to think, as the operation of turning is so easily accomplished, that it would be better at once to have recourse to it, than to trust to the forceps if further assistance should be required. At all events it is invariably necessary to rupture the second set of membranes, if you determine to leave the expulsion of the second child to nature, for the uterus may remain twenty-four hours or longer quiescent if this is not done. After the delivery of both children, always remember the danger of uterine hæmorrhage.

CLINICAL LECTURES
ON THE
THEORY & MEDICAL TREATMENT
OF INSANITY,

Delivered at St. Luke's Hospital,

May 1st, 3d, and 5th.

BY ALEXANDER JOHN SUTHERLAND.

LECTURE III.—(concluded.)

Of Narcotics; use and abuse of opium.
— *Sedatives.* — *Hydrocyanic acid.* —
Digitalis. — *Diuretics.* — *Tonics.* — *Mineral tonics.* — *Of blood-letting, leeches,*
cupping. — *Counter-irritants.* — *Setons.* —
Baths. — *Antispasmodics.* — *Conclusion.*

NARCOTICS are placed by some in the first rank of remedies in the treatment of madness. Much difference of opinion exists as to the propriety of prescribing them. Esquirol says, "that these are rather injurious than useful, especially if there be plethora, or congestion about the head. Long since, Valsalva and Morgagni prescribed opiates, and daily experience confirms the opinion of these great masters. Diet, employment, exercise, are the true remedies for sleeplessness; tepid or cold baths induce sleep, and are truly efficacious, and no bad results ever followed their use."

Some authors and practical men of the present day join with M. Esquirol's opinion upon this subject. Dr. Cox considered that opium produced no permanent effect upon the insane.

On the other hand, we find medical men of great experience in the treatment of this disease, who prescribe it in large doses, and some, too, who think it possesses in these complaints virtues almost of a specific nature. Dr. Halloran, as quoted by Crowther, speaks of certain cases where sleep had been a stranger for 48 hours in succession, and where he had no doubt, but for the intervention of an opiate to the extent of 240 drops of the tincture of opium, at three short intervals, no rest could have been procured: he goes on to state that sleep approaching to apoplexy had been obtained in consequence, for nearly 24 hours, and that it was evidently the means of effecting an entire and lasting return of the mental faculty." Crowther says, the same effect was produced in the cases in which he employed it. His patients were relieved from insanity after waking out of a long and sound sleep. The same effect has been stated to me to have been produced in some cases under the care of Mr. Phillips, at the White House, Bethnal Green. Dr. Ogle and Mr. Winkle, of the Oxford Asylum, are

likewise in the habit of prescribing large doses of these medicines, which have also found an able advocate in Dr. Seymour for their employment. What is to be said, when we find such difference of opinion among practical men? M. Foville has truly said, that the particular cases of insanity in which narcotics are useful have not been clearly pointed out. My own experience would lead me to the conclusion, that opiates are of essential service in those cases of insanity which border closely upon delirium tremens; in cases of puerperal mania; in the first breaking out of an attack of madness, before congestion has taken place; in cases where there is great nervous irritability, from poverty of blood; and in cases of cachexia from starvation, and other causes: they are contraindicated wherever there is the least sign of general paralysis or congestion about the head. Prescribed indiscriminately, or not in proper doses, narcotics do more harm than good; they keep up irritation, and add to the excitement, instead of allaying it. I have seen sometimes a very simple case converted into a very complicated one by the excessive use of narcotics. There is an idiosyncrasy, as every one knows, in some constitutions which does not admit of the exhibition of narcotics, especially morphia, even in the smallest dose: $\frac{1}{8}$ th of a grain will sometimes produce such incessant vomiting as to endanger the life of the patient. Great care also should be taken, even when the use of opiates is indicated, not to continue them too long, for if narcotization is produced, much harm will follow: the evacuations are hard and black; the irritation is extreme.

It must not be thought that opium and morphia are entirely to supersede other narcotics; there are others, as hyoscyamus and conium, which are equally serviceable in the treatment of insanity. I am often in the habit of prescribing the hyoscyamus; I find that it agrees better with the stomach, and it does not constipate the bowels: in fact, we know from experience that it has an opposite tendency, and it likewise increases the secretion of the kidneys and of the skin. Combined with the potassio-tartrate of antimony it is serviceable in the paroxysms of furor; considerable lassitude is apt to follow when a draught containing \mathfrak{ss} . of the tinct. of the former, with gr. $\frac{1}{4}$ of the latter, is administered. This, in some cases, is of course not to be desired.

Combined with camphor, opium allays the irritability of those suffering under madness, either combined with some degree of delirium tremens, or preceded by it.

Conium has high antiquity to recommend it, and is useful both given alone or in combination with hyoscyamus and opium. The boasted effects of camphor have not been

do not return, rupture the membranes, tighten the binder, and bring down the lower extremities, and deliver the child in the manner already described when the nates present. No good can in any case be produced by allowing the child to remain longer in the uterus than an hour after the birth of the first.

If a shoulder or superior extremity of the second child presents, proceed immediately to perform the operation of turning, which is easy and safe both for the mother and child, if you pass up the hand into the uterus, before the membranes are ruptured.

In twin cases, where the head of the second child presents, apply the binder, rupture the membranes, and the uterus will visibly contract upon the child and expel

it without any artificial assistance. If, however, the labour has been very protracted, and there is great exhaustion, and some risk lest the natural powers should be insufficient for the delivery of the second child, I am disposed to think, as the operation of turning is so easily accomplished, that it would be better at once to have recourse to it, than to trust to the forceps if further assistance should be required. At all events it is invariably necessary to rupture the second set of membranes, if you determine to leave the expulsion of the second child to nature, for the uterus may remain twenty-four hours or longer quiescent if this is not done. After the delivery of both children, always remember the danger of uterine hæmorrhage.

cupping. — *Counter-irritants.* — *Setons.* —
Baths. — *Antispasmodics.* — *Conclusion.*

NARCOTICS are placed by some in the first rank of remedies in the treatment of madness. Much difference of opinion exists as to the propriety of prescribing them. Esquirol says, "that these are rather injurious than useful, especially if there be plethora, or congestion about the head. Long since, Valsalva and Morgagni prescribed opiates, and daily experience confirms the opinion of these great masters. Diet, employment, exercise, are the true remedies for sleeplessness; tepid or cold baths induce sleep, and are truly efficacious, and no bad results ever followed their use."

Some authors and practical men of the present day join with M. Esquirol's opinion upon this subject. Dr. Cox considered that opium produced no permanent effect upon the insane.

On the other hand, we find medical men of great experience in the treatment of this disease, who prescribe it in large doses, and some, too, who think it possesses in these complaints virtues almost of a specific nature. Dr. Halloran, as quoted by Crowther, speaks of certain cases where sleep had been a stranger for 48 hours in succession, and where he had no doubt, but for the intervention of an opiate to the extent of 240 drops of the tincture of opium, at three short intervals, no rest could have been procured: he goes on to state that sleep approaching to apoplexy had been obtained in consequence, for nearly 24 hours, and that it was evidently the means of effecting an entire and lasting return of the mental faculty." Crowther says, the same effect was produced in the cases in which he employed it. His patients were relieved from insanity after waking out of a long and sound sleep. The same effect has been stated to me to have been produced in some cases under the care of Mr. Phillips, at the White House, Bethnal Green. Dr. Ogle and Mr. Wintle, of the Oxford Asylum, are

likewise in the habit of prescribing large doses of these medicines, which have also found an able advocate in Dr. Seymour for their employment. What is to be said, when we find such difference of opinion among practical men? M. Foville has truly said, that the particular cases of insanity in which narcotics are useful have not been clearly pointed out. My own experience would lead me to the conclusion, that opiates are of essential service in those cases of insanity which border closely upon delirium tremens; in cases of puerperal mania; in the first breaking out of an attack of madness, before congestion has taken place; in cases where there is great nervous irritability, from poverty of blood; and in cases of cachexia from starvation, and other causes: they are contraindicated wherever there is the least sign of general paralysis or congestion about the head. NARCOTICS are placed by some in the first rank of remedies in the treatment of madness. Much difference of opinion exists as to the propriety of prescribing them. Esquirol says, "that these are rather injurious than useful, especially if there be plethora, or congestion about the head. Long since, Valsalva and Morgagni proscribed opiates, and daily experience confirms the opinion of these great masters. Diet, employment, exercise, are the true remedies for sleeplessness; tepid or cold baths induce sleep, and are truly efficacious, and no bad results ever followed their use."

Some authors and practical men of the present day join with M. Esquirol's opinion upon this subject. Dr. Cox considered that opium produced no permanent effect upon the insane.

On the other hand, we find medical men of great experience in the treatment of this disease, who prescribe it in large doses, and some, too, who think it possesses in these complaints virtues almost of a specific nature. Dr. Halloran, as quoted by Crowther, speaks of certain cases where sleep had been a stranger for 48 hours in succession, and where he had no doubt, but for the intervention of an opiate to the extent of 240 drops of the tincture of opium, at three short intervals, no rest could have been procured: he goes on to state that sleep approaching to apoplexy had been obtained in consequence, for nearly 24 hours, and that it was evidently the means of effecting an entire and lasting return of the mental faculty." Crowther says, the same effect was produced in the cases in which he employed it. His patients were relieved from insanity after waking out of a long and sound sleep. The same effect has been stated to me to have been produced in some cases under the care of Mr. Phillips, at the White House, Bethnal Green. Dr. Ogle and Mr. Wintle, of the Oxford Asylum, are

likewise in the habit of prescribing large doses of these medicines, which have also found an able advocate in Dr. Seymour for their employment. What is to be said, when we find such difference of opinion among practical men? M. Foville has truly said, that the particular cases of insanity in which narcotics are useful have not been clearly pointed out. My own experience would lead me to the conclusion, that opiates are of essential service in those cases of insanity which border closely upon delirium tremens; in cases of puerperal mania; in the first breaking out of an attack of madness, before congestion has taken place; in cases where there is great nervous irritability, from poverty of blood; and in cases of cachexia from starvation, and other causes: they are contraindicated wherever there is the least sign of general paralysis or congestion about the head. Prescribed indiscriminately, or not in proper doses, narcotics do more harm than good; they keep up irritation, and add to the excitement, instead of allaying it. I have seen sometimes a very simple case converted into a very complicated one by the excessive use of narcotics. There is an idiosyncrasy, as every one knows, in some constitutions which does not admit of the exhibition of narcotics, especially morphia, even in the smallest dose: $\frac{1}{8}$ th of a grain will sometimes produce such incessant vomiting as to endanger the life of the patient. Great care also should be taken, even when the use of opiates is indicated, not to continue them too long, for if narcotization is produced, much harm will follow: the evacuations are hard and black; the irritation is extreme.

It must not be thought that opium and morphia are entirely to supersede other narcotics; there are others, as hyoscyamus and conium, which are equally serviceable in the treatment of insanity. I am often in the habit of prescribing the hyoscyamus; I find that it agrees better with the stomach, and it does not constipate the bowels: in fact, we know from experience that it has an opposite tendency, and it likewise increases the secretion of the kidneys and of the skin. Combined with the potassio-tartrate of antimony it is serviceable in the paroxysms of furor; considerable lassitude is apt to follow when a draught containing \mathfrak{ss} . of the tinct. of the former, with gr. $\frac{1}{4}$ of the latter, is administered. This, in some cases, is of course not to be desired.

Combined with camphor, opium allays the irritability of those suffering under madness, either combined with some degree of delirium tremens, or preceded by it.

Conium has high antiquity to recommend it, and is useful both given alone or in combination with hyoscyamus and opium. The boasted effects of camphor have not been

realized, to the extent at least which some of its advocates have stated. Dr. Perfect was in the habit of giving it in large doses; in one case he gave ℥ij. with grs. xv. of potassa nitras. I have found a mixture (often prescribed by my late colleague), containing myrrh and camphor, of use, in cases where there is debility with depression. Stramonium has frequently been given in mania. It was first recommended by Stoerck, as Dr. Paris informs us, because, as it deranged the mind of the sane, it might possibly correct that of the insane. Experience, he states, has not confirmed the sanguine expectations of Stoerck, but it has satisfactorily shown its occasional value in violent paroxysms, in quieting the mind, and procuring rest: for such purposes it has been given at the Fort Clarence, by Dr. Davy, very frequently and successfully. I have given the stramonium in large doses, and I have not derived any benefit from its use: after such praise of a remedy from Dr. Paris, however, it should not be thrown aside, particularly as we also learn from Dr. Prichard that Dr. Schneider derived great benefit from its use. I believe, nevertheless, that it will be found quite inferior to morphia and henbane in its narcotic properties, and to tartarized antimony in its power of subduing the paroxysm.

Belladonna and aconite may be placed in the same category with stramonium. There may, nevertheless, be here and there a case which may be benefitted by their use. Franck states belladonna to be useful in insanity complicated with epilepsy. I recollect obtaining some good effect from aconite in a case of intermitting insanity, when every thing else had failed; but neither the one or the other are remedies of much importance. In prescribing narcotics in insanity and other diseases you will often find that one preparation of a medicine will agree, while another will disagree with the stomach. I have found Squire's solution of the meconate of morphia very serviceable in some cases where the hydrochlorate and acetate could not be given. You will also find, as you no doubt already know, that the combination of narcotics is occasionally highly advantageous. I am not in the habit of prescribing narcotics as heroics; but it is very material that they should be given in sufficiently large doses. A patient labouring under insanity from drink, and coupled with delirium tremens, will bear, or rather require, large doses of morphia or the tincture of opium. It is necessary sometimes in these cases, and in others where there is great restlessness and irritability, to repeat the dose every three or four hours.

Hydrocyanic acid is a very useful sedative, and is beneficial in those cases where there is pain and a sense of weight about the

præcordia. If acid eructations be present, it may be combined with soda; and if there be much action of the heart and arteries, with digitalis. The latter remedy has been much used by some practitioners in the treatment of insanity. Dr. Cox speaks highly in its favour. The case of a gentleman whom he attended has been quoted by most modern writers on insanity, as proving the effect of digitalis: it is stated that when the pulse was 90, he was furious; when at 70, rational; at 50, melancholic; at 40, half dead. Dr. Cox says that the patient was cured by keeping the pulse at 70. No doubt the digitalis in this case effected much good, but I have found it difficult, in using this medicine, to ensure the constant slow action of the heart and arteries in some patients, when kept in a recumbent posture, without any excitement; still more so is it in insanity. I think the good results from administering digitalis in insanity are due quite as much to its diuretic as to its sedative effects; and this leads us to speak of a class of remedies either entirely overlooked, or at least much neglected in the treatment of insanity.

The urine of insane patients is very frequently, at the commencement of the attack of mania, scanty and high coloured, with a lateritious sediment. Sometimes no water is secreted for a day, sometimes for two days. There are also patients whose urine is retained for a great length of time, as there are others who pass it involuntarily; but of these last I do not now speak. I recommend you always to examine the state of the urine for yourselves, as you cannot depend upon the account given you by the patients: you will find it necessary, sometimes, to give ℥ss. or 3j. of Nitric Æther, either in distilled water, with gr. x. of Nitrate of Potash, ℥ss. of Infusion of Digitalis, and 3j. of the Compound Decoction of Scoparius, as the symptoms may require it. You will very seldom have to prescribe the more powerful diuretics, as cantharides; unless you give it in those cases where you suspect effusion, or, as has been recommended, in incipient paralysis. I have prescribed it in these cases, and have been much disappointed with it. I have not seen the symptoms of general paralysis yield to its influence, but great excitement and paroxysms of furor have sometimes been brought on, which have subsided when the medicine has been omitted. The bichloride of mercury is a remedy of far greater importance in these cases. Where symptoms of effusion are present, I have not derived much benefit from the Lytta, given, of course, I mean, in insanity; for its influence, when there is effusion in other cases, and also in hemiplegia and paraplegia, cannot be denied. I cannot help thinking that a very different state of the capillary vessels of the brain

exists where there is effusion after an attack of insanity, from that after one of acute inflammation of the brain and its membranes, for I have been surprised to find the stupor vanish, and the pupil become natural, under the influence of tonics and stimulants. I have before stated to you in what particular cases there appears to me to be passive congestion; if in these cases the vessels can but be induced by proper remedies to recover their tone, the patients will in all probability do well.

Tonics.—Since the insane have been better fed, there have been, on an average, more recoveries and fewer deaths. Even during the acute stage of mania we must not only regard the present symptoms, but future probable consequences of the disease, and of our treatment. The brain, in acute mania, with frequent recurrence of paroxysms of furor, suffers the wear and tear of many years, and the exhaustion of mind and body which follows is excessive. Patients who, previously to their admission into the hospital, have undergone a long course of lowering treatment, and whose strength is consequently much reduced, have derived benefit from an infusion of a light bitter, as calumba or cascarrilla, with the sesquicarbonate of ammonia. Sometimes patients are brought to the hospital whose insanity has been caused by starvation and wretchedness; many of these are cachectic, and have an eruption of boils. These will often bear the Compound Decoction of Bark, with ʒj. of the Liquor Potassæ, to which you may add, if there be irritability, ʒj. of the Tincture of Henbane.

There is a case reported by M. Andral of a person who laboured under intermittent cerebral congestion, who was cured by large doses of quinine, internally and externally administered. I have found this and other tonics of use in intermittent cases, where their employment is not contraindicated. Arsenic, either in the form of the Liquor Potassæ Arsenitis of the Pharmacopœia, or Solution of the Chloride of Arsenic, as prepared at Apothecaries' Hall, are likewise valuable remedies here. Mineral tonics are not to be laid aside on account of any theoretical notions about congestion of the brain. I have sometimes commenced with them from the first day of a patient's admission; for instance, in those cases when the disease is complicated with chlorosis or chorea, or when the patient is enfeebled by self-abuse, or any other cause. I have seen some of our patients rapidly improve, after the acute stage has passed over, by taking the Tinctura Ferri Sesquichloridi in an Infusion of Quassia, and the combination of a chalybeate with a purgative is occasionally of great service to us in treating insanity. The preparations of Iron, the Sulphate of

Zinc, and the Salts of Copper, are also valuable medicines in nervous disorders.

Of blood-letting.—The great advocate for large general bleedings in insanity is Dr. Rush. This practice fortunately does not retain in England the same credit which it formerly did, as Esquirol somewhat archly says, "they thought they had cured their patients by venæsection, when in truth they had reduced them to a state of incurable fatuity." M. Georget, and M. Foville, recommended general bleeding. The latter says, "without having pushed venæsection so far as either Rush or J. Franck, I confess that it appears to me to be one of the means on the efficacy of which we can most rely in recent acute cases."

M. Pinel and M. Esquirol were decidedly opposed to general bleeding in cases of insanity. In acute mania with plethora, heat of head, injected conjunctivæ, and full pulse, we should certainly propose to ourselves to unload as speedily and as safely as possible the minute capillary tubes.

This can be the only reason for employing general bleeding, but this is for the most part very much more safely effected by local abstraction of blood. The best mode of doing this is by leeches, for cupping is apt to frighten the patient.

In cases of nymphomania, of suppression of the catamenia, and of suppression of hæmorrhoids, leeches are of very great importance applied periodically. Dr. Watson has some valuable remarks upon the subject of general bleeding: he says, "the state of constitution may be such that the disposition to local plethora would be increased by the loss of blood. Disordered action, and undue susceptibility of the nervous system, are apt to be aggravated by bleeding, and in proportion as the nervous functions are irregularly performed does the tendency to unequal distribution of blood in the capillary vessels augment: we have daily examples of this in hysterical young women. It is not, therefore, the mere congestion that we have to consider; we must look deeper for its cause."

If you were called in to see an epileptic patient, and found him in a state of profound coma, you would order him to be bled; it is a matter of life and death; but you would be very sure that the fits would come on more frequently. So, in insanity, you may find it absolutely necessary to employ venæsection—in cases, for instance, with vertigo from plethora—but you would do it at the risk of producing nervous irritability. M. Foville was an advocate for the employment of general bleeding when at the Hospital near Rouen; it would be interesting to know whether he still holds the same opinion since his appointment to Charenton. The ener-

vated inhabitants of a capital would not so well endure the abstraction of blood as the hardy and robust peasants of the lower Seine.

Of counter-irritants.—Blisters are very generally employed in the treatment of insanity; in the acute stage of mania, however, they should never be used; certainly not till the heat of skin and general irritation from the loaded vessels have subsided. I need not dwell here upon the several modes of action of blisters; they must be familiar to you already.

I have only to recommend you in insanity to employ the acetum instead of the emplastrum lyttæ as a general rule, as you will find it more convenient; the present acetum lyttæ of the Pharmacopœia acts with sufficient certainty, and generally speaking uniformly.

In some cases of insanity which run their course sluggishly, or where there is a healed ulcer, or a suppressed discharge, setons are of great service. Esquirol says they act as if by enchantment. The Ung. Antim. Pot. Tart. proves beneficial in some cases of suppressed eruptions, and as a counter-irritant.

Strychnine, either given internally or mixed with prepared lard, and rubbed along the spine, I have found serviceable in the few cases of catalepsy in which I have tried it. It is also useful in cases of insanity accompanied with paralysis.

When patients have illusions of hearing, M. Foville suggests that cotton on which laudanum has been dropped should be put in their ears. I have tried this, and have in one or two cases found it beneficial. In cases of this description it is likewise of use to order the ears to be syringed, or to place small blisters behind each ear, in order to divert the attention of the patient from the noises and whisperings on which his imagination dwells.

The function of the skin is frequently badly performed in insanity. The peculiar smell which some madmen have I have often heard spoken of by those who have had much experience in these cases, and I always attributed it to the uncleanness of the patient, but since my attention has been more particularly drawn to it I think that the peculiar odour is due to the disease: when it exists, however, it is a very unfavourable sign; the only thing I can compare it to is the smell of a person just prior to dissolution. Baths of all descriptions have very properly been recommended to ensure the due performance of this important function. In the hospital we employ hot and cold baths, the hip bath, the shower bath, pediluvia, and the douche. The tepid bath is of great service in subduing irritability and excite-

ment. It is sometimes necessary that the patient should remain in it for an hour and a half, or two hours. Ice or cold lotions to the head should be applied at the same time: it may be necessary to repeat it every day, sometimes twice daily, till some effect is produced.

If the irritation is not subdued by the application, I have found it beneficial to apply a blister to the nape of the neck immediately that the patient leaves the bath.

In acute dementia, I have seen much benefit derived from the douche, but this is a remedy which requires caution, and is not by any means to be ordered for those patients who are liable to congestion of the head, or have any tendency to paralysis.

The shower bath, with antispasmodics, is a valuable means of subduing the symptoms of madness with hysteria and hypochondriasis.

When a patient has passed into what is termed the chronic stage of the complaint it by no means follows that nothing is to be done for him; something can be effected by medicine even here, in shortening the paroxysms of furor, in procuring sleep for the restless, and improving the general health of the debilitated.

It now only remains for me to speak of the manner in which the different species of the complaint should be treated: this I propose to do by placing examples before you of mania, monomania, puerperal mania, acute dementia, and general paralysis. When the cases are read you will probably be better able to understand my reasons for adopting the plan of treatment.

In summing up the observations which I have made in these lectures, it will not be necessary for me to recapitulate what I have said as to the mode of treatment; as to the nature of the disease, however, I wish to remind you that I stated it as my opinion that insanity, properly so called, was either primarily or secondarily a disease of the brain; that sometimes the irritation is due to the nerves, sometimes to the blood; thus proving the relation of the disorder to those diseases which are accompanied by congestion, in that it is apt to recur; and, on the other hand, to those of the nervous system, in that it is often intermittent. Irritation is not to be rejected as a cause of insanity merely on account of there being something in it which we cannot explain: we are quite justified in such an obscure disease in appealing to effects, although the knife of the anatomist fails to point out to us any characteristic distinction in the minute alterations of structure which take place in the delicate granular matter, or in the thin filaments of the fibrous structure in the brain of the insane. Were we able to show this

first departure from healthy structure under a powerful lens, I think that we should find it to be an alteration differing in degree, and not in kind, from that presumed to exist in other diseases of the nervous system. I believe that insanity, divested of the halo of metaphysics with which it is sometimes surrounded in order to dazzle and bewilder, is a disease which is subject to the same laws of pathology as all other diseases; still I acknowledge that it is a very obscure disorder, perhaps the most complicated one to which man is subject, and I do not presume to dictate upon a subject so abstruse. It might, perhaps, have been more satisfactory to some had I attempted to trace all the phenomena of insanity to one source—for instance, inflammation: a theory of disease which professes to account for every thing, which reduces the various symptoms into a systematic arrangement, and refers them to one cause, is sure to be popular, because it saves men the trouble of thinking for themselves; and having once obtained possession of the mind it becomes very difficult to eradicate: but before we attempt such a task we shall do well to recollect the words of the great master of inductive science—"Another error," says Bacon, "to the advancement of learning is the over-early and peremptory reduction of knowledge into arts and methods." I have not thought it necessary to state all the theories of the nature of insanity; what I have endeavoured to do has been to make my observations on this part of my subject tend as far as possible to some practical use. It would, indeed, have been an unprofitable task to have gone through them all, for there are few diseases which have been explained by more various and opposite theories than madness. One fatal error has been, the mistaking the causes for the disease itself: it is this that has led to the theory that insanity is a disease of the mind; it is this which has been the cause of the notion that madness consists in a wrong action of the soul. Another theory of recent date would tend to make the subject still more complicated: Leibnitz, in his doctrine of "Pre-established Harmony," and Malebranche, in that of "Occasional Causes," were bold enough to decide the manner in which mind acted upon matter; there does not, however, appear to be the slightest reason for supposing that the one does not act directly upon the other, and there seems to be no cause for believing that a *tertium quid*, some subtle entity, is necessary to keep up the mutual action of the material upon the immaterial portion of our being. To say that "electricity is the connecting link between mind and matter," is to assume what has not yet been proved; and if we imagine that we have advanced one step in the explanation of this subject, or in our

knowledge of the nature of mind, we very greatly deceive ourselves; electricity is itself a principle of matter, and as such is subject to the laws which bind matter. How mind acts upon matter, and matter upon mind, we cannot explain. Future observations and experiments may make us more perfectly acquainted with the instrument of mind, the brain, and the exact change of structure which prevents its minute fibres ministering to the will, but it is not easy to imagine that we shall ever be able to discover how the one acts upon the other. Locke, Leibnitz, Malebranche, have all failed in their attempts to solve this most difficult problem. There are bounds to all sciences, beyond which we cannot rove; we have a clear perception only of few things, all else is either obscurely seen in the twilight of probability, or hid in darkness.

ON THE
TISSUE UPON WHICH THE RE-
MOTE ACTION OF POISONS IS
EXERTED.

BY W. WATTS, M.D.
Honorary Physician to the Nottingham Union
Dispensary.

(*For the London Medical Gazette.*)

[Concluded from page 473.]

THE following experiment made by Magendie is taken from Morgan and Addison's Essay, page 39.

"The femoral artery and vein of the animal" (a dog, previously stupified with opium) "having been divided on one side, the continuity of the canal was re-established by the intervening connecting medium of small cylinders of quill to which the truncated extremities of the vessels were attached, and through which quills consequently the blood passed in the usual course of the circulation. With the exception of the femoral artery and vein, thus divided, and reconnected by quills, the limb was then amputated from the body, so that in this case the separated member was deprived of all nervous connection with the body, at the same time that circulation was allowed to continue through its main vessels. The poison of upas was then applied to a wound in the severed limb; which produced its effects upon the system after the lapse of the interval of time usual under the common circumstances."

Thus we see that the cerebro-spinal system is not the remote recipient of impressions made by poisonous agents. If, then, the brain and spinal cord,

The influence of the central ganglia seems to be moderated or altered by the lesser ganglia.—Sec. 35, 36.

It seems probable, from the circumstance of a separate ganglion or plexus, or both, of the ganglial system, being generally assigned to each important secreting or animalizing organ, that the centre or source of vital influence does not supply the whole vitality distributed by the ganglial ramifications to the individual organs or textures, but that the vital influence proceeding from this centre is reinforced and modified by that which is produced by the subordinate ganglia, so as to give rise (with the difference of structure) to the specific difference of function which each performs.—Sec. 40.

6thly, The general diffusion of vital influence.

The vital influence being thus produced in the centre of the body, and reinforced and modified by subordinate ganglia allotted to the individual organs, according to their functions, is propagated along the distributions of the system on which it depends, and is inherent throughout the whole body.—Sec. 41.

The remote action of poisons upon the sympathetic system of nerves is alike deducible by reasoning and demonstrable by experiment.

As all the organs of our frame require to be endowed with nervous influence before they can offer any manifestation of action, and that innervation can be derived but from two sources, if it can be shown, as I trust I have, that one of those sources (the cerebro-spinal) is not in any way *remotely* affected by poisons, and that they produce their effects under all possible variation of circumstances, as regards these organs, as of integrity of structure and of medium of communication, it must follow as a natural consequence that it is by the other (the sympathetic system) that the remote impressions of poisons are received, and that all the effects of those impressions manifested by distant organs must arise from the connexion which exists between this system and those organs, through which connexion they receive a modification, either in kind or degree, of that influence, a healthy condition of which is necessary to the proper performance of their functions.

The following experiments demonstrate the truth of the above conclusion, as in each instance the poison was applied to a part upon which nerves from the sympathetic alone ramify, and its influence is exerted upon the fibre of an involuntary muscle, the irritability of which is solely dependent upon the sympathetic system.

“But a still more striking example of the immediate action of a poison upon the part to which it is applied was afforded during one of our experiments upon a dying guinea-pig, by the accidental contact of a very minute portion of *ticunas* with the still living intestine. In this case the consequence was a complete and instantaneous suspension of the peristaltic motion in that part of the bowel to which the poison was immediately applied; and in repeating the application of the poison to other parts of the intestinal canal in the same animal, we found precisely the same local paralysis was produced*.”

“The most unequivocal instance I know of a similar impression on internal parts, is a fact related by Dr. Wilson Philip with regard to opium: when this poison was applied to the inner coat of the intestines of a rabbit during life, the muscular contractions of the gut were immediately paralysed, without the general system being for some time affected†.”

This brings us to the consideration of the second proposition under our immediate notice: viz. the capability of the organ remotely acted upon to manifest its reception of the impression made by poisons upon it.

When the function of a system or organ is to exert control over others, and to endow them with that innervation which enables their structures to perform their proper functions in a healthy manner, we must look to those organs so endowed for manifestations of derangement in the source of the innervating power; and if they offer no organic change in their structure sufficient to account for the existing error in function, we are entitled to attribute that error to deviation, either in kind or degree, from the healthy standard of the nervous influence which

* Morgan and Addison's Essay, p. 63.

† Christison on Poisons, p. 2.

controls and regulates their motions. And again, when we see a large number of organs, unconnected with each other, but each dependent upon the same system of nerves for the influence which actuates them, simultaneously presenting derangements in their functions, without offering any structural change in each as the cause of that deviation, we must look to the nervous centre which supplies them all for the remote cause of their various functional lesions, and are justified in attributing to it the remote deviation from the normal state; and also in looking upon the various derangements of the organs it supplies as the proximate effects of that remote action, and as arising from their being actuated by an abnormal controlling power.

Now, as all the organs which are subservient to the maintenance of organic life are under the control of the great sympathetic system of nerves, when any material deviation in their action from its normal condition occurs, not the effect of structural change, it must, I contend, be attributed to deviation from the healthy standard of that nervous influence; and we must attribute to the system generating it the remote cause of the proximate derangement of function. I shall now proceed to show that the *remote* action of poisons is upon the great sympathetic, and their effects are produced in strict accordance with the laws of that system.

The sympathetic system is affected both *locally* and *generally*.

Each part of our frame seems to possess the power, to a certain extent, of generating organic nervous influence by means of the action of its parenchyma, endowed with sufficient vitality, acting upon healthy arterial blood; and this power is not entirely destroyed, though it is certainly diminished, by separation of the part from its continuity with the centre of the great sympathetic system. The reason for this is thus described by the late Dr. Fletcher*:—"But it is probable that no impediment whatever is offered to the function of a ganglionic nerve by such a division as would entirely paralyse one from the cerebro-spinal system. Such is the case with the latter, only because the white matter of the

nerve being dependent for its energy, in all probability, upon the grey matter of the central parts of this system, becomes, of course, inert when separated from it. But no such line of demarcation exists in the ganglionic system; every point of every nerve of which contains white and grey matter intimately interwoven together, and may be considered, therefore, as a centre of nervous energy to itself (Bichât): and it is in this way only that it can be explained how the total removal of a muscle from the rest of the body, which implies a division as well of its blood-vessels as of its nerves, is not, for some time, effectual in destroying its irritability." How far this explanation may be anatomically correct I am not capable of deciding; but the facts which it is put forward to elucidate are perfectly known to every surgeon; as, for instance, the re-union of parts which have been entirely separated from the system. This accounts for an independent *local* action of the great sympathetic system.

It has also a *general* action. That it is capable of exerting a power over all the organs to which it is distributed is undoubted, but that the derangement in each individual organ should be different in kind, though similar in degree, seems difficult to comprehend at first sight; yet if we remember that difference of structure, though actuated by the same innervating principle, and acting upon the same fluid, the blood, produces difference in its secretions, the apparent anomaly disappears. The following passage from the same work as the preceding seems to offer a very satisfactory physical reason for it*. "The last circumstance to be mentioned, as tending to the conclusion that the ganglionic system of nerves is the immediate seat of irritability, is that of the nerves of this system, while they are of a similar form, colour, and consistence, when distributed on parts the irritability of which is of the same character—that is to say, which are liable to be excited in the same manner by the same stimuli—being quite dissimilar in all these respects when they supply parts the irritability of which is different. Thus, while the filaments going from the ganglions to the several voluntary muscles, all of which have one general

* Rudiments of Physiology: by Dr. Fletcher, p. 74.

character of irritability, are said to display the same general aspect and physical properties, those which proceed from the cæliac ganglion, for example, respectively to the stomach, liver, and other organs, (each of which has a character of irritability, however, to itself) have these properties very distinct; those sent to the stomach being conical, white, and firm; those to the liver, cylindrical, red, and soft; and similar differences manifesting themselves between the filaments respectively of the splenic, mesenteric, hypogastric, and other plexuses. (Lobstein). This remarkable coincidence, then, if generally admitted, of certain modifications of a common faculty, as displayed by different organs, and corresponding modifications of a common system of nerves, as distributed to these different organs, seems to be a strong testimony in favour of the doctrine that this general system of nerves ministers directly to the general faculty in question."

In conformity with these laws of the great sympathetic systems, poisons act remotely upon it both *locally* and *generally*.

The examples of a *local* action of poison have been given in the two experiments quoted from Morgan and Addison, and Wilson Philip, and others will present themselves to the minds of every one of my readers. I need not, therefore, adduce others. The poison, in producing only a local action, seems to be applied in such a quantity, or upon such a surface, that but a very small quantity is capable of acting at the same time; so that the effect of the impression of the particles first acting partly subsides before those acting later are capable of effecting their impression; or if all the particles applied do act at once, then the impression they create is of so slight a nature, as not, should it be felt by the central portions of the system, to be able to act upon it so as to cause the impulse they communicate to modify the nervous influence thence proceeding in such a degree as to cause the other organs supplied by it to evince derangement in the performance of their functions; while a *general* action is the effect of a poison applied in such a form, and in a sufficient quantity, upon such a surface as to create upon the organic nerves in its substance impres-

sions of so powerful a nature as that they are propagated to the central ganglia, and there act upon it in such a manner as to modify the influence transmitted thence to all its related organs and structures; that modification varying from the very slightest alteration to extreme excitement or complete extinction.

Having stated upon what tissue the remote effects of poisons are exerted, and in what manner that tissue may be affected, I shall now proceed to notice the action of poisons upon the blood; a point more conveniently discussed here than previously.

Wedemeyer's and Marshall Hall's experiments, in each of which the spinal cord was divided, and one of the hind extremities inoculated, in one instance, with hydrocyanic acid, and in the other with strychnia, and in which the muscles supplied by nerves given off from the cord above the section were influenced by the poison, as well as those below, have countenanced the supposition that the poison was absorbed, and, being carried into the circulation, would be equally applied to the upper as well as the lower part of the spinal cord, and so stimulate each to the production of the tetanic affection in the muscles they supplied. But this theory, viz. that these actions were the consequence of the immediate application of the poison to the spinal cord by means of its absorption and general diffusion through the blood, is open to the following objections:—

1st, If this position were correct, then should the action of the poison upon the lower portion of the spinal cord be simultaneous with that upon the upper: yet in Dr. Hall's experiment an interval of thirty minutes intervened between the appearance of the spasms in the anterior extremities and the hind ones. 2dly. We have seen that neither the brain or spinal cord are in the slightest degree affected when a poison is directly applied to their substance. And, 3dly, Because the symptoms are more probably produced by the impression of the poison being *remotely* exerted upon the great sympathetic, there inducing a modification of the influence transmitted from it to the spinal cord through those fibrillæ which pass to it from the sympathetic to the intervertebral foramina; the in-

terval between the occurrence of the tetanic symptoms in the opposite extremities being produced by the lower portion of the spinal cord having its structure injured, and its cerebral influence cut off by means of the section.

In these cases of poisoning, the tetanus was the *proximate* affection of the spinal cord, the effect of the *remote* action of the great sympathetic system upon it, and not the remote effect itself.

That poisons are absorbed into the circulation of the blood by veins, I think few who have paid any attention to the subject will deny; certainly, I am not among that number: but I cannot agree with Mr. Blake* that they act by being allowed to enter the circulation, and by being directly applied to the tissue the functions of which are affected. Whenever a poison is absorbed, if it be from the periphery of the body, then it is taken by the veins directly into the right side of the heart, and thence passes into the lungs: or if it be absorbed by the portal veins, it passes directly into the liver: in the ultimate divisions of each of these viscera the most important changes are effected in its constitution. In order that these alterations may be effected, the acini of the liver and the bronchial vesicles of the lung are largely endowed with organic nerves from the plexuses and ganglia appropriated to each of these structures; and it is upon these nerves there expanded that the primary impressions of poisons are made when they are absorbed, and not by being carried by the arterial circulation into the various organs whose functions are proximately affected.

The phenomena attendant upon the absorption of white lead confirm this view. Those who are in the habit of working in it, if they use the necessary precautions, do not suffer from the paralysis it otherwise induces, but if they do not, the lead passes through the cuticle and becomes absorbed. Now the paralysis thus produced is entirely a local one, and seems to be caused by the lead acting upon the nervous influence generated in the part itself to which it is applied, it being greatest in the muscles which produce the lesser movements of the fingers, and less so in those which move the hand upon the fore-arm. The action of the lead in this instance is by

remotely affecting the source of irritability in the muscular fibres, destroying it in the hand, and diminishing it in the fore-arm, and not by acting upon the spine, for the act of volition is obeyed by those muscles which still retain their irritability, as may be seen in the slight remains of voluntary motion in the wrist, which irritability is the result of the local action of an influence partly derived from the central ganglia of the sympathetic, and partly generated in the muscular fibre by the action of the former upon healthy arterial, by means of the muscular parenchyma. Such a local paralysis would not result if it were caused by the lead being absorbed by the veins then passing into the arterial system, and so being conveyed by it to the muscles of the hand and fore-arm; for if it were, then should the muscles of the latter be as completely affected as those of the hand, which is not the case; and also, all the other voluntary muscles in the body should be paralysed, which they are not, though the constant presence of the blue line in the gums in these cases fairly shows that the lead is absorbed, has been taken into the arterial system, and has been deposited from it. Nor can the remote action be upon the elements of the blood. This fluid, being possessed of vital as well as material properties, a natural condition of each of which is necessary to its full action in the system, can be affected either as to its vitality or as to its material constitution. If a poison act upon the blood, destroying its vitality, without affecting any previous change in its chemical properties, and that vitality be derived from the action of the organic nervous influence, then I infer that its action is remotely exerted upon the source of that influence. But if the composition of the blood be altered by the poison, then, also, I contend that the action is previously upon the source of its vitality, for the first law of life is, "that it preserves material particles in such chemical relations as to prevent other chemical relations from inducing disorganization." Thus, if a poison act upon the blood so as to induce any chemical alteration in the relation of its particles, that very alteration necessarily implies a previous alteration in the kind or degree of the nervous influence which bestows vitality upon the blood, and

* Edinburgh Med. and Surg. Journ. vol. liii. p. 37.

do not return, rupture the membranes, tighten the binder, and bring down the lower extremities, and deliver the child in the manner already described when the nates present. No good can in any case be produced by allowing the child to remain longer in the uterus than an hour after the birth of the first.

If a shoulder or superior extremity of the second child presents, proceed immediately to perform the operation of turning, which is easy and safe both for the mother and child, if you pass up the hand into the uterus, before the membranes are ruptured.

In twin cases, where the head of the second child presents, apply the binder, rupture the membranes, and the uterus will probably contract upon the child and expel

it without any artificial assistance. If, however, the labour has been very protracted, and there is great exhaustion, and some risk lest the natural powers should be insufficient for the delivery of the second child, I am disposed to think, as the operation of turning is so easily accomplished, that it would be better at once to have recourse to it, than to trust to the forceps if farther assistance should be required. At all events it is invariably necessary to rupture the second set of membranes, if you determine to leave the expulsion of the second child to nature, for the uterus may remain twenty-four hours or longer quiescent if this is not done. After the delivery of both children, always remember the danger of uterine hæmorrhage.

CLINICAL LECTURES
ON THE
THEORY & MEDICAL TREATMENT
OF INSANITY,

*Delivered at St. Luke's Hospital,
May 1st, 3d, and 5th.*

BY ALEXANDER JOHN SUTHERLAND.

LECTURE III.—(concluded.)

*Of Narcotics; use and abuse of opium.
— Sedatives. — Hydrocyanic acid. —
Digitalis. — Diuretics. — Tonics. — Mi-
neral tonics. — Of blood-letting, leeches,
cupping. — Counter-irritants. — Setons. —
Baths. — Antispasmodics. — Conclusion.*

NARCOTICS are placed by some in the first rank of remedies in the treatment of madness. Much difference of opinion exists as to the propriety of prescribing them. Esquirol says, "that these are rather injurious than useful, especially if there be plethora, or congestion about the head. Long since, Valsalva and Morgagni proscribed opiates, and daily experience confirms the opinion of these great masters. Diet, employment, exercise, are the true remedies for sleeplessness; tepid or cold baths induce sleep, and are truly efficacious, and no bad results ever followed their use."

Some authors and practical men of the present day join with M. Esquirol's opinion upon this subject. Dr. Cox considered that opium produced no permanent effect upon the insane.

On the other hand, we find medical men of great experience in the treatment of this disease, who prescribe it in large doses, and some, too, who think it possesses in these complaints virtues almost of a specific nature. Dr. Halloran, as quoted by Crowther, speaks of certain cases where sleep had been a stranger for 48 hours in succession, and where he had no doubt, but for the intervention of an opiate to the extent of 240 drops of the tincture of opium, at three short intervals, no rest could have been procured: he goes on to state that sleep approaching to apoplexy had been obtained in consequence, for nearly 24 hours, and that it was evidently the means of effecting an entire and lasting return of the mental faculty." Crowther says, the same effect was produced in the cases in which he employed it. His patients were relieved from insanity after waking out of a long and sound sleep. The same effect has been stated to me to have been produced in some cases under the care of Mr. Phillips, at the White House, Bethnal Green. Dr. Ogle and Mr. Wintle, of the Oxford Asylum, are

likewise in the habit of prescribing large doses of these medicines, which have also found an able advocate in Dr. Seymour for their employment. What is to be said, when we find such difference of opinion among practical men? M. Foville has truly said, that the particular cases of insanity in which narcotics are useful have not been clearly pointed out. My own experience would lead me to the conclusion, that opiates are of essential service in those cases of insanity which border closely upon delirium tremens; in cases of puerperal mania; in the first breaking out of an attack of madness, before congestion has taken place; in cases where there is great nervous irritability, from poverty of blood; and in cases of cachexia from starvation, and other causes: they are contraindicated wherever there is the least sign of general paralysis or congestion about the head. Prescribed indiscriminately, or not in proper doses, narcotics do more harm than good; they keep up irritation, and add to the excitement, instead of allaying it. I have seen sometimes a very simple case converted into a very complicated one by the excessive use of narcotics. There is an idiosyncrasy, as every one knows, in some constitutions which does not admit of the exhibition of narcotics, especially morphia, even in the smallest dose: $\frac{1}{8}$ th of a grain will sometimes produce such incessant vomiting as to endanger the life of the patient. Great care also should be taken, even when the use of opiates is indicated, not to continue them too long, for if narcotization is produced, much harm will follow: the evacuations are hard and black; the irritation is extreme.

It must not be thought that opium and morphia are entirely to supersede other narcotics; there are others, as hyoscyamus and conium, which are equally serviceable in the treatment of insanity. I am often in the habit of prescribing the hyoscyamus; I find that it agrees better with the stomach, and it does not constipate the bowels: in fact, we know from experience that it has an opposite tendency, and it likewise increases the secretion of the kidneys and of the skin. Combined with the potassio-tartrate of antimony it is serviceable in the paroxysms of furor; considerable lassitude is apt to follow when a draught containing \mathfrak{ss} . of the tinct. of the former, with gr. $\frac{1}{4}$ of the latter, is administered. This, in some cases, is of course not to be desired.

Combined with camphor, opium allays the irritability of those suffering under madness, either combined with some degree of delirium tremens, or preceded by it.

Conium has high antiquity to recommend it, and is useful both given alone or in combination with hyoscyamus and opium. The boasted effects of camphor have not been

which, did it remain unimpaired, would effectually have prevented any change.

Affirming that the great sympathetic system is the tissue remotely acted upon by poisons, I will now proceed to strengthen this position by shewing the very close similarity which exists between the effects of direct injury upon the former, and the symptoms produced by poisons.

The consequences of direct injury either upon a ganglion of the great sympathetic system, or a part very largely endowed with nerves from it, may be thus divided:—

1st, Sudden and immediate death.

2d, Gradual sinking of the vital powers.

3d, Death after reaction from lesion of any organ the healthy performance of whose function is necessary to the continuance of life.

The two first of these modes of death merge into each other. I shall therefore consider them together.

Sudden and immediate death follows blows upon the epigastrium, or over any of the lesser ganglia, where they are so situated as to be liable to compression—as, for instance, the middle cervical ganglion. Death from the former injury is, unfortunately, not uncommon, two cases having fallen under my own observation; and of the latter a very melancholy instance occurred, towards the close of the last year, in Ireland. Two medical gentlemen, one of whom had lately returned from India, were taking soda-water with each other; one of them, while loosening the cork of one of the bottles, held it in such a direction as that when the wires were cut the cork was driven with force against his friend, striking him violently on the neck, and causing almost an immediate death.

When parts largely supplied with nerves from the sympathetic system, as the testicles and kidneys, are suddenly and violently injured, death takes place without any of the signs of reaction appearing. The symptoms which precede it are thus described by Dr. Copland:—“paleness; entire loss of muscular power; a most distressing death-like sensation; coldness of the skin, which is damp and pale; slow and feeble respiration; pulse feeble, slow, irregular, intermitting, scarcely to be felt; the eyes are fixed; the countenance collapsed; lips pale; the surface and

extremities become quickly cold; the muscles are flaccid; the joints pliable; and in some instances the sphincters relaxed. If the powers of life be not rallied at this time, all these phenomena increase, until the action of the heart and respiration entirely cease.”

Life is also extinguished in each of these two ways through the action of some kinds of poisons. Magendie, describing the action of hydrocyanic acid, resembled it to the effect of a common shot, or thunder-bolt; he found that one drop of pure hydrocyanic acid, placed on the tongue of the most vigorous dog, causes it to fall dead after two or three hurried respirations; and that if the nose of a rabbit be introduced into a receiver filled with hydrocyanic vapour, the animal drops dead *instantly**. Sir B. Brodie applied the essential oil of bitter almonds to the tongue of a cat, in consequence of which the life of the animal was instantly destroyed. Dr. Christison says he has killed an animal outright in four seconds: and that Pelletier and Caventou found strychnia begin to act in fifteen seconds.

It is recorded†, that at the time the plague was raging at Marseilles “the men who were employed by the merchants to carry the infected goods from the ships to the warehouses fell down and suddenly expired, from the first impression made upon the system by the effluvia arising from the burdens which they were carrying.” Death without reaction follows the bite of the rattlesnake, and ticunas; inoculation with the woorara, woorali, and the upas poisons; after poisoning by tobacco, oxalic acid, and others. In both these instances of death following injury or poisoning, the symptoms are the same; those following the action of poisons being, according to Dr. Christison, “deadly paleness; extreme prostration of strength; feeble, irregular, and depressed pulse; mortal fainting, and coldness of the extremities.”

The third mode of death, from the proximate disease of some important organ, resulting from the remote action of poisons upon the sympathetic, is also common to them and to injuries. Regarding the possibility of the occurrence of a chain of action necessary to its production, it may, perhaps, be questioned, how is it possible for any

* Christison.

† Morgan and Addison's Essay, p. 29.

agent, not a poison, applied to any part of the body, to induce symptoms of disease or derangement in distant organs? To this it may be replied, that as the impressions of these agents are received remotely by a system of nerves common to every part of the frame, there need be no difficulty in assenting to this proposition, which has been, in fact, recognised in pathology from the infancy of medicine. It is through their mutual connexion with the great sympathetic system that injuries of the head, or testes, induce sickness or other derangement of the stomach: that urticaria follows the ingestion of improper food into the same viscus: that the mammæ are enlarged before the catamenial discharge: the manifestations of mind are affected by the state of the alimentary canal: that the functions of the spinal cord are affected when convulsions result from the presence of indigestible aliment or worms in the primæ viæ: that ascarides induce cough; that hæmorrhoids are at times accompanied with frequent and forcible efforts at micturition. In the same conformity with this principle of proximate derangement of function in distant organs, depending upon the remote action of a central common influence, we see tobacco producing pallor, sickness, relaxation of muscular fibre, syncope, and irregularity in, or cessation of, the heart's action: cantharides, though applied to the skin, inducing strangury, or stimulating the spinal cord to the production of convulsions: opium exciting the cerebro-spinal system to increased activity, while, at the same time, it deranges the liver and the stomach: strychnia acting as tonic to the stomach, and producing twitching in the voluntary muscular fibres: oxalic acid inducing coma, sudden death by paralysis of the heart, or tetanic spasms; and by its action upon this common centre it is that arsenic, wherever applied, so often induces vomiting, while it can produce, also, inflammation "in the throat, gullet, stomach, and intestines, the lining membrane of the nostrils and eyelids, the bladder, vagina, and kidneys," and is able to act upon the brain, the heart, and lungs: evidences of every one of these effects being, at times, found in the same person*.

* Christison.

Having, I trust, satisfactorily shewn that death or disease may follow impressions made upon the great sympathetic system, and that the mode in which the former occurs, and the symptoms which characterise the latter, are not essentially different from those produced by the remote action of poisons, I am compelled to believe that action is upon the great sympathetic system of nerves.

The full comprehension of this most interesting subject is not to be attained until the manner in which circumstances affect the production of the effects of poisons, such as, for instance, age, sex, idiosyncrasy, states of nervous and vascular system, dose, &c. To the elucidation of these influences I shall devote another paper.

CONTRIBUTIONS

TO

ANATOMY AND PHYSIOLOGY.

By ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 467.]

On some Varieties in Human Structure, with Remarks on the Doctrine of "Unity of the Organization."

Osseous system.—The cranium.

A FEW years ago, there was reported in a weekly journal, but very briefly, the case of a labouring man, who falling from a scaffolding, or having been accidentally knocked down in some way or other, was carried senseless and motionless into one of the largest metropolitan hospitals. The distinguished surgeon into whose hands this patient came having examined his head carefully, discovered on its surface a remarkable depression, and assuming this to be the probable cause of the loss of sense and motion, he proposed the application of the trephine as the most appropriate remedy. But, fortunately for the patient and for the surgeon, the patient's wife appeared in the hospital, and the nature of the operation, with the reasons for operating, having been explained to her, she objected to its being proceeded with on the following very sufficient grounds: viz. that ever since she became acquainted with her husband, the patient, his head had

always presented that identical depression, and therefore—but I may leave her conclusions (with which the surgeon agreed) to every sound reasoner. The patient, if I remember right, recovered without the performance of any operation. Now, I had seen similar cases before, or at least some very puzzling appearances on the surface of the cranium in persons otherwise quite well, and great difficulties have occasionally arisen as to how the surgeon ought to act; but I am not quite sure that anatomy can always furnish him with the means for arriving at a sound judgment; in two circumstances, however, I think it may assist in the arriving at a correct diagnosis; the first great object of the surgeon no less than of the physician. An incision, as an exploratory step, made in the scalp so as to expose the cranium, may appear to many by no means a formidable operation, and this undoubtedly is true; but neither is the extirpating a trifling corn on the toes an important matter, and yet an estimable lady lost her life a few days ago in the hands of a distinguished professor of surgery in this place, in consequence of submitting to so very simple an operation.

If a considerable number of crania be examined (I mean of crania as they are preserved in museums) a certain few will exhibit the following peculiarity: along nearly the whole line of the lambdoidal or parieto-occipital suture the occipital bone will occasionally so overlap the parietal, or at least be so raised above it, as to give the false appearance of a deep depression of the parietal. This singular overlapping of these bones, or perhaps rather elevation of the occipital, I find, on examining the museum, to be by no means infrequent, and in various heads to present a great variety of appearances, agreeing, however, all in this, that on passing the hand from the occipital to the parietal bones a sudden depression will be felt, occasioned by the greater elevation of the former. The second circumstance in respect to such elevations at various points of the cranium is even more interesting than the first; it is of rarer occurrence, and more likely, therefore, to lead the surgeon into error. The elevation occurs in the line of the fronto-parietal suture, and is caused by an overlapping of the parietal by the frontal bone, or at least

by a greater elevation of the former. Of at least a hundred crania in the museum, there is not one showing this variety in its form, at least to any extent; and a specimen exhibited by Dr. J. A. Robertson to the Anatomical and Physiological Society was the first I had an opportunity of carefully examining. What made this case peculiarly interesting was its occurrence in a person who had met with a severe injury to the head, which ultimately proved fatal. The *seeming* depression close to the fronto-parietal suture was so great as nearly to induce the attending surgeons to apply the trephine; but the death of the person taking place very soon after enabled the medical attendant to discover the very serious error into which he must have fallen had he persisted in his intention of trephining: the real seat of injury was through the base of the skull, with fatal effusion of blood, altogether beyond the reach of the operator.

Before adverting to other varieties in form met with on the surface of the cranium, I may briefly notice the German transcendental theory, which endeavours to explain these varieties, to reduce them to a law, the law of "deformation," and to bring them within the range of the philosophy of animal beings. The theory, which must be well known to most of my hearers, is, that these "deformations" simply reproduce a structural form, which, however rare in man, and therefore in him "abnormal," will yet be found to be the regular law in many animals placed lower than man in the scale, and therefore are in them quite regular, or "normal." But why should they appear in man at all? This difficulty the German theorist meets by reminding you of another law, viz. unity of organization: that in the embryo there is unity of organization: that the embryo of most animals runs through certain phases or "developments:" that the earliest of these developments resemble, therefore, certain animals, and the latest, others: that should the change, from any cause whatever, known or unknown, not take place, there is then an imperfect development, "*arrêt de développement*," and that this may take place at any stage, giving even to the human form the peculiar arrangement of parts belonging to a lower class of animals, or retaining in the adult the

embryonic form of its own organs. To apply these laws to the peculiarities in question, we have only to say with the German, that the human cranium, which, when fully developed, ought to present a uniform and comparatively smooth surface, and a series of immoveable sutures, has, in the foetus, a totally different character; in it, the sutures are moveable, and slide freely over each other, in short, may be made to overlap each other; that when dried, prepared, and deposited in our museums, the foetal head actually presents these appearances; that should the adult head present a similar form in some, it is merely an "*arrêt de développement*;" and finally, this very irregularity, by the great law of unity of organization, is the usual normal form in many species of the lower animals; in them the "arrest of development" is the law; in man it is the exception.

I shall afterwards endeavour to show that these are the only views which, in the present state of science, can be adopted, and that what has been written against them in France, and more especially in England, is simply, and, to use the mildest phrase, ingenious nonsense; sometimes very pompous and imposing, as in the Bridgewater Treatises, but still downright nonsense, and not meriting the smallest attention from any philosophic mind. The German theory, or rather the theory of Goethe, (for it is his) requires very considerable modification before it can be applied extensively to the history of organization. Let us proceed, in the meantime, with details.

On examining the museum to find the crania of those animals which ought, according to the theory, to present the peculiar form or forms above described as "anormal" in man, but "normal" in them, it is not so easy to find them. That such exist I have no doubt, but the examination of some hundred specimens of the crania of different mammaliæ has not furnished me with any clear illustrations of the law. By descending lower, however, in the scale, we must meet with them; the cranial bones of the Cetacea overlap each other at many points; and so more especially do those of fishes. The law of unity admits, nay requires, that we should include the entire scale in the inquiry after truth.

If we do not work with great num-

bers, and on an extended scale, the theory cannot be supported on all occasions: it is a psychological and metaphysical theory, as well as a physical, and they who do not admit this, either do not understand it, or are unwilling to be informed as to its truth.

Of other appearances met with occasionally on the outer surface of the cranium I shall mention but a few. There are first those ridges, single or double, running in the line of, or parallel to and at a little distance from, the parietal suture, remarkably developed in a skull-cap now before me. These elevated parietal lines or *cristæ*, are simply the superior parietal crests generally not perceivable in the human cranium; at other times, as in this instance, quite distinct. They are of course quite common in many of the mammalia, but are only seen in some men. They may occupy the proper parietal suture, as in some animals, or be a little apart: they must not be confounded with the inferior parietal crest running continuously with the external frontal crest (also distinct enough in some men), and which, from the narrowness of the parietal bones in some mammals, approach close to the vertex, enlarging thus greatly the temporal fossæ: the crests I here allude to are different from these temporal crests, but may coincide in some animals: in man they do not, and this is owing in him to the great breadth of the parietal bones. But the crania of mammals present every variety in respect to the extent, direction, elevation, and number of these occipital, parietal, and frontal crests, whose outlines may all be seen on man, fortunately but little developed in him, the "arrest" being in him happily the law; the full development, on the contrary, being the law in the highest of the quadrumana.

It has always appeared to me, that these crests, although they be but imperfectly developed in man, ought to be named in accordance with their real nature and meaning; they have little or nothing to do with the history of the cranial sutures, whose course, indeed, they do not generally follow: the temporal crests of the frontal and parietal bones are continuous, running directly across the suture, which they do not regard; the occipital crest is on the occipital bone, and not in the lamb-

doidal suture, and the superior parietal crests when found in man do not seem to me to run in the parietal suture, but parallel to it; in many animals, however, there is a parietal crest continuous with the anterior branch of the occipital crest, directly in the line of the suture. The reason why such crests should be found on the surface of the cranium in different animals it seems to me impossible to say; even in my youngest days I had always philosophy enough in me to laugh at the Bridgewater nonsense (a theory all but exhausted by Philo, Derham, and Paley), which would assign to them the mechanical reason for "extending the attachments of certain muscles."

There is a slight remark more I beg leave to make in respect to these crests; they are not more fully developed in the darker race of men, than in the Saxon, Celt, or Pelasgian races: at least it appears so to me from all the specimens I have examined: if we are then to denominate them an "arrest of development" (although this is clearly a misnomer in one sense), it ought to be kept in view that the occurrence is in no shape peculiar to the dark races of men.

Occasionally on the surface of the cranium we meet with an absolute depression, sudden, and as if scooped out at the expense of the outer table and diploe alone; nothing can be more likely to mislead the surgeon. I find them in crania which appear to me otherwise quite healthy, but still they may have been occasioned by a blow inflicted when young: even by the forceps of the accoucheur. If my recollection be correct, I think I remember a cranium which was presented by Sir G. Ballingall to the College of Surgeons, whose surface was completely notched and indented with blows; it belonged to a native of Australia. On the other hand, these depressions occasionally correspond with exostoses found projecting from the inner table, which possibly during life may have given rise to much distress.

There is a skull-cap now before me, and I can produce several others, in which such remarkable appearances are not limited to the exterior table; in this cranium the anterior half nearly of the inner table is rough, with sharp elevations; the bones are thickened generally, and at two points absorption had commenced in the inner

table, and all but perforated the bone, and still there is nothing visible on the outer table as regards this remarkable change in the interior of the frontal bone. What may be observed on the outer table is a prominence of the parietal sutures, and an elevation of the outer wall of the left frontal sinus: the prominence of the bone at this point during life would have strongly resembled an exostosis; and yet it is not so, but merely a general thickening of the outer table and diploe, extending from over the sinus to beyond the external angular process of the bone.

The last variety I shall allude to is that peculiar deformity, for it must be so called, which consists in a want of symmetry in its various parts.

About a year ago, a naval surgeon, who had formerly studied anatomy with me, had the obliging kindness to present me with a remarkable cranium; being no less than the cranium of one of the party who attacked and slew our immortal circumnavigator, Cook. This cranium, which I now place before my audience,* unquestionably belonged to a native of the Sandwich Isles; its resemblance to those crania met with in museums as Peruvian and Brazilian, is remarkable, more especially in respect to its want of symmetry, thus shewing an affiliation between the aborigines of the mainland of America and those of certain islands, but not of others, as of Van Diemen's Land for example, or Australia: the crania of the natives of these islands appeared to me different from that I now speak of. I shall consider the want of symmetry more in detail in a special lecture.

[To be continued.]

ON MOLECULES AND MOLECULAR MOTION.

To the Editor of the Medical Gazette.

SIR,

IF the following observations are sufficiently interesting to occupy a place in your valuable journal, you will oblige me by inserting them.—I am, sir,

Your obedient servant,

J. W. GRIFFITH, M.D. F.L.S. &c.

9, St. John's Square.

June 13, 1843.

* These contributions were mostly submitted to my anatomical class at various meetings.

I have been induced to offer a few observations on the nature and peculiarities of the minute particles into which ponderable bodies are often subdivided, and a form of spontaneous or innate motion which accompanies them under certain circumstances, in consequence of having perceived, in one of our latest treatises, and which is likely to be a most valuable one, on anatomy and physiology, the statement that the movements of molecules are "attributed to currents produced in the fluid by evaporation at its surface or edges, for they may be arrested by covering the fluid with oil."

I have, as must every one who has paid much attention to microscopic observations, long been acquainted with the peculiar movements of these minute atoms, and have often sought for the excitor of their motion, but in vain. Nor is the explanation of it, by evaporation, at all capable of solving the difficulty, as will be perceived when this paper has been perused.

The views of some of the older authors respecting the existence of certain definite molecules or particles, arising from the separation and decomposition of organic bodies, and their transmutations into animal and vegetable bodies, when placed under appropriate circumstances, are so curious, and so rarely noticed in the works of our own country, that they cannot fail to be interesting to the reader.

Buffon says, "Il me paroît donc très vraisemblable qu'il existe réellement dans la nature une infinité de petits êtres organisés, semblables en tout aux grands êtres organisés qui figurent dans le monde, que ces petits êtres organisés sont composés de parties organiques vivantes qui sont communes aux animaux et aux végétaux, que ces parties organiques sont des parties primitives et incorruptibles, que l'assemblage de ces parties forme à nos yeux des êtres organisés, et que par conséquent la reproduction ou la génération n'est qu'un changement de forme qui se fait et s'opère par la seule addition de ces parties semblables, comme la destruction de l'être organisé se fait par la division de ces mêmes parties. Destruire un être organisé n'est que séparer les parties organiques dont il est composé; ces mêmes parties restent séparées jusqu'à ce qu'elles

soient réunies par quelque puissance active."

M. Buffon then goes on to say, that when this nutritious and reproductive matter, in passing through an animal or vegetable, finds a suitable matrix, it produces an animal or vegetable of the same kind, but when otherwise, it produces organised beings differing from plants and animals, as the bodies which move and grow, and as we see in the seminal fluid, in the infusions of the germs of plants, &c. These molecules were also noticed by our countryman Needham, on their exit from the pollen, when moistened.

Wrisberg, when examining some infusion of garden peas, observed in it some white flocculent matter; this, when dried, appeared reduced to minute granules: "repræsentat quasi convolutum illarum exilium molecularum, rudimenta procal dubio futurorum animalculorum." Wrisberg was fully aware of the inorganic nature of the molecules, and of their non-identity with the infusoria: thus, when examining infusion of parsley, he says, "myriades parvarum molecularum inorganicarum vidi-mus; omnes hæ molecule eandem habent magnitudinem, quibusdam paucis exceptis, quæ minores sunt. Quædam harum molecularum jam motu voluntario agitabantur, admodum tardò autem, quasi viribus suis nondum confiderent libero sese exponendi oceano." After saying that we are too apt to attribute life to particles which move, he says. Multa sane dantur in natura motus, ubi ne minimum quidem animalium vestigium est; fere in uniuscujusque aquæ purissimæ guttulæ superficie, magisque autem ubi saponis quicquam admixtum est, particularum exilissimarum observamus motum, quamvis rationem illius vix reddere possimus."

O. F. Müller also imagined that the ultimate granules of organic matter became immediately reorganised and restored to life.

"Partes nempe animales et vegetabiles per decompositionem resolvuntur in pelliculas vesiculares, quarum vesiculæ seu globuli, sensim a massa communi laxati reviviscunt et animalcula spermatica et infusoria agunt."

Gleichen long since pointed out what he imagined to be the transformation of vegetable into animal matter: in

speaking of the pollen of plants, he says, "Quand on la laisse quelque tems dans l'eau, elle se métamorphose elle même en animalcules d'infusion." "et dans quelques jours toute ma poussière* étoit devenu vivante."

Dr. Milne Edwards, after examining many of the tissues of animal bodies,† says, "Je n'étois pas éloigné de croire que les molécules animales, solides et organisés, affectent toujours une forme primitive, constante et déterminée, celle de globules du diamètre d'environ $\frac{1}{1000}$ de millimètre‡."

The observations on the molecules of bodies, made by Dr. Brown, are the only definite and distinct ones I have met with. This most able observer first detected the motion of the particles within the pollen grains of *Clarkia pulchella*, then in that of some other *Onagraceæ* and *Lolium*; afterwards in all organic bodies; animal and vegetable tissues, whether living or dead; gum resins; pit coal; fossil wood; powdered glass; earths and metals; rocks, &c. In a word, in every mineral which could be reduced to a powder sufficiently fine to be temporarily suspended in water. Dr. Brown could not obtain them from resin, wax, sulphur, and such of the metals as could not be reduced to the minute state of division necessary for their separation; and soluble bodies. He further states the molecules to be spherical, and the elongated ones sometimes found to be aggregations of the simple ones; that they are of a uniform size, varying from $\frac{1}{1000}$ to $\frac{1}{2000}$ of an inch. Now it might perhaps be considered presumption on my part to call in question the accuracy of the observations of so distinguished a naturalist as Dr. Brown, but as the motion of these minute particles or molecules has been stated as depending upon the evaporation of the liquid in which they are immersed, notwithstanding Dr. Brown's assertion that "these motions were such as to satisfy me, after frequently repeated observation, that they arose neither from currents in the fluid, nor from its gradual evaporation," still, as evaporation is mentioned as having taken place in his experiments (thus he says, "on con-

tinuing to observe them until the water had entirely evaporated;") I have very carefully repeated them, avoiding what I considered sources of fallacy.

In all cases where I examined the molecules, the glass slider (made of plate glass), was fixed horizontally, so as to avoid the influence of gravitation in causing currents. The fluid containing the molecules was covered by a layer of exceedingly thin glass, which of course prevents any evaporation taking place from the surface of the liquid it covers; the evaporation at the edges being prevented by a rim of olive, or almond oil, or lamp-black mixed with gold size (the ordinary mode of preserving microscopic objects). I have examined a large number of inorganic substances powdered in a mortar to the finest powder, and have found no difficulty in detecting the peculiar motion in any substance save semi-fluid bodies, or solids which cannot (whether from their tenacity or extreme hardness) be reduced to a sufficiently fine powder. Some bodies, as sulphur, cannot be reduced to a very fine powder, but loose floating particles can be here and there seen in the field of the microscope, which exhibit the motion most distinctly. Some precipitates which are extremely dense show this property with great difficulty, as the chloride of silver, &c. The motion is quite destroyed by immersion in oil, thick gum, or syrup; here the viscosity of the liquids seems to prevent its taking place. It has appeared to me to ensue most readily in water, less so in spirit, and least of all in ether. The extremely low sp. gr. of the substance seems in some cases to prevent the development of this force, and also its great tendency in some cases to agglutination into masses, as in powdered sulphur, resin, precipitated prussian blue, &c.

Gamboge exhibits it very perfectly, as do many gum-resins, in which it is most easily observed, on account of the resinous particles being insoluble in water, which retains them in suspension. Moreover, when any liquid (as placed between two glasses) in which this motion is perceived, is surrounded at the edges with oil, varnish, gold-size, lamp-black, or any other agent which entirely prevents evaporation, this peculiar motion continues perfectly un-

* Poussière fructifiante, pollen.

† That the texture of most organic tissues of vertebrated animals is globular, and that there is great uniformity in the "organic elements" as they may be called.

affected, and in fact a specimen put up in this manner may be permanently preserved so as to show it at any time. Again, this movement is totally different from that of particles which are moved by currents excited by evaporation. These latter hurl a number of molecules in vortices with great rapidity (varying according to the evaporation); these sometimes meet, when the direction of the different particles may be distinctly perceived; and in these cases a number of molecules assume a similar and parallel direction, which is totally distinct from that of the true molecular movement, wherein the molecules oscillate or vibrate, moving but very slowly from place to place, sometimes remaining in the same spot for hours, and having an apparent repulsion for all other particles; but I am satisfied that the surrounding particles have nothing to do with the cause of this movement, because in some cases we can clearly perceive a single molecule, quite distinct from others, and enjoying its own spherical movements. But the most important circumstance connected with the vibration of these atoms is their size; and I am convinced that the smaller they are the more vivid is the motion; moreover, I am certain that they possess no definite size or shape. All bodies less than a certain size have a tendency to appear circular or spherical, when examined under a microscope; and we can often see some molecules more than ten times the size of others, still exhibiting this movement. It may be objected that these larger particles are aggregations of the smaller molecules, but we have not the slightest ground for so believing; the molecules observed by Dr. Brown varied in size from $\frac{1}{10000}$ to $\frac{1}{50000}$ of an inch; whilst those measured by Mr. Dalrymple in the transparent cell at the extremity of the Closteria varied from the $\frac{1}{50000}$ to the $\frac{1}{100000}$ of an inch.

The true molecular motion belongs, as pointed out by Dr. Brown, to the particle itself; and the circumstances necessary for its exhibition, are, 1st, an extremely minute state of subdivision of the matter; 2d, such a relation between the sp. gr. of the molecule and its medium as shall allow it to be freely suspended; 3d, absence of all impeding viscosity or tenacity of the liquid. Under these circumstances any forms of

ponderable matter will freely exhibit this motion, whether organic or inorganic; and it takes place in all situations, perfectly uninfluenced by evaporation, and distinguished readily from the motion of particles produced by evaporation by its tremulous, vibratory, and not distinctly progressive motion, whereas in the latter the motion of neighbouring particles is similar, determinate, and often parallel. The cause of this motion is unknown. The influence of electricity might be suspected of being its excitor. With a view of testing this, I made some experiments; although the extreme minuteness of these atoms is such, that I could not depend upon my results as positive. Thus, I procured a very clean piece of steel, and mixed a little gamboge with water on its surface, covered it with very thin glass, then viewed the molecules as opaque objects; they were seen distinctly in motion: on connecting the extremity of this steel plate with the nob of a charged electrical jar, no alteration was produced, the motion continued; again, water with the molecules in suspension was placed on a layer of plate glass, next covered with a slip of thin glass; between the two glasses touching the liquid was laid a slip of tin-foil; at the end of the foil the molecules were in vivid motion: on connecting its other extremity with the interior of a charged jar no alteration in the motion took place. These experiments were repeated, insulating at the same time the microscope, but with the same effect. I know of no cause which can in any way explain this phenomenon. It takes place when examined between two large pieces of glass equally at the circumference as at the centre, which would not be the case were evaporation the cause.

The ingenious views of the older authors, quoted at the commencement of this paper, considering the particles or molecules of organic bodies separated by decomposition to be revived and produce either animals or vegetables, &c. according to circumstances, are of course erroneous; but they long remained a source of fallacy that few, unguided by analogy, would be able to avoid. The experiments of Professor Schultze seem to have settled the point as regards infusoria. The views of Dr. Milne Edwards, regarding a certain globule as the basis of animal bodies,

have not been since borne out, although the formation from primary cells is well established.

The utility of the molecular movement is not particularly evident. The particles or molecules themselves in their solid state form the food of the minutest forms of living matter; when in solution, or in the gaseous state from decomposition, they nourish the vegetable kingdom. Their freedom of motion, isolating them from surrounding particles, keeps them surrounded by liquid, and to a certain extent would facilitate their solution.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

A Treatise on Food and Diet; with Observations on the Dietetical Regimen suited for Disordered States of the Digestive Organs, &c. &c. By JONATHAN PEREIRA, M.D. F.R.S. and L.S. &c. &c. Longman and Co. 1843.

THE plan of this work is considerably different from that of any other on the same subject which has fallen under our notice. A much fuller account is given of the chemical elements of food than we have met with elsewhere; and the number of alimentary principles admitted is greater than had been adopted by Prout, or other distinguished writers who have preceded him. (Common salt, for example, and lemon-juice, are enumerated among the articles of food.) We have also some very valuable tables indicating the proportions of the most important chemical elements and alimentary principles in various kinds of nutriment. A very considerable space is likewise given to dietaries, as adapted to different diseases and conditions — as, those fit for children, for paupers, for prisoners, for the sick, for the insane, &c. &c.

The work altogether bears the stamp of originality, and will, we are convinced, be found most useful. We shall take occasion, in future numbers, to give a few extracts as specimens: meantime we must content ourselves with this general recommendation.

Medical History of the Expedition to the Niger during the Years 1841-2; comprising an Account of the Fever which led to its abrupt termination. By J. O. M'WILLIAM, M.D., Surgeon of H.M.S. Albert, and Senior Medical Officer of the Expedition. With Plates. London, 1843. 8vo. pp. 287.

THIS work is divided into three chapters. The first gives the history of the expedition, and the second the history of the fever. The third contains four sections, which treat of the state of medicine in the Niger; ventilation; meteorology; and the geology of the Niger. It appears that of 145 whites belonging to this expedition, 130 were attacked by the fever, and 40 died; of 25 men of colour entered in England (with one exception), 11 were attacked, but none died; and of the blacks entered on the coast of Africa, not one was attacked. Hence, if the attempt is repeated, and the Niger is again ascended, with the noble object of extinguishing the slave trade, by civilizing the nations which carry it on, the number of whites must be as small as possible.

Dr. M'William's book shews good sense and judgment, and will be consulted by the physician desirous to study the nature of remittent fever in its severest form; and by the philanthropist, who, lamenting the failure of so benevolent an expedition, is eager to see it renewed under better auspices.

MEDICAL GAZETTE.

Friday, June 30, 1843.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

EMPLOYMENT OF WOMEN AND CHILDREN IN AGRICULTURE.

THE story of the two knights who quarrelled about the metal of the shield before which they severally stood, is but a type of the difficulties which embarrass human evidence. The shield was gold on one side, and silver on the other, so that each doughty horseman saw a different sight, and did but contend for

the evidence of his own senses. Just so it is with the ordinary controversies of life; the most faithful witnesses can but tell what they have seen, and perfectly different spectacles have been represented on their retinæ. Besides which, the eye is under the guidance of the mind, and if the same general scenes are spread before it, different points are selected by different observers; a Rembrandt and a Rubens do not see with the same eyes, any more than they paint with the same brush.

The celebrated picture of the happiness of a country life, in the Georgics, and the painful descriptions of agricultural destitution in more prosaic writers, are quite reconcileable, when we consider that the Latin poet drew the small farmer, and the prose historians his half-starved drudge.

The pauper's funeral, given with hard fidelity by Crabbe, depresses the reader's mind. Not so the picture where Poussin has represented a dance of nymphs and their swains, near a monument bearing the inscription *ego quoque lusi in Arcadiâ*.

However similar objects may be, nay if they are absolutely identical, they become different when viewed through the tinged lens of different spectators. To some melancholy Jaques the county of Hampshire may seem a huge mass of discontented husbandmen, who feed the bacon which they must not eat; to Miss Mitford it is an Arcadia of happy faces, where the very Doricisms are delightful.

The rustic gallantry, too, which has ever been the accompaniment of hay-making, is viewed in a different light by the withered critic, and the genial poet of the Seasons. But however opinion may differ on these points, there is one on which it is unanimous. Husbandmen, the most useful members of society, are everywhere, as far as

regards the reward of their labours, at the bottom of the social scale. In some countries they are still serfs, in others but lately emancipated from serfdom; but throughout Europe their state is so little raised above that of villenage, that nothing but the main force of the law, nothing but wisdom guided by benevolence (the two are, perhaps, one), can save them from sinking into this slough of despond.

In England the system of prædial bondage died out in the reign of Elizabeth; in some of the mines of Scotland, it existed, as we learn from Walter Scott, as late as the middle of the last century. In Franche-Comté, according to Voltaire, it not only existed, but, by an incredible refinement of absurdity, the cultivation of certain farms imposed the state of villains on those who were previously free; so that while the touch of our British soil gave freedom to the slave, the cultivation of this wretched country deprived the husbandman of the birthright of the human race.

In Prussia, the emancipation of the bondmen did not take place till 1807. Even before the battle of Jena thinking men had seen that villenage was one of the great causes of the weakness of the Prussian monarchy. It had been denounced by Frederic the Great as a "*gestion abominable*;" but it was not until the kingdom had fallen at the shock of a single battle, that Stein, the statesman who then conducted the destinies of Prussia, determined to heal this devouring ulcer.

Yet in all these countries, even in England itself, the rustic population is prevented from sinking back into serfdom, rather by the benevolent interference of the educated classes, than by any dogged spirit of resistance in the husbandmen themselves. Were the matter left entirely to ploughmen and petty farmers to settle between them,

without the interference of the law, or the criticism of public opinion, our half-fed cottagers might too often sell their birthright for a mess of pottage. As it is, the condition of our farm apprentices approaches far nearer to that of slaves or serfs than it is pleasant to acknowledge.

By the French Code, indeed, no contract is valid by which a man barter away his liberty; and it is to be hoped that should a fit occasion arise, our common law would be interpreted in a similar spirit.

These preliminary reflections have been called forth by the late reports of the special Assistant Poor Law Commissioners, on the employment of women and children in agriculture, now lying before us.

These Commissioners were four in number, all barristers; and they were directed to inquire into the sorts of labour at which women and children are employed in agriculture; the wages which they receive; the hours of work; the age at which they begin to work; and the effects which their occupation produces upon their health, as well as upon their opportunities for obtaining school instruction and religious education; and they were also desired to investigate the condition of the children of agricultural labourers apprenticed by parish officers.

The four Assistant-Commissioners examined into the state of twelve counties; and as their time was limited to thirty days, it is obvious that much of their information must have been picked up at a canter. Yet, in spite of this disadvantage, their reports read like the compilation of sensible men, not very deeply tinctured with Malthusian fantasies; and some part of it will be a novelty, not only to the natives of the *pays de cocagne*, but even to the home-bred rustics of the very counties themselves. Mr. Alfred Aus-

tin, whose report stands first in the book, took the counties of Wilts, Dorset, Devon, and Somerset; and in order not to fritter away his time in forced marches over so large a space, he confined himself to two districts in Devonshire, and one in each of the remaining counties. The wages of women who work in the fields vary, in general, from 7d. to 1s. a day in these counties; though rates above and below these are mentioned. For this slender stipend they work from 8 A.M. to 4 P.M. in winter; at other times, from 8 to 6, and in the hay harvest from 6 to 6.

The effect of out-door farm labour on adult women appears to be favourable to health. Mr. Austin did not meet with an instance of a woman complaining of its being injurious.

"Sometimes such work, particularly in the hay and corn harvests, was represented by women who performed it as being laborious, as making them stiff at first, or even as straining them; but I did not find that any woman, from her own statement, had become subject to any permanent disease or infirmity from the employment in question."

There is a good deal of evidence, however, scattered up and down these reports, to show that field-work demoralises women, or at any rate, girls. Woman is a domestic creature, and a mother does more service to society by tending her children, and going through the details of her little household, than by mowing grass, or hoeing turnips. On the Continent, where the employment of women in field-labour is even more common than in England, it has always seemed to us that it rapidly destroys the graces of youth, and gives the look of a hard-a-weather sailor to a middle-aged woman. But it is more easy to see the evil than to provide a remedy.

The next question is, how are these

labouring women placed with regard to food, clothing, and lodging?

The majority of them are married, and the greater number of the single ones live with their parents. (Mr. Austin says they are "sometimes grown-up daughters living with their parents.") Hence their earnings are merely part of the aggregate income of the family; and to know their condition we must learn that of their husbands and fathers.

Now, the wages of the labourer in the district of Wiltshire visited by Mr. Austin (in the neighbourhood of Calne) are from 8 to 10 shillings a week; in the Dorsetshire district they are higher; in the Devonshire one about the same as in Dorsetshire. In the part of Somersetshire visited, they are even lower than in Wiltshire; but here the labourer has an allowance of three pints of cider daily, which are considered both by master and man to be worth a shilling or fifteen-pence per week. Sometimes, of course, the income is beyond this, as when the wife and children add to the common fund, but, on the whole, the receipts of a labourer are exceedingly small, and his diet low in proportion. Thus, in Wiltshire, the food of the labourer and his family is bread and potatoes, with the occasional luxury of beer, a little butter, and tea. To these are sometimes added cheese and bacon, and near Calne, the entrails, or "in'ards," of the pig. "In more than one cottage," says Mr. Austin, "where the mother went out to work, or two of the boys were earning perhaps 3s. or 3s. 6d. a week between them, I saw a side of bacon hanging against the wall; but nothing of the kind was visible when the only earnings were those of the husband, or the family was numerous and young. Where, from poverty, bacon cannot be obtained, a little fat is used to give a flavour to the potatoes."

In Dorset and Devon matters are a trifle better; but Somerset is on a level with Wilts.

As to lodging, Mr. Austin's account is painful indeed, both physically and morally. Let us hope that, to use the phrasology of the day, he has drawn his induction from too small a number of instances. He says, that the want of sufficient accommodation seems universal. Cottages, generally speaking, have only one, or at most two, bedrooms, so that adults of both sexes constantly sleep in the same room, and not unfrequently three or four persons in the same bed.

At Stourpain, a village near Blandford, he found in a cottage a bedroom, ten feet square, containing three beds and eleven occupants of them! The father, mother, two infants, two twin daughters aged 20, and a son aged 17, were among the tenants of this crowded room. In Stourpain, there is a row of labourers' cottages so miserably constructed that they are surrounded by streams of filth from pig-sties, and privies placed a few yards above them. "It was in these cottages that a malignant typhus broke out two years ago, which afterwards spread through the village."

Nor are the moral consequences less grievous than the physical.

If we may believe Mr. Austin, the licentiousness produced by this deficient accommodation has not always respected the family relationship!

In this, as in other matters, much depends on the landlord. Thus in Studley the rent of cottages is from £3 to £4 a year, and families are crowded together in the most indecent manner. In Foxton, which adjoins it, the cottages all belong to the Marquis of Lansdowne, who lets them at half that rent, but will not allow more than one family to occupy one tenement at the same time. Each cottage has at least three

rooms. In consequence of this difference in the arrangements, says Lord Lansdowne's agent, the labourers at Foxton are a superior kind of people to those at Studley.

We will continue this subject on an early occasion.

DR. STÖBER ON THE DISEASES OF CHILDREN.

THE author, who is physician to the *clinique* for children's diseases at Strasburgh, has published a work entitled, "*La clinique des maladies des enfans de la faculté de Strasbourg, pendant les trois années scolaires, 1837-1840, &c.*"

What follows is taken from a review of the work in the *Zeitschrift für die gesamte Medicin* for March 1843.

The *clinique* consists of a large ward, made into two by a wooden partition; the larger division containing fourteen beds for girls and infants, the smaller one six beds for boys. Children are admitted from the age of one year to fifteen; but those who are to undergo important operations, or who are suffering from fractures, tch, or scalled head, are admitted into other wards, which, however, are to be united to the *clinique*.

The mortality during the three years has been 1 in 7.

Typhus fever.—The author agrees with Taupin, Rilliet, Rodet, and Ruz, that this disease frequently occurs among children, but with slight modifications. He had twenty-six cases, in half of which the patients were above ten years of age. It is remarkable, that at an age where the nervous system is so excitable, and not only important diseases, but occasionally even slight indispositions are accompanied by convulsive motions, nervous phenomena are less violent in typhus than among adults. All the patients suffered from debility, with sleepiness and more or less stupor; and in more than half, delirium was present, but slighter than in adults. Ten patients suffered from deafness; with the exception of four, all had diarrhoea; some, however, only at first, which was then followed by costiveness. Three had red lenticular spots, and ten had petechiæ.

Only three had epistaxis. Only one child died out of the twenty-six; and, in general, severe cases of this disease are rarer than among adults. All the patients had a cough.

Scarlatina.—From the autumn of 1838 to the spring of 1840, this disease prevailed at Strasburgh in a rather malignant form;

many children died, in particular, of its sequelæ, namely, dropsy, and inflammation of the parotid glands. Of five children but one died in the hospital, while only one was saved out of eight suffering from the sequelæ. The disease appeared under different forms; one is described by the author under the name of *Scarlatina rubeolosa* (the *Röteln* of the Germans) but considered by him as a mere variety of scarlet-fever. The dispute concerning the identity of the two diseases is by no means cleared up by his cases. In one instance of typhoid scarlatina, he exhibited carbonate of ammonia, and with success. The author does not hold that the subsequent dropsy always proceeds from taking cold; an observation in which he had been preceded by German physicians. Of eight patients two had anasarca alone, four ascites at the same time, and two hydrothorax. The rapidity with which water is sometimes effused in the internal cavities is shown by the following case. A boy, aged ten, entered the institution suffering under a slight degree of anasarca, with an accelerated pulse. On the following day he walked barefoot across a passage, then returned to bed, complained of a feeling of oppression, and a few minutes afterwards had symptoms of suffocation and orthopnoea; his countenance turned blue and swelled, and in half an hour he was a corpse. On examination, a considerable quantity of water was found in the pleura and pericardium.

Stomatitis ulcerosa.—Under this name Dr. Stöber describes an ulceration of the inner surfaces of the cheeks and the edge of the tongue, which is deep and uneven, and has edges which bleed easily, and a dirty greyish-yellow bottom. It attacks only one side of the mouth, is oblong, and exactly corresponds with the dental arch, so that when the mouth is shut the ulcerated parts touch the teeth. The teeth are covered with tartar; the breath is fetid, and the glands on the affected side of the neck are swollen. The author believes incrustation or caries of the teeth to be the cause of the disease.

Acute Laryngitis.—The author treats it like croup, in which he justly extols the sulphate of copper given at the very beginning of the disease.

Pneumonia.—This disease in children is often secondary, and complicated with other maladies. Contrary to the assertion of many physicians, the author has found but one instance of lobular pneumonia among 17 cases. In all the other cases it was lobar. In six instances it was seated in both lungs, though less marked on one side than the other. The chief thing which distinguishes the pneumonia of children from that of adults, anatomically, is the variety of hepatization compared with carnification. The author has seen grey hepatization but once, and the

red four times. In twelve patients the diseased lung was of the colour of lees of wine, indurated, and impermeable to air; it did not easily tear under the fingers, and was without granulations, as in cases of hepatization; the upper surface when cut into was smooth, and looked like a piece of muscle without fibres. This complication was observed in children who died on the 10th day of the disease, or in a month. The disease is less easy to recognise in children than in adults, as they are unable to point out the pain, and there is no expectoration. [In many cases, however, says the German translator, the expression of pain may be recognised, particularly when the patient coughs.] The cough is sometimes violent, the respiration and circulation are always quickened, and the temperature increased. From the screaming and disquietude of children, the crepitous rattle can be heard. More frequently there is a slight or sub-crepitous mucous rattle; and this sound, too, is not present long, for in the majority of cases bronchophony and bronchial respiration alone are to be heard. It is probable that the pneumonia of children soon passes into the second stage, or rather it often remains latent during the first stage. The seat of the disease is generally discovered on percussion, and it is only in lobular or central pneumonia that it cannot be distinguished in this manner. The great sonorousness of the chest in children sometimes causes the dull sound to be less marked in them than in adults. But if we compare the sound on both sides of the chest, and at the same time attend to the sensation experienced by the percussing finger, the impenetrability of the lung will be recognised. The younger children are the more they appear to be exposed to pneumonia; and it is also more violent in early infancy than after the seventh year. Cases are most numerous in the first four months of the year. Pneumonia is almost always fatal, when combined with a chronic disease, which has already weakened the constitution.

As to the treatment, there is a great difference between children and old persons. From the latter it is well known that much blood should rarely be taken, and the best remedy is tartar emetic; while in the pneumonia of children without complication, the abstraction of blood is generally very useful. The author bled children from 5 to 6 years old, and found venesection better than local bleeding. Besides this, he gave tartar emetic, or white oxide of antimony, of which he prefers the former. He combines it with *tisane* or gum mucilage, to avoid ulcers in the mouth and pharynx.

[To be continued.]

PROFESSOR ROSAS' OPERATIONS ON THE EYE.

Rosas is a dexterous and steady operator. In his extraction the patient is seated on a low stool, with the head placed obliquely to the light, and resting against the breast of an assistant who raises the upper lid, while the operator depresses the lower with the middle and forefingers in the usual manner. He makes the downward section with a knife somewhat different from that of Beer, as originally used by him, and figured in his work in 1830. This knife is much shorter in the blade than Beer's; its posterior edge (or back) is also sharp and slightly convex. Holding it between the thumb and the index and middle fingers, the ring-finger bent unto the hollow of the hand, and the little one resting on the cheek-bone, he introduces the point at a right angle with the cornea, (to prevent its catching in its layers,) a little above the transverse axis of the eye, and having entered the anterior chamber, he alters the position of the instrument by depressing its handle towards the temporal fossa, and thus brings the surface of the blade on the same plane with that of the iris. Having passed it rapidly through the chamber and made the counter-punctuation, so that a full quarter of an inch of the point has passed through the inner margin of the cornea, he then *draws* it slowly downwards, and slightly outwards, and so completes the section. If the case is one of double cataract he makes the corneal section, and concludes the operation in the second eye before he extracts the lens of the first. He opens the capsule with a Langenbeck's needle, sharpened on its concave edge, and extracts the lens by gently pressing on the upper portion of the cornea with the flat of the needle.

The object aimed at in having the back of the knife curved is, to give it shortness as well as breadth, and thus avoid pricking the side of the nose; and its posterior sharp edge is to permit of its cutting upwards as well as downwards, and thus not only pass through the cornea with greater facility, but also enable the operator to extend the incision upwards if the original punctuation is too low. Another reason assigned by the inventor of this knife is, that its blade by being sharp at both sides, and forming in its section a compressed ellipse, permits less escape of the aqueous fluid in passing through the chamber, than the ordinary instrument.

In this manner Rosas operates with the most marked success; but in other hands, especially beginners, his method and instruments are open to many objections. The

insertion of the knife at right angles with the cornea is very liable to transfix the iris, and by twisting the cornea itself, renders its further insertion less smooth and easy; and its cutting back endangers both sclerotic and iris, especially in turning its lower edge outward when completing the incision; — and when the iris happens to roll over the back of the knife, it cannot be pressed off with the same facility as when the posterior part is blunt; — should the point of the knife get entangled with the iris, he withdraws it and re-introduces it in another place; if the corneal opening is too small he enlarges it with a Daviel's scissors.

The operations of depression and reclin-
ation are much more common in the Viennese school than in England. In this clinique, these, as well as the operation for solution, are performed *per scleroticam*. In artificial pupil Rosas generally adopts the methods of Beer and Langenbeck, but removes the portion of iris drawn through the wound.—*Wilde's Austria*.

OCULISTS IN AUSTRIA.

EVERY student intending to become a doctor of medicine or surgery must attend the ophthalmic clinique during the first six months of his fifth year; and at his final examination (*Zweyte Prüfung*,) his knowledge of ophthalmic surgery is strictly inquired into. Every *Civil-und-Landwundarzt* studies in this school during the second six months of his third year, and upon taking his degree he is examined upon ophthalmology by the professor of that branch.

In order, however, to perform operations on the eye, and practise this branch of medicine as a speciality, it is necessary that an additional year (after the degree has been obtained from the university) be spent in attendance upon the eye-clinique, at the end of which period some public operations, performed in the presence of the professor, are required as a test of the person's right to practise. This latter course is frequently attended by medical men who have been already in practice, and also by foreigners. A special degree is granted for it.

The practitioners thus educated, and styled town and country oculists, *Land-und-Stadt-Augenärzte* are distributed throughout the whole of this great empire; no town of any consequence is without one; they are paid by the state, and obliged to administer medicine and advice to the poor in all cases of eye-disease, and also to furnish the board of medical direction with a monthly *Protokol*, or sanatory report of the progress of such affections among the people of their district.—*Ibid*.

LECTURES

ON THE

THEORY AND PRACTICE OF MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXXIII.

On Labours complicated with Uterine Hæmorrhage from Placental Presenta- tion.

THE placenta may adhere to any part of the inner surface of the uterus—to the fundus, body, or cervix, and hæmorrhage never takes place to a dangerous extent during pregnancy or labour, unless the connection of the placenta with the uterus has been destroyed. A solution of continuity must take place between these organs before it is possible for a considerable hæmorrhage to occur from the gravid uterus. The partial detachment of the membranes from the vicinity of the cervix might occasion a slight oozing of blood, from the rupture of some small decidual arteries and veins, but the quantity proceeding from this source can never be great, or produce what is usually called a flooding. It is from the great semilunar, valvular-like, venous openings in the lining membrane of the uterus, which you have seen in various preparations, and of the arteries which are laid open by the separation of the placenta, that the blood alone flows in uterine hæmorrhage. All the different causes of flooding produce their effect by separating and exposing the arteries and veins by which the circulation of the maternal blood is carried on in the placenta. Blows, falls, shocks of various kinds, mental and physical, bodily exertion

and fatigue, the movements of a carriage along a rough road, attempts to raise a heavy weight, dancing, the abuse of stimulants, frequenting hot crowded assemblies, morbid conditions of the placenta, twisting of the umbilical cord round the neck of the child, attachment of the placenta to the cervix uteri; all these causes produce hæmorrhage, by mechanically separating the placenta from the part of the uterus to which it is attached. There is not an actual wound in the uterus where the placenta adhered, the lining or mucous membrane is not detached and expelled, yet there is a considerable resemblance, as has already been stated, between this portion of the inner surface of the organ after delivery, and a stump after amputation; in both the cavities of the arteries and veins are laid open or exposed, and they are consequently liable to be affected by similar diseases.

Dr. Jones first proved by experiment that when an artery is divided, nature employs certain means adapted to arrest the flow of blood, the most important of which are the retraction and contraction of the divided extremity of the vessel and the formation of a coagulum of blood within its orifice, or rather two coagula, one within the contracted orifice of the vessel, and the other within its sheath. Nearly similar means are employed by nature for preventing fatal hæmorrhage from the uterus, when the placenta is detached; and if nature did not employ these means and at the proper period, and with sufficient force, death from hæmorrhage would probably take place in all cases immediately after the expulsion of the child and separation of the placenta. The same muscular contractions which expel the contents of the gravid uterus close the mouths of the exposed vessels in the lining membrane, until coagula of the fibrine of the blood are formed within them, which establish a permanent barrier against the further effusion of blood. The oblique valvular manner in which the veins open into the

cavity of the uterus must contribute powerfully to accomplish the same purpose. Before delivery the contractile powers of the uterus cannot be effectually exerted in closing these vessels; consequently the orifices of the veins must be stopped in a temporary manner by coagula, and the insufficiency of these plugs without uterine contraction to restrain hæmorrhage is proved by the frequent return of the accident on the application of the slightest occasional cause, and the consequent insecurity of the patient from a recurrence of the discharge, fresh portions of the placenta being likewise often separated till the contents of the uterus be expelled, and the orifices of the vessels closed by the muscular contractions of the organ. All the different efficient means which are employed for checking the discharge in uterine hæmorrhage, either excite the contractions of the uterus or promote the coagulation of the blood itself within the vessels.

Until the seventh month of pregnancy the blood-vessels of the uterus have not attained a sufficient size to pour out blood in so great a quantity as suddenly to destroy life, though the discharge may be very profuse, and produce alarming symptoms. The remedies which ought to be employed when hæmorrhage takes place in the early months have already been described, and are chiefly as follows: venesection, where the patient is plethoric and the circulation excited; rest in the horizontal position; the free admission of cool air; ice in a bladder, or cold vinegar and water, laid over the hypogastrium; cold acidulated drinks; the use of superacetate of lead and opium; the introduction of a sponge into the upper part of the vagina, and, where these fail, puncturing the ovum, exhibiting the ergot of rye, and endeavouring by all other means to excite the contraction of the uterus and the expulsion of its contents. There are very few if any cases in which it is safe to attempt to introduce the whole hand into the uterus, to deliver by turning the child, before the end of the sixth month. Uterine hæmorrhage in the latter months of pregnancy, and during labour, is always accompanied with great danger; it does and ought to excite alarm in all cases, and it occurs, *first*, where the placenta presents, or has originally adhered to the cervix uteri, and been afterwards detached from the uterus in consequence of the shortening of the cervix which takes place in the seventh month; and, *secondly*, where the placenta has adhered to the fundus or body of the uterus, and been separated from it by external violence, the umbilical cord surrounding the neck of the child, a morbid state of the placenta itself, or some other accidental cause. The first of these varieties is usually called unavoidable, the second, accidental, uterine hæmorrhage.

On Uterine Hæmorrhage from Placental Presentation.

Hippocrates says, the after-birth should come after the child, for if it were to come out first, the child could not live, because it derives its life from the after-birth, as a plant does from the earth. Cases of uterine hæmorrhage from placental presentation must have been frequently observed by the ancients, but they have not been described in their writings. In 1609, Guillemeau stated that the placenta sometimes presents or comes before the child, and that this gives rise to a dangerous hæmorrhage which nature is unable to suppress. In Chapter XII. which is entitled "*Le moyen de secourir la femme quand l'arrierefais se presente le premier*," he states that when the placenta comes first, the most certain and expedient measure is immediate delivery, because there is usually a constant flooding in consequence of the openings in the veins, which are situated in the walls of the uterus to which those of the placenta are joined, being laid open or exposed, and that the blood flows out whenever the uterus contracts, as in labour, to expel the child. The source of the discharge and cause of the death of the foetus is thus accurately described. "*D'autrepart l'enfant estant enfermé en la matrice, l'orifice estant bouche par le dit arrierefais, ne respire plus par les arteres de la mère, sera tost suffoqué faute d'ayde, et mesme englouty du sang qui est contenu en la matrice, et qui coule des veines qui sont ouvertes en icelle.*" But before attempting anything, two circumstances, he says, are to be observed: the first is, to consider whether the placenta is little or far advanced; for if the former, having placed the mother in the proper position, it must be replaced and pushed back with the greatest diligence, and if the head presents, it must be brought down that it may be expelled as in natural labour. But if some difficulty should occur, so that the head could not advance, or that the mother, or infant, or both, are feeble, and there is a probability of the labour being protracted, without doubt the best expedient is to bring down the feet of the child, and deliver as gently as possible. The other point to be observed is, that if the after-birth is much advanced, and cannot be replaced in consequence of its size and the hæmorrhage, and that the child is closely following it, and requires only to pass into the world, the placenta must be completely drawn forth. The works of Guillemeau do not contain a single observation to justify the assertion that he evidently supposed that this presentation of the placenta at the os uteri was owing to its having been separated from its usual situation in the uterus and fallen down to the lower part. Not only has this groundless assertion been made respecting

Guillemeau, but other authors, who have expressly stated that on introducing the hand into the uterus to deliver by turning, they felt the placenta adhering all round to the cervix.

The 28th Chapter of Mauriceau's Treatise (1668) is entitled, "De l'accouchement auquel l'arriere-faix se presente le premier, ou est tout-à-fait sortit devant l'enfant." The symptoms and treatment of cases of placental presentation are here accurately described, and in all cases of hæmorrhage from this cause he recommends immediate delivery. If the placenta has not entirely escaped, and the membranes are not ruptured, he advises the part of the placenta which presents to be put aside with the hand, which is to be passed up into the uterus, the membranes ruptured, and the delivery completed by turning. The rules for the treatment of these cases are laid down with the greatest precision. When the placenta was entirely separated, then only did he consider it as a foreign body, and recommend its extraction before the child, as Guillemeau had done: but to this practice he states, as an obvious objection, that the placenta is strongly attached to the membranes which surround it, and that it cannot be drawn out without the membranes enveloping the child being drawn out also. It has also been most erroneously asserted, that Mauriceau invariably speaks of the placenta when at the os uteri as "entirely detached." In the history of his case 423, related at p. 350, the following observation occurs, which I may adduce as a proof perfectly conclusive that Mauriceau does not invariably speak of the placenta when at the os uteri as entirely detached, but, on the contrary, was fully aware of the fact, that the placenta had not been detached from the fundus and pushed down to the orifice by its own gravity. "Mais quoique j'aye dit que l'arriere-faix de cette femme presentoit le premier au passage, dans le temps que je l'accouchai, et que l'excessive perte de sang qu'elle avoit vint de ce detachment, *il ne faut pas croire que cet arriere-faix fut ainsi entièrement detaché de la matrice*, depuis tout le temps que cette perte de sang avoit commencé à paroître en cette femme: car si cela eut été, l'enfant seroit mort en très peu de temps, ne pouvant pas être vivifié que par le communication du sang de la mère, dont il est privé aussitôt que l'arriere-faix est entièrement detaché de la matrice: mais comme il n'y avoit dans le commencement de cette perte de sang que quelque petite partie de l'arriere-faix qui s'en étoit un peu detachée, elle n'avoit pas empêché l'enfant d'être nourri du sang de tout le reste de l'arriere-faix, qui n'avoit pas été entièrement séparé de la matrice." Mauriceau has related seventeen cases of uterine hæmorrhage, in the latter months of pregnancy,

from presentation of the placenta, and in sixteen of these delivery was accomplished by passing the hand through the opening formed by the separation of the placenta from the uterus, rupturing the membranes, and turning the child. Two women died after this operation, and one who would not consent to have it performed died undelivered.

These cases are Nos. 8, 55, 59, 68, 106, 170, 175, 210, 423, 428, 438, 454, 484, 502, 597, 651. The first occurred in 1669; the last in 1692.

Portal's Treatise (1685) contains the histories of eight or more cases of uterine hæmorrhage, in which he found, on introducing the hand to turn the child, that the placenta was not merely at the os uteri, but adhering to the cervix all round; and he states, in the most clear and forcible manner, after relating his first case, that artificial delivery is the only remedy that can preserve the life of women under such circumstances, and that by this means he had saved the lives of several women at the Hôtel-Dieu. In 1664, Case No. 2 occurred during the eighth month, in which, on passing his hand into the uterus, he felt a soft body, which was the after-birth, which he gently separated from the uterus, then ruptured the membranes, and brought down the feet of the child and extracted it, dead. In Case 29 (1671), the placenta presented, and the head of the child was forced against it so strongly, that it was torn, and the infant expelled dead. Case 39 occurred also in 1671, in the history of which he states that he felt the placenta adhering on all sides to the orifice of the uterus. "Sur cette assurance je glissay mes doigts dans les orifices, où je sentis l'arriere-faix qui se presentoit, et qui bouchoit l'orifice de la matrice *de tous costez avec adherances* en toutes ses parties, excepté par le milieu, qui se trouvoit devisé jusques à la membrane, laquelle n'estant pas ouverte, ny les eaux ecoulées, j'eus beaucoup de facilité à tourner l'enfant." This woman died from loss of blood some time after delivery, there being scarcely a drop found in the arteries and veins on dissection; and Portal complains, with justice, that the body was examined in his absence by a distinguished accoucheur, but in the presence of the wife of the greatest and most illustrious physician of the age, whose name he has not recorded, and whose memory has probably perished many years ago. "C'est ce que me fait dire, qu'on a beau faire, ou ne fait jamais rien: *quelque belle operation qu'on puisse faire, elle ne fait point d'eclat*: mais bien tout le contraire, qu'une femme soit si bien accouché qu'on souhaitera et que malheureusement elle vient à mourir, ce sera tousjours la faute de celui ou de celle qui aura accouché la femme: tant la médi-

sance a de l'empire sur la verité." Portal's 42d case happened in 1672, in which there was also a considerable hæmorrhage, and on passing the hand into the orifice of the uterus, he says he felt the placenta presenting, which he gently separated ("parcequ'il estoit collé à l'orifice interne") because it was glued to the internal orifice. Portal's 43d case, which also occurred in 1672, was one of hæmorrhage with placental presentation during the sixth month of pregnancy, and here he also passed up his hand between the uterus and placenta, where the partial detachment had taken place, and brought down the feet of the child; "ensuite je glissay ma main dans l'entrée de la matrice, où je sentis l'arriere-faix qui se presentoit. L'ayant separé, afin de me frayer le chemin, je sentis les membranes des eaux que je percay," &c. Another similar case, No. 51, took place in the same year, 1672, and to this history is subjoined a correct explanation of the cause of the hæmorrhage which occurs in the latter months of pregnancy, where the placenta adheres to the neck of the uterus. On introducing the hand into the uterus, he says, "J'ouvris cet anneau en telle sorte que je n'eus point de peine à porter ma main dans le fond de la matrice, où en la glissant je sentis le placenta qui environnoit en dedans l'orifice interne: ce qui estoit la cause de la perte de sang, parceque lorsque l'ouverture de cet anneau se faisoit, le placenta qui se trouvoit contigu à cet orifice, à cause de quelque contiguité qu'il a avec la matrice, à l'endroit où il y est adherant, cet orifice venant à s'ouvrir, il se divise, et en mesme temps les vaisseaux venant à se diviser, cela fait que le sang de la malade se perd en abondance; et si elle n'est promptement secourue, elle meurt bien-tost." He then turned and delivered the child. In concluding the history of this case he states, that in the year 1683 he had completed the delivery successfully in five similar cases, all the women having recovered. His 69th case occurred in 1679, in which he likewise found, on passing the hand, that the placenta was every where firmly adherent to the neck of the uterus, which was the cause of the great hæmorrhage. "In Portal's Cases in Midwifery," observes Dr. Rigby, in his Essay on Uterine Hæmorrhage, "there are eight in which he was under the necessity of delivering by art, on account of dangerous hæmorrhages, and in all of them he found the placenta at the mouth of the womb." This important fact, that in all these cases the placenta was found not merely at the mouth of the womb, but adherent to the neck of the uterus, in some all round to it, is suppressed by Dr. Rigby, nor are the practical conclusions, which Portal drew from it, described by him.

Dr. Edward Rigby asserts, that "in one case only does Portal attempt to make any practical inference whatever, having, in all the others, contented himself with merely stating the fact of the placenta adhering to the os uteri." The operation of passing the hand between the placenta and uterus, bringing down the feet and turning the child, which Portal had recourse to so promptly in most of the preceding cases, I think you will be disposed to regard as the very best practical inference which he could have drawn, or has yet been drawn by others from the knowledge of the fact. It has likewise been affirmed by him that "all the authors in midwifery, up to the time of Röderer and Levret were ignorant of Portal's explanation." The truth of this you may estimate by the following facts.

In the History of the Royal Academy of Sciences for 1728, it is stated, that Petit examined the body of a woman who had died from flooding when near the full period, and he found the placenta adherent to the neck of the uterus, and exactly closing the orifice except at one part, where it was detached, and from whence the discharge of blood had taken place.

Giffard has recorded about twenty cases of placental presentation, and he was likewise completely aware of the fact, that the placenta sometimes adheres to the inferior part of the uterus. He concludes the history of his 115th case with the following observation. "I cannot implicitly accede to the opinion of most writers on midwifery, which is, that the placenta always adheres to the fundus uteri, for in this, as well as many former instances, I have good reason to believe that it sometimes adheres to or near the os internum, and that the opening of it occasions a separation, and consequently a flooding." In the history of Case 116 he states that he told the patient "that the only way to save her life was a speedy delivery." When he passed his hand through the os uteri, the first thing he met with was the placenta, which he "found closely adhering round the os internum" of the uterus; which, amongst many other instances, is a proof that the placenta is not always fixed to the bottom of the uterus, according to the opinion of some writers in midwifery; its adhering to the os internum was in my opinion the occasion of the flooding; for as the os internum was gradually dilated, the placenta at the same time was separated, from whence proceeded the effusion of blood. The placenta presented in Cases 120, 121, 158, 160, 184, 209, and 224. In the last of these cases he "felt part of the placenta adhering round about the orifice of the uterus." "This case occurred in 1731; and in a further communication of its details, he observes, as he had done before; "I beg leave," before I

proceed to give any further account of the delivery, to give my opinion on a point of midwifery in which I differ from most authors that have wrote on the subject. It is generally believed that the ovum after its impregnation and separation from the ovarium, and its passage through the tuba fallopiana, always adheres, and is fixed after some time to the fundus uteri; in this case the placenta adhered, and was fixed close and round about the cervix uteri, as I have found it in many other cases, so that upon a dilatation of the os uteri a separation has always followed, whence a flooding naturally ensues."

"Giffard," says Dr. Rigby, "has more than twenty cases where the placenta was found at the os uteri: but *plainly supposes that it had not been originally fixed there*, for he says, "it is customary in floodings to find the placenta sunk down to the mouth of the womb."

Puzos knew that the placenta sometimes adhered to the cervix uteri: all the authors on midwifery who lived from the time of Portal to that of Roederer and Levret were not, therefore, ignorant of the fact.

"Il y a eu plus d'un exemple de femmes qui n'ont pû accoucher," he observes at page 98, "parceque le placenta s'étoit collé sur l'orifice de la matrice, qu'il le tenoit hermétiquement clos, et qu'il empêchoit sa dilatation lors du terme de l'accouchement. C'est donc un peu légèrement que Daventersoutient que le placenta est toujours au fond de la matrice."

Roederer has given a clear account of the symptoms and treatment of cases of uterine hæmorrhage from attachment of the placenta to the lower part of the uterus, in his *Elements of Midwifery*, published at Göttingen in 1759. The placenta, he states, can be felt firmly adhering to its inferior segment. He denies the possibility from any cause of the placenta being detached from the fundus uteri and falling down to the cervix. In some cases the whole placenta covers the orifice of the uterus; in others, and these are much less dangerous, and may be committed to nature, he states that it adheres only to the side of the aperture. He has described with great minuteness the operation of turning the child, and pointed out its necessity in all those cases in which a large portion of the placenta adheres to the neck of the uterus. He recommends the dilatation of the orifice to be slowly and cautiously effected with the hand, which, he says, is not to be pushed through the centre of the placenta, but through the opening formed by its detachment from the uterus.

Levret, in his *Dissertation* 1761, undertook to prove, what it appears had previously been demonstrated.—1. That the placenta

sometimes adheres to the circumference of the internal orifice of the uterus; 2. That where this occurs, uterine hæmorrhage is *inevitable* in the latter months of pregnancy; and 3d, that the only method of obviating this dangerous accident is to deliver immediately by turning the child. He refers to the cases of Van Horne, Schaeher, Plasner, Brunet, Huster, Portal, Petit, and to those which came under his observation, to prove the truth of his first proposition. He quotes also in its support the opinions of Massa, Drelincourt, Mauriceau, Bidloc, and Noortwyk, that the outer membrane of the ovum adheres to the whole inner surface of the uterus, and that the spheroidal mass, being equally compressed on all sides by the uterus, cannot be displaced, nor the placenta slide down from the fundus to the cervix, as Daventer supposed. Levret observed that uterine contractions invariably increased the hæmorrhage, where the placenta had been implanted over the cervix uteri, and that the contrary effect was produced where the placenta had adhered to the fundus uteri, and been detached by an accidental cause.

In a case which occurred in 1752, he passed the hand through the substance of the placenta, and delivered the child. The child was dead, and the mother died soon after. Levret appears to have been one of the first who recommended, as a general rule, forcing the hand through the centre of the placenta, instead of passing it between the uterus and its margin, as Mauriceau and Portal had done. The occurrence of uterine hæmorrhage from placental presentation he attributed to a development of the cervix uteri from above downward, in consequence of which a separation took place between the two organs, and the vessels of the uterus were exposed.

Smellie also knew, in 1745, that the placenta sometimes adheres to the lower part of the uterus, and he has related nine cases to illustrate the fact, and the appropriate treatment. "The edge or middle of the placenta sometimes adheres," he observes, "over the inside of the os internum, which frequently begins to open several weeks before the full time; and if this be the case a flooding begins at the same time, and seldom ceases entirely until the woman is delivered. The discharge may, indeed, be terminated by coagulums that stop up the passage; but when they are removed, it returns with its former violence, and demands the same treatment that is recommended above"—viz. artificial delivery.

"A case of hæmorrhage," observes Dr. Rigby, in the preface to the sixth edition of his *Essay*, 1822, "in which I found the placenta attached to the os uteri, occurred at a very early period of my practice; but

not finding such a circumstance recorded in the lectures which I had attended or taken notice of in the common elementary treatises on midwifery, I considered it at first merely as a casual and rare deviation from nature. In a few years, however, so many similar instances fell under my notice, as to convince me that it was a circumstance necessary to be inquired after in every case of hæmorrhage; and this conviction was confirmed by the perusal of cases in midwifery; for I then found that the fact of the placenta being thus situated had been recorded by many writers, though in no instance, which had then reached me, had any practical inferences been deduced from it. It appeared to me, indeed, most extraordinary, that such a fact, known to so many celebrated practitioners, should not long before have led to its practical application, and, in consequence, to more fixed principles in the treatment of hæmorrhage from the gravid uterus; and I may perhaps be allowed to say, that I congratulate myself, young in years and in practice as I then was, in being probably the first to suggest an important improvement in the treatment of one of the most perplexing and dangerous cases in midwifery, and that I committed my observations on the subject to paper, not only under a conviction of their practical utility, but certainly also under an impression that my suggestions were original. Not long after the first edition was at press, indeed before the first sheet was printed (1776), Levret's dissertation on this subject fell into my hands; and in a note I referred to it as additional testimony in proof of the placenta in these cases being originally attached to the os uteri. I have been led into this little detail, because it has been suggested that I have borrowed my theory from Levret. After remarking the gross folly I should have been guilty of in quoting Levret, had I furtively adopted his opinions, it will, I trust, be sufficient for me unequivocally to declare, that my original ideas on the subject were derived solely from my own personal observation and experience; and that, having previously *neither read nor heard of the placenta being ever fixed to the os uteri*, the knowledge of such a circumstance, derived as before observed, came to me, and impressed me as a discovery. I was certainly afterwards struck with the coincidence of the sentiments of Levret and myself on the subject—with the similarity of our practical deductions, and, allowing for the difference of language, even with the sameness of our expressions. But is it extraordinary that two persons should have deduced the same conclusions from similar premises? In the present instance, where the inferences are so obvious, the contrary,

as I have before remarked, is surely the more extraordinary, that other writers who have noticed the fact should not have deduced them; that Dionis, Mauriceau, Deventer, La Motte, Portal, Ruysch, Giffard, Smellie, Hunter, &c. whom I have quoted as having found the placenta at the os uteri, should not practically have applied it, than that Levret or myself should have done it. I am further not reluctant to acknowledge that, after reading Levret's dissertation, I felt less entitled to the claim of absolute originality on the subject; and I now rest perfectly satisfied to divide with him the credit arising from the mere circumstance of communicating a new physiological fact." "Levret's facts, moreover, though they proved that the placenta might be originally attached to the os uteri (and a single instance would establish this) were scarcely sufficient to prove the frequency of its occurrence, from which alone arises the necessity of practically attending to it in every case of hæmorrhage. His observations (perhaps even more creditable to him for being founded on such scanty materials), were derived from four cases only, but of these but two were under his immediate cognizance; whereas, in the first edition of this essay, my opinions were supported by 36 detailed cases, in 13 of which the placenta was found at the os uteri; and in the fourth edition the number was increased to 106, 43 of which were produced by this peculiar original situation of the placenta."

In the Maternité at Paris, from the year 1797 to 1811, during which period 20,357 women were delivered, Madame Boivin reports there were 8 cases of placental presentation, being in the proportion of 1 in 2554. During six years and nine months 10,387 cases of labour occurred in the Dublin Lying-in Hospital, under the mastership of Dr. Joseph Clarke, and there were 4 cases of placental presentation, or 1 in 2596. One of these proved fatal. Dr. Collins met with 11 cases of placental presentation in 16,654 labours, being nearly in the proportion of 1 to 1492. Eight of the children presented naturally, four of which were turned; one was delivered by the natural efforts; one with the forceps; and in the other two the head was lessened. Of the remaining three, two presented with the feet, and one with the breech. Six of the children were born alive. Of the five still-born, two were putrid. Two of the women, where the children were turned, died: all the rest recovered. Dr. Ramsbotham has related 19 cases of placental presentation, eight of which proved fatal. In fine, the placenta was only partially adherent to the cervix, and in three the expulsion of the placenta took place before the child. Out of

174 cases of placental presentation recorded by different authors, Dr. Churchill states that 48 proved fatal, or nearly 1 in 3; and that in 85 cases of uterine hæmorrhage, where the placenta was at the fundus, 24 proved fatal, the proportions being nearly the same.

I have seen 38 cases of uterine hæmorrhage in the latter months of pregnancy from partial or complete attachment of the placenta to the neck of the uterus. Seven of these women died soon after delivery, from the loss of blood they had sustained. One died undelivered, from the first attack, before being seen; one from rupture of the uterus; and five from uterine phlebitis and other forms of uterine inflammation. The subjoined table of these cases, constructed by Edmund Johnson, Esq. will enable you in a very short time to become acquainted with all their most important details.

In the greater number of cases of placental presentation the discharge of blood takes place spontaneously in the seventh and eighth months of pregnancy, and cannot be referred either to bodily exertion, external violence, nor to any unusual determination to the uterine organs, or congestion of their vessels. The hæmorrhage generally comes on suddenly, when the woman is in a state of rest, and the blood continues to flow until faintness or even syncope takes place. It often ceases entirely, and the patient resumes her usual occupations, and has no dread of another attack. But after an interval of several days, and sometimes not before two or three weeks, the flooding is renewed, and perhaps with increased violence, or a constant profuse discharge takes place, and a decided effect is produced upon the constitution,—the pulse becomes rapid and feeble, and the countenance pale. Similar attacks return at longer or shorter intervals, and if delivery be not accomplished by art, sooner or later death takes place. The first attack of flooding seldom proves fatal, but it sometimes does so; for in the second case related in the table, which occurred in the British Lying-in Hospital, the life of the patient was at once extinguished by a single gush of blood from the uterus. I examined the body after death. The centre of the placenta was over the centre of the os uteri.

When flooding takes place to an alarming extent in the seventh or eighth months of gestation, you ought first to ascertain, by a careful internal examination, whether or not the placenta be situated at the os uteri. It is impossible, from the manner in which the discharge of blood takes place, to be certain of the fact; for there are some cases of hæmorrhage from detachment of the placenta from the upper part of the uterus, where the flooding occurs spontaneously, and to as great an extent as in cases where the placenta pre-

sents. In some cases I have been induced, from the symptoms, to believe that the placenta was at the os uteri when it was not. As the treatment and the successful or fatal result of the case will, in a great measure, depend on the correctness of the diagnosis, the examination should be conducted with so much care and circumspection as to leave no room for doubt on the subject. An ordinary examination, with the fore and middle fingers, is generally sufficient to enable us to ascertain the true state of the case, but where the os uteri is very high up, and directed backwards, it becomes requisite to introduce the whole hand within the vagina. The finger should then be passed gently through the os uteri, and, if the placenta adheres to the cervix, it will be distinguished from coagulated blood, the only substance with which it can be confounded, by its firmer, fibrous, vascular structure, and, above all, by its adhering at one part to the uterus, and being separated at another. If you will take the trouble to pass the finger carefully and repeatedly over the uterine surface of a recently expelled placenta, you will never, in actual practice, mistake a placenta at the os uteri for a clot of blood, however firm. In all cases it is requisite to proceed at once to determine by an examination, so carefully conducted as to render a mistake impossible, whether or not the placenta presents—even though the hæmorrhage should be slightly renewed by the displacement of the coagula; you cannot be too early acquainted with the precise condition of the patient. You ought, at the same time, to ascertain whether the placenta adheres partially or completely to the cervix uteri, and whether the os uteri is in a condition to admit of the operation of turning being performed.

The operation of turning, which is required in all cases of complete placental presentation, is not necessary in the greater number of cases in which the edge of the placenta passing into the membranes can be distinctly felt through the os uteri. Sometimes there is profuse and dangerous hæmorrhage where the placenta does not adhere all round to the neck of the uterus, but only partially. If the os uteri is not much dilated or dilatable, the best practice in these cases is to rupture the membranes, to excite the uterus to contract vigorously, by the binder, ergot, and all other means, and to leave the case to nature: by adopting this treatment the operation of turning may be avoided with advantage in the greater number of cases of partial placental presentation. But, if the hæmorrhage is profuse, has returned at different intervals, and a great quantity has been lost, and the constitution is really affected, it is the safest practice at once, if the orifice of the uterus is in a condition to allow the hand to

pass without difficulty, to deliver by turning the child.

Where the placental presentation is complete, the operation of turning should be performed, in all cases, as soon as the orifice of the uterus is so much dilated or dilatable as to allow the hand to be introduced without the employment of much force. It is seldom safe to attempt to deliver by turning before the os uteri is so far dilated that you can easily introduce the points of the four fingers and thumb within it: however soft and relaxed it may be, until dilatation has commenced, and proceeded so far, I am convinced there are very few cases in which the operation of turning will be required, or completed without the risk of inflicting some injury on the os uteri. This is a point of the greatest practical importance, but I do not know in what manner to communicate to you, in words, a more clear and definite idea of the grounds upon which you ought to proceed.

In every case, before attempting to turn, make a most careful examination of the os uteri, and endeavour, from the degree of dilatation, and the thinness and softness, of the orifice, to form a correct judgment upon this point before interfering, for the hæmorrhage will be renewed if the attempt is unsuccessful, and the patient will be placed in a worse condition than she was before. When you have resolved to turn, let the patient lie on the left side, with the pelvis close to the edge of the bed, and introduce the right hand into the vagina as before described, and then pass the fingers and hand gently and slowly in a conical form through the os uteri, giving it time to dilate, and onward into the cavity between the detached portion of the placenta and the uterus: then force the fingers through the membranes, grasp both feet, and bring them down into the vagina, and slowly extract the child as in cases of nates presentation, and do not afterwards be in a hurry to remove the placenta, unless it is wholly detached and lying in the upper part of the vagina. This operation is easily and speedily performed when the os uteri is widely dilated and dilatable. It is, however, a great exaggeration of the facility with which turning may be accomplished in these cases, to represent it as a very simple process, like putting the hand into the coat pocket and pulling out your handkerchief. At the best it is a dangerous operation, and you can never tell with certainty whether or not the patient will recover after its performance, however easily it may have been effected.

But there is not unfrequently most profuse and alarming flooding from complete placental presentation, where the os uteri is so thick, rigid, and undilatable, that it is impossible to introduce the hand into the uterus without producing certain mischief.

A TABULAR VIEW OF THIRTY-EIGHT CASES OF UTERINE HÆMORRHAGE FROM PLACENTAL PRESENTATION.

1	July 22, 1828	Profuse hæmorrhage seven days before labour; placenta adhered to neck of uterus all round; rigidity of os uteri; turning attempted, but could not be performed; the plug employed for several days, but much blood lost; turning at last accomplished with little difficulty, but followed by alarming exhaustion	Died 18 days after delivery; extensive inflammation of the placenta, with gangrene of the inferior lobe of the left lung, and inflammation of the left spermatic vein. Died.
2	1828	Sudden profuse hæmorrhage at ninth month, which continued till death, which took place suddenly; no accident or uneasy sensation before discharge commenced; placenta found on dissection adhering around cervix uteri; died undelivered, before she could receive any assistance, or was seen by any medical practitioner	Recovered.
3	October 24, 1829	Hæmorrhage at seventh and a half month; thirty-six hours before medical aid was procured; placenta found hanging out of orifice of uterus; operation of turning proposed, but the patient would not allow it to be performed; violent flooding for several hours; placenta and foetus expelled without assistance; great exhaustion	Recovered.
4	February 8, 1830	Profuse hæmorrhage in the seventh month; placenta protruding through orifice of uterus; placenta extracted, and a dead child followed; great hæmorrhage; insensibility and coldness of extremities, &c.	Recovered.

5	March 24, 1835	Hæmorrhage; exhaustion; os uteri soft and widely dilated; hand passed into uterus through opening made by detachment of placenta from cervix uteri; membranes ruptured and turning effected; child dead	Recovered.
6	March 1835	Hæmorrhage during eighth month; placenta attached to lower part of uterus; usual effects of loss of blood; os uteri widely dilated, and placenta hanging partially through it; turning easily performed; child dead	Recovered.
7	April 26, 1835	Hæmorrhage at seventh and a half month; oozing of blood for fourteen days, which came on without any accident or injury when in bed, preceded by no uneasiness; orifice of uterus hard and undilatable; hand unable to be introduced; hæmorrhage checked for two days by cold and rest; sudden renewal of flooding to a great extent; syncope at last came on, and turning was easily accomplished; child alive	Died in a few days from the effects of loss of blood.
8	October 7, 1835	Hæmorrhage in the seventh month; slight oozing of blood for three weeks, at the end of which period several pints were suddenly discharged; pulse imperceptible; extremities cold; respiration feeble; os uteri very rigid, and little dilated; repeated attempts to turn; a foot at last grasped, and the operation completed with difficulty; hæmorrhage arrested; exhaustion, rigors, and death threatened	Recovered.
9	October 18, 1835	Profuse hæmorrhage in the eighth month; placenta found hanging out of os uteri; hand could not be introduced to turn the child, in consequence of rigidity of os uteri and distortion of the pelvis; hæmorrhage continued; head felt above brim of pelvis; craniotomy performed, and delivery completed after four hours with great difficulty	Recovered.
10	October 28, 1835	Hæmorrhage during seventh month, occurring spontaneously twice in fourteen days; renewed at last with violence; placenta found protruding through os uteri; traction made on placenta, and the contents of the uterus were expelled entire; hæmorrhage ceased after cold being applied	Recovered.
11	October 30, 1835	Slight hæmorrhage, lasting fourteen days, terminating with an immense discharge; placenta partially adherent to cervix; syncope; os uteri rigid, dilated to the size of a crown piece; placenta detached at posterior part of neck of uterus; membranes felt; head presented; membranes ruptured; hæmorrhage arrested; child expelled by the natural efforts	Recovered; sanguineous discharge from uterus for months.
12	Nov. 10, 1835	Profuse hæmorrhage during eighth month; first discharge on the 4th of November; placenta presented, and adhered all round to cervix uteri; vagina filled with coagula; insensibility and cold extremities; os uteri considerably dilated; placenta separated from uterus with the fingers, and turning performed; hæmorrhage after the expulsion of placenta; pulse imperceptible; respiration hurried; lips and hands livid; stimulants ineffectual	Died two hours after delivery.
13	Nov. 17, 1835	Hæmorrhage in the eighth month, after great bodily exertion; placenta detached from orifice of uterus; os uteri rigid and slightly patulous; rest and cold employed for a day, after which period the membranes were ruptured; head descended between placenta and uterus, and delivery was completed without hæmorrhage	Died at a remote period from deep-seated uterine inflammation.

14 March 24, 1836

Hæmorrhage in seventh month, continuing for several days, exhaustion at last taking place after a discharge of blood; placenta felt at posterior part of cervix uteri; membranes felt at anterior part; membranes ruptured; hæmorrhage ceased; labour did not come on for two days; uterine phlebitis

Died 11th of April, from phlebitis and inflammation of the lungs.

15 Dec. 3, 1836

Hæmorrhage in seventh month; ergot of rye had been repeatedly administered without presenting part being known; os uteri widely dilated; placenta found adhering to the posterior part of cervix uteri; turning performed in five minutes with ease; child dead; no hæmorrhage followed

Died ten days after, from inflammation of the veins of uterus.

16 Dec. 20, 1836

Repeated attacks of hæmorrhage during the eighth month; placenta felt presenting through os uteri; great exhaustion; rigidity; hæmorrhage controlled for some days; turning at last performed; child alive; recovered for two hours

Died suddenly, two hours after delivery.

17 Dec. 25, 1836

Severe hæmorrhage after a fit of coughing; pulse rapid and feeble; no uterine contractions; os uteri soft and dilatable; placenta detached, and a portion hanging out of orifice of uterus; turning easily performed; child born alive; placenta allowed to remain for some time to act as a plug

Recovered.

18 March 10, 1837

Hæmorrhage in the sixth month, occurring at intervals during four weeks; ergot of rye given without the presenting part being ascertained; os uteri soft and widely dilated, and a portion of the detached placenta hanging through it; turning easily performed; child alive

Recovered.

19 July 19, 1837

Hæmorrhage at intervals, for several days, during ninth month; extreme debility; os uteri slightly dilated; hand passed into the uterus; membranes ruptured and a foot brought down, and the delivery easily accomplished; no hæmorrhage followed

Recovered after severe uterine and crural phlebitis.

20 Dec. 27, 1837

Hæmorrhage during the ninth month; os uteri slightly dilated; partial placental presentation; discharge of blood slight; no constitutional symptoms present; os uteri became widely dilated at the end of twenty-four hours; edge of placenta felt; membranes were ruptured; head descended; child born alive by natural efforts

Recovered.

21 May 12, 1838

Hæmorrhage, lasting three days; orifice of uterus at commencement of attack high up, and slightly dilated; by end of third day largely dilated; a great discharge of blood at last took place; turning easily performed; child dead

Recovered.

22 June 11, 1838

Flooding during the seventh month, lasting at intervals for five days, and producing fits of syncope; turning performed; hæmorrhage arrested; faintness, cold extremities, and exhaustion

Died at a remote period from uterine phlebitis.

23 Jan. 12, 1839

Hæmorrhage at eight and a half months; three attacks during one month, at long intervals; renewed spontaneously with the utmost violence; os uteri thick and rigid; vagina filled with coagula; placenta adhering all round to inner surface of cervix; artificial dilatation attempted, but without success; membranes about to be ruptured when two fingers were passed between the placenta and uterus, a foot was felt and brought down into vagina, and turning accomplished with great difficulty, from the orifice of uterus firmly grasping like a rope the neck of the child; labour in half an hour, completed by artificial dilatation; but the hæmorrhage continued, in spite of all treatment, and complete exhaustion followed

Died half an hour after delivery from loss of blood.

24	Feb. 1839	<p>Hæmorrhage at seventh and a half month; placenta adhering all round to neck of uterus; os uteri rigid and undilatable, being the size of a crown-piece; head presenting; hæmorrhage arrested for a time by cold, but renewed; fingers were pushed through the placenta, and the membranes ruptured; head descended and hæmorrhage ceased; os uteri continued rigid, so that perforation could not be employed; labour lasted during the day, when exhaustion came on, without further loss of blood; craniotomy at last performed, and extraction completed with great difficulty, in consequence of the extreme rigidity; complete exhaustion</p>	<p>Died soon after delivery from loss of blood.</p>
25	July 30, 1839	<p>Flooding during the seventh month; placenta adhered to neck of uterus; os uteri thick and rigid; hæmorrhage profuse; syncope; the whole hand could not be passed into uterus; two fingers were introduced within its orifice, and a foot easily brought down before the membranes were ruptured; turning easily performed; hæmorrhage arrested; child dead</p>	<p>Recovered.</p>
26	Feb. 22, 1840	<p>Profuse hæmorrhage at the five and a half month; repeated again at the seventh month, when it lasted three days; placenta entirely situate over orifice of uterus, and adhering to the cervix; hand thrust through placenta, and delivery completed by turning; head extracted with great difficulty; exhaustion from time of delivery. (When called to this patient, Dr. Lee found her dead)</p>	<p>Died an hour and a half after delivery. <i>Post-mortem examination:</i> Extensive laceration of muscular and mucous coats of cervix uteri on the left side; a superficial rent on right side; placenta had adhered to whole circumference of cervix uteri; pelvis distorted to a high degree</p>
27	October 9, 1840	<p>Profuse hæmorrhage in the seventh month; experienced for days previously a sense of weight and uneasiness; edge of placenta felt through orifice of uterus; membranes ruptured, which induced strong labour pains; hæmorrhage was arrested; child expelled dead in an hour and a half</p>	<p>Recovered.</p>
28	April 7, 1841	<p>Uterine hæmorrhage during seventh month; repeated twice at short intervals during the eighth month; an immense discharge at last took place, producing syncope; os uteri thick, high up, and but little dilated; the whole hand could not be passed into the uterus; placenta adhering all round to cervix uteri; the fore and middle finger introduced between placenta and uterus; a foot brought down with great difficulty; head extracted after great exertion, os uteri having grasped the child with great force</p>	<p>Recovered.</p>
29	May 19, 1841	<p>Two attacks of uterine hæmorrhage during the seventh month, at intervals of three weeks, the last producing syncope; os uteri dilated to size of a crown-piece; placenta presenting, and adhering nearly all round to cervix uteri; turning accomplished in quarter of an hour by another practitioner; convulsions came on during extraction of child, which continued until her death</p>	<p>Died four hours after delivery from convulsions.</p>

30	May 26, 1841	Spontaneous hæmorrhage in the eighth month; had several attacks, but not very profuse; os uteri rigid, high up, and dilated to the size of a half-crown; placenta adhered every where to the neck of uterus; child turned without difficulty; hæmorrhage arrested	Recovered.
31	Nov. 10, 1841	Hæmorrhage in the ninth month; placenta detached, and a large portion hanging out of orifice of the uterus; syncope; hæmorrhage arrested for a time; membranes at last gave way, and the child was born alive, without artificial assistance	Recovered.
32	Nov. 13, 1841	Profuse hæmorrhage in the eighth month; os uteri high up, and directed backward; thick, but dilatable; finger with difficulty introduced within it; placenta found adhering to cervix uteri; turning performed with ease; child alive	Recovered.
33	Jan. 5, 1842	Hæmorrhage at the end of seventh month; os uteri dilated to size of a half-crown; not rigid; placenta adhered all round to the cervix uteri; hand passed into uterus, and a foot brought down without difficulty; nates firmly grasped by os uteri	Recovered.
34	April 15, 1842	Hæmorrhage during sixth month; placenta partially adherent to cervix; membranes were ruptured, and a dead child expelled, without turning being employed; hæmorrhage arrested	Recovered.
35	July 1842	Hæmorrhage at the beginning of the eighth month; renewed after an interval of a month, with great severity; placenta adherent all round to cervix; os uteri dilated to the size of a half-crown, thin and dilatable; turning easily performed by another practitioner; syncope, with the usual symptoms of great loss of blood, followed, from which she never recovered	Died four hours after delivery.
36	Sept. 7, 1843	Hæmorrhage first commenced during the seventh month, but arrested; renewed after six weeks, with syncope; os uteri dilated to size of half-a-crown; placenta adhered so firmly to cervix uteri that the fingers were obliged to be forced through its structure, and the operation of turning performed; hæmorrhage ceased, and delivery was easily accomplished, followed by great faintness	Recovered.
37	Oct 15, 1842.	Hæmorrhage in eighth month; placenta adhering all round; hæmorrhage at intervals for two or three weeks; os uteri little dilated, but dilatable; immediately passed up the hand into the uterus, brought down the feet, and turned; child dead	Recovered.
38	Feb. 24, 1843	Profuse discharge for three weeks in the seventh month; placenta adhering all round; os uteri dilated to the size of a crown-piece, dilatable; passed the whole hand into the vagina; finding some difficulty in introducing it through os uteri, passed the fore and middle finger between the anterior part of the uterus and placenta; ruptured the membranes; grasped a foot, and easily extracted the child alive	Recovered.

In 13 of the 36 cases contained in the preceding table the os uteri was rigid and undilatable. The tampon or plug has no power to restrain the hæmorrhage in such cases, nor do I know of any other means—either cold, quietness, nor opium—which effectually have, and it is sometimes absolutely necessary under such circumstances to deliver by turning, before the hand can possibly be introduced into the uterus without producing fatal contusion or laceration of the part. I have found in several of these cases, however, that the delivery may be safely accomplished by merely passing the hand into the vagina, and afterwards the fore and middle fingers between the uterus and detached portion of the placenta, grasping with them the feet, which are generally situated near the os uteri, and drawing down the inferior extremities into the vagina, and delivering. I know that the inferior extremities may often be brought down in this way where it is impossible to pass the whole hand through the os uteri.

CASE OF DIABETES MELLITUS.

To the Editor of the Medical Gazette.

SIR,

THERE are few diseases the satisfactory treatment of which presents greater difficulties to the country practitioner than diabetes mellitus. It is only in the wards of an hospital that we can enforce any lengthened observance of a regulated diet, or expect to secure that careful obedience to our directions which is so necessary in the management of that formidable malady. It must be from this difficulty that so few contributions have been made to the history of diabetes in this country, except by the officers of public charities. Believing that every faithful record of facts is valuable to science, I send you the notes of a case which lately occurred to me; it will, I trust, prove interesting to some of your readers.

I remain, sir,

Your obedient servant,

JOHN F. HODGES,

Downpatrick, Co. Down, Surgeon, &c.
June 12, 1843.

May 20th, 1843. — Susan C., æt. 17, a thin delicate-looking girl, resides with her mother, a very poor woman. About two years ago she received a severe fall, which was followed by excessive epistaxis, which, she says, could not be stopped for two days. After the fall, her health, which had previously been

good, declined; she lost flesh; the quantity of urine discharged by her gradually increased, and her appetite for meat and drink became most inordinate. She has been repeatedly under treatment without much benefit. She states that the quantity of urine at present amounts to twenty-four pints in twenty-four hours, and that she drinks about the same amount of liquors. She is exceedingly weak and desponding; pulse 90; tongue white at the sides, red in the centre, and moist; abdomen swollen; bowels regular; has occasionally a burning pain in stomach, and almost every month severe attacks of diarrhœa and vomiting. Catamenia have not yet appeared. Her skin is dry and rough, and on her face there is a slight herpetic eruption. Has no cough or uneasiness in chest, except from occasional attacks of palpitation. Has at present no pain in back, or swelling in her limbs, but says that some time ago her legs swelled considerably, and that her left leg is sometimes painful to the touch, and weak. Her thirst is greatest after eating, but during the night it is also severe. Urine has a light straw colour, and a smell something resembling sour milk; tastes very sweet; sp. gr. 1.030; no deposit on standing; reddens litmus paper; not altered by heat or nitric acid, except that it is rendered slightly pinkish by the latter. When set aside for some days it fermented spontaneously, and emitted a strong alcoholic smell. Sugar in large quantity could easily be procured by simple evaporation from the fresh urine. The girl herself was frequently surprised by observing parts of her dress on which urine had fallen covered with a white powder, sweet to the taste. When first consulted, I prescribed for some days opiates, as pulv. Doveri, &c. but without any material effect. Upon reflecting upon the case, it occurred to me that it would be a most suitable one for giving a trial to the nitrogenizing plan proposed by Dr. Barlow, of Guy's Hospital, in the valuable Reports of that celebrated charity*. I accordingly commenced by prescribing the sesquicarbonate of ammonia in doses of five grains every three hours, with coffee and bacon for breakfast, animal food

* M. Bouchardat, in a memoir communicated to the French Academy, also recommended the carb. ammonia in the treatment of this usually intractable disease.

and cruciferous vegetables for dinner; and directed friction of the skin and warm flannel clothing. After pursuing this treatment about four days, a very marked improvement took place; her urine was diminished to fourteen pints in twenty-four hours, the specific gravity continuing the same. She stated that her health was greatly improved. The ammonia made her very warm, but produced no perspiration. Directed her to take five grains of the sesquicarbonate, dissolved in water, every two hours.

April 1st.—Continues to improve; was able the other day to attend church, the first time for a very long period; has perspired profusely; discharge of urine diminished to eight pints in twenty-four hours; appetite not now troublesome; says she does not feel hungry between meal times. Tongue red and clean; has no pain in any part.

3d.—Ingesta nine pints, urine ten pints, in twenty-four hours. About half an hour before coming to see me had taken her breakfast of bacon and coffee. Tongue red; saliva acid; skin warm. The medicine sickens her considerably; to take it only every third hour.

5th.—Drink, six pints; urine, eight pints; neutral to litmus. Tongue red; pulse 80.

8th.—Drink, seven pints; urine, eight pints; sp. gr. 1.030; tongue red; pulse 86.

13th.—Drink, five pints; urine, five pints; neutral; sp. gr. 1.030; expresses herself better than she has been since her first illness; no swelling in legs, or uneasiness in any part. The urine of this date, when set aside, became like milk very much diluted with water; a creamy-like pellicle formed on its surface; it did not undergo spontaneous fermentation.

16th.—Drink, three pints; urine, four pints; neutral. Tongue red; pulse 90; urine of higher colour than since commencement of treatment; sp. gr. reduced to 1.020; has lost its sweet taste; is slightly acid.

21st.—Drink, two pints; urine, four pints.

29th.—No relapse; states that she never enjoyed so good health; pulse 80; tongue clean; urine about four pints in twenty-four hours; appetite natural.

June 12th.—Has gained flesh and colour; considers herself quite recovered.

Results of the action of reagents on the urine of Susan C., April 13.

Ebullition . . .	No change.
Nitric acid . . .	No change.
Muriatic acid . . .	No change.
Sol. oxalate amm.	White troubling.
Sol. nitrate silver .	Dense deposit, insoluble in nitric acid.
Sol. potass . . .	No change.
Ammonia . . .	White deposit upon standing for some hours.
Chloride barium .	White precipitate
Sp. gravity . . .	1.030.
Litmus . . .	Neutral.
Taste . . .	Sweet.
Colour . . .	Pale straw.
Smell . . .	Sour milk.

OBSERVATIONS.—The successful treatment of the above case of this formidable disease is opposed to the opinions of many recent writers, that it proves "sooner or later inevitably mortal," and encourages us to expect that the insight which the remarkable progress of organic chemistry, chiefly by the indefatigable labours of Liebig, and of our celebrated countryman Dr. Prout, has already afforded us into many hitherto obscure processes in the animal economy, will enable us to proceed with greater confidence and success in our treatment of diabetes and many other functional diseases. It is, indeed, but fair to conclude that, in the treatment of diseases which produce a change in the chemical constitution of the animal fluids, the exhibition of remedies which, in ordinary chemical researches, possess a decided influence in counteracting or modifying those changes, should deserve the attention of the physician, and particularly when experience has shown that the same agents are capable of producing similar effects within the body. It is the duty of every observer carefully to record and communicate such results as may confirm or oppose these views.

The effects of the nitrogenizing treatment in the above case, in diminishing the quantity of urine, was well marked. When first submitted to treatment, Susan C. voided the very large quantity of twenty-four pints in twenty-four hours, of the density 1.030, which, calculated from the table published by

Dr. Golding Bird in his most interesting and instructive lectures, contained rather more than twenty-one and a half ounces of dry solid matter!

The density of the urine continued very nearly the same until the sweet taste had disappeared, when it was reduced to 1.020, and exhibited the colour and smell of healthy urine. Most of your readers must be aware of the ingenious reasoning of Dr. Barlow with respect to the operation of ammonia in diabetes. He considers that it is useful not merely by its stimulant properties, but from its elementary constitution; the chemical constitution of ammonia and sugar exhibiting a remarkable similarity with albumen, the nitrogenized product of healthy digestion. Thus Dr. Barlow shows, that when the atomic numbers of certain proportions of ammonia, sugar, carbonic acid, and water, are reckoned together, we obtain the numbers which represent the atomic constitution of albumen. With respect to this ingenious theory, such transformations may be effected within the human body by the agency of nitrogenizing remedies; and the success of the treatment founded upon it tends to confirm the opinion that the formulæ given in Dr. Barlow's paper are not like too many of the present day, which, though looking most plausible on paper, are only to be verified in the laboratory of the chemist. It has been asserted that even the illustrious Professor of Giessen has been carried away by his love of chemical theory beyond the limits which sound physiological experience justifies. We should then be careful, that in our zeal for the novel and unexpected light which that truly distinguished inquirer has thrown upon so many departments of the chemistry of the human body, we should be induced to forget that the stomach is not like the test-glass of the chemist, in which all his agents act according to certain laws, the effects of which are well known and clearly determined. We should remember that Liebig himself cautions us to bear in mind that all the chemical forces which act within the body are influenced by "a power distinct from all other powers of nature, namely, the vital principle;" and, also, "that a rational physiology cannot be founded on mere reactions, and the living body cannot be viewed

as a chemical laboratory." (Organic Chemistry, p. xv.)

With respect to the cause of the disease in the above case, Susan C. does not appear to have inherited any disposition to it, for her mother affirms that none of her relatives were ever affected in a similar manner. The exciting cause was evidently the great loss of blood which she had experienced. Like too many of the poorer classes in this country, she had been in the habit of living almost exclusively on potatoes and other vegetables; but the comparative rarity of diabetes among our potatoe eating population, proves, that though a diet exclusively vegetable may aggravate the disease when once formed, yet that it is not of itself sufficient to induce diabetic symptoms.

OPHTHALMIC SURGERY.

REMARKS ON THE ROYAL WESTMINSTER OPHTHALMIC REPORT.

To the Editor of the Medical Gazette.

SIR,

ALLOW me to inquire, through the medium of your journal, whether some grave error have not inadvertently crept into the report, circulated recently by the committee of the Royal Westminster Ophthalmic Hospital.

It would appear from that statement, dated 25th of May last, not only that during the past year six operations for artificial pupil have been performed, every one of which succeeded, both "in making a new pupil, and in restoring sight;" but, also, that since April 1840, the large number of 1474 operations for strabismus have taken place "without even the occurrence of a single accident."

It is not, however, sir, upon these triumphs of art, surprising as they are, that I intend to trouble you with further observations; the more important item of the report, and that which has called forth my remarks, is to the effect, that of 85 operations for cataract during the past year, 78 or 11-12ths of the entire number have been "completely successful." Of the remaining 7.5 were "partially so;" hence there remain but 2 cases of failure, which are to those of success as 1 to 42.

I presume that by the expression "completely successful" is implied

that, in the cases so described, perfect vision was restored; and that in the other 5, at least imperfect sight was regained. Now, this proportion of cures is almost incredible, because utterly unprecedented,—far exceeding that which has hitherto attended the efforts of able operators, so far, at least, as I have obtained numerical records of their experience. There are in the subjoined list but two accounts of success which in any wise approach the one given in the circular in question; and neither of these is entitled to unhesitating belief, as all the cases in the former were treated by depression, and it is probable, therefore, were discharged at a very early period from beneath the observation of the surgeon, and the latter is in some degree invalidated by the diverse statement of another and a disinterested inquirer. In the following list which I have drawn out, by way of giving a fair view of the usual results of operations for cataract, I have placed these two disputable estimates first: all those which follow are apparently genuine and correct.

In 72* cases of depression at the Hôtel-Dieu of Paris, between the years 1808 and 1819, there were unsuccessful only 9; being one-eighth of the entire number.

In 206† cases of extraction by Daviel, reported by himself, there were unsuccessful 24; less than one-eighth.

In 34‡ extractions by Daviel, reported by Laqué, there were decided failures 9: more than one-fourth. (Between the date of operation and that of the report more than two years elapsed, during which 9 persons additional had left Rheims. Suppose all these to have been successful, still the proportion of failures will be one-fifth.)

In 64* extractions at La Charité between 1808 and 1819, there were failures 25, or two-fifths.

In 10‡ extractions by Richter, there were failures 3: one-third.

In 33* extractions by Antoine Petit, there were failures 8: one-fourth.

In 8* extractions by Dupuytren, there were failures 3: one-third.

In 253* depressions by Dupuytren, there were failures 53: one-fifth.

In 19‡ extractions and depressions

by Morand, La Faye, and Poyet, 7 failed: one-third.

In 19 extractions by Sharp, but half had "tolerable success:" failures one-half.

In 113 extractions and depressions at Hôtel-Dieu, between the years 1806 and 1810, there were 53 more or less successful. Of the 60 in which the result was unfortunate or unknown, allow but 30 for failures, viz. one-fourth of the entire number.

In 179 extractions by Roux, there were failures 72: one-third.

In the total number, therefore, of 1019 cases, 252, or about one-fourth, failed.

Dr. Mackenzie, from whose work I have extracted the three last reports, may be considered to convey his experience in saying, "In the practice of one thoroughly acquainted with eye disease, able to discriminate the cases fitted for extraction and those fitted for division, able to perform those operations well, careful and skilful in the after-treatment, I should think three-fourths of those operated on would recover useful vision, and two-thirds excellent vision:"—a conclusion which tallies pretty closely with the result deduced from consideration of the series of cases just given.

Now although it is probable that, among the 78 cataracts successfully treated by operation at the Westminster Ophthalmic Hospital, several were soft, perhaps congenital, and readily absorbed after exposure to the solvent action of the aqueous humour by the safe operation of division, which does not appear to have been practised in any of the cases cited above; yet so great is the difference between the results obtained in these latter, and those reported from the Ophthalmic Hospital, that one cannot but suppose, unless the report be confirmed, that some mistake has occurred in it. Should such prove to be the case, I shall not regret having called attention to the subject, as an erroneously favourable description of operations is injurious alike to the public, who are led thereby to expect too much, and to the profession, whose members find themselves unable to realize in practice the overwrought anticipations of their patients.

I am, sir,

Your obedient servant,

JOHN F. FRANCE.

CONTRIBUTIONS

to

ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

(Continued from p. 502.)

*On some Varieties in Human Structure, with Remarks on the Doctrine of "Unity of the Organization."*II.—*The humerus : its supra-condyloid process.*

COMPARATIVE anatomists had long ago described a foramen, or short canal, traversing the humerus somewhat obliquely in carnivorous mammals, and they had also described, what could not well escape the most casual observer, that this canal was situated a short way above the inner condyle of the humerus; that it was formed by a process of bone running from the shaft to the inner condyle, and that the humeral artery and its accompanying nerve, the median, in its descent to the bend of the elbow, first passed behind this process, thereafter returning to their original course, or nearly so, by traversing the canal thus formed. Physiologists, as usual, offered a mechanical reason for this deviation in certain animals from the more common structures, and, as usual, their reasons were destitute of common sense. It is not even worth while adverting to them. They resembled Sir A. Cooper's reason for there being two mammae, and Bartholin's reasons for the male having rudimentary breasts, *ne gloriatur femina*, &c.; it is a vile patchwork, almost peculiar to British physiology, a jumble of expedients and contrivances to meet difficulties.

The possible occurrence of such a process as a supra-condyloid in man, accompanied by a corresponding deviation in the course of the artery and nerve, was to be foretold, according to the theories of Goethe, and was, perhaps, perfectly well understood in Germany, but certainly not in this country. I do not believe that any similar preparation to the one now before you exists in Britain. It is not my intention to describe it at any length here, having already done so in a memoir

read to the Anatomical and Physiological Society, and printed in the *Edin. Med. and Surg. Journ.* for 1841. All I mean to do is simply to notice it as a process found on the humerus, a short way above the inner condyle, of varying length, tending downwards towards the condyle, and connected to it by ligamentous or aponeurotic fibres. In most humeral bones I have examined the process is entirely wanting, or nearly so, its absence being a specific human characteristic; in others, human also, there exists a rudiment of it, with a groove above and below it; and in the one before me the process is at least half an inch in length; the artery and nerve pass behind it, and the structures are extremely analogous to those of the panther, tiger, cat, &c. It will not be objected, I trust, to this view that the process is incomplete, seeing that it does not reach the condyle. The course followed by the artery and nerve will form the subject of a few remarks when I speak of the varieties of the human arteries, and referring, therefore, my audience to the memoir already published by me on this matter, I shall confine myself to a single additional remark.

However well known the doctrines of transcendental anatomy were to Goethe, Frank, and others in Germany, there were still some first-rate anatomists, also German, who, about that period, and for some time afterwards, did not rightly comprehend them. Amongst these, it is surprising to find the name of the illustrious Tiedemann, the first of living anatomists. In his great work on the Human Arteries, a very splendid engraving is given of a variety in the course of the interosseal artery, which arose in this case from the humeral artery about the middle of the arm: quitting the course of the larger vessel, the interosseal descended towards the internal inter-muscular ligament, or partition, and passing behind a supra-condyloid process represented in the engraving, fully as well developed as in the specimen on the table, it afterwards regained its position in the bend of the elbow, ultimately following the course of the interosseal. This supra-condyloid process, as it really and truly was, with its ligamentous band tying it to the inner condyle, M. Tiedemann calls an "*ex-crescentia ossis humeri in solita*."

III.—*Osseous system.*

The comparatively rare occurrence of pre-sternal bones in man, more especially perhaps in this country, induces me to publish the following observations respecting them. During the whole period in which I have superintended rooms for teaching practical anatomy in this city, I have never had occasion to observe in a single instance the presence of pre-sternal bones in men, although nearly all the more rare forms of the human sternum have come under my notice; until a few months ago, when describing to my morning class the anatomy of the thorax and its contained viscera. The person in whom these bones occurred was a stout muscular man of a stature exceeding six feet, and about 25 years of age; his general shape was somewhat peculiar, and this, added to a remarkably swarthy skin and black hair, induced me to suppose that notwithstanding his Saxon name, the individual was really of the Celtic race.

But be this as it may, I requested the gentlemen engaged in the dissections to look carefully for any variety in form which might occur, and one of the first was noticed by myself in examining the sternum. Whilst describing the superior aperture of the thorax still covered with soft parts, I remarked to the class that although the sternum was sufficiently broad in most parts, it presented at its *tracheal incisura* or notch a peculiar arrangement, which led me to suspect the presence of an anomalous structure.

Soon after the lecture I examined into what this anomaly might be, and found the narrowness of the superior portion, or rather margin, of the sternum to be owing to the presence of two episternal bones, occupying precisely the position in which they were first noticed by Beclard,* and afterwards by M. Breschet,† and by Mr. King‡ of London.

The specimen I examined with a good deal of attention, but found little to add to the extremely accurate descriptions of preceding observers: situated behind the sternal attachments of the sterno-mastoid muscles, and mesially in respect to the articular surface for the clavicles, the pre-sternal bones are attached by their bases to

the inner or deeper margin of the notch of the manubrium of the sternum; they are of a pyramidal form, and approach each other slightly at their summits. The base of each appeared to me encrusted with cartilage, and there existed a close but distinct moveable joint, with a synovial apparatus, and strong ligamentous bands of a peculiar reddish colour, between them and the sternum; one was less moveable than the other, and a ligamentous band connected them to each other. A few muscular looking fibres, but extremely short, ran from the sternum to these bones.

It is not my intention to enter upon the much disputed ground as to the nature and true signification of these pre-sternal bones; Beclard fancied they might be the rudiments of the fourchette (*clavicule furculaire*), fully developed in birds, and reduced to a mere rudiment, and that too only occasionally present in man; but this idea, however plausible, has not been generally adopted by anatomists: I know not, indeed, that any philosophic anatomist coincides with this view of Beclard's. Mr. Breschet's opinion is, that the sus-sternal or pre-sternal bones represent, or are in man the rudiments of a cervical rib, of which the vertebral portion is very usually found in connection with the 7th cervical vertebra, and was first described by Humauld; and the *sternal* portions of these ribs M. Breschet supposes to be represented by the episternal bones.

Having made extensive researches into the history of these cervical ribs, I am aware of certain difficulties which are opposed to the adoption of these views of M. Breschet. But whatever may be the ultimate determination in respect to the real nature of these bones, it is surely more philosophic to suppose them "rudimentary" of some structure more highly developed in some other class of animals, than to adopt the "Bridgewater" and "Guy's Hospital" physiology, which argues that every animal is made for itself alone, stands alone, and has nothing to do with any other, and that the individual organs of man and animals are to be explained by a physiology whose highest stretch of generalization is to represent the *mammæ* of the human female as having been purposely created double, that the accidental loss of one, by milk abscess, or otherwise, might occasion no

* *Mem. sur Osteos*, p. 83.

† *Annales des Sciences Naturelles*, 1838, p. 91.

‡ *Guy's Hospital Reports*, Vol. 5, p. 227.

interruption to their function! * Profound philosophy! but proving, at the same time, to how little purpose Mr. John Hunter lived and laboured, and bequeathed to Britain his immortal museum, seeing that into the educational institutions of his adopted city he failed to introduce a single spark of his philosophy.

IV.—*Muscular system.*—*Varieties in muscles; musculus-hepatico-diaphragmaticus.*

Muscular system.

In the same person whose sternum presented the pre-sternal bones, I discovered a muscle in a situation altogether unexpected and extraordinary. I shall call it the *musculus hepatico-diaphragmaticus*, or *M. diaphragmatico-umbilicalis*, both names expressing in part its singular course and connexions. The dissection of the part was made in presence of, and explained to, the anatomical class. I copy the description dictated by myself at the time to Mr. Morris, one of the most talented students.

This anomalous and very singular muscle arose, or was connected by a broad tendinous base to the cordiform tendon of the diaphragm, about an inch to the left of the gullet. It was connected with the diaphragm in two ways, or by two slips or attachments: the superior slip terminated shortly in a tendon which descended perpendicularly, or in the axis of the body; the inferior by a series of tendinous fibres which came directly from the tendinous fibres of the diaphragm itself (left portion), and of its cordiform tendon. The muscle or muscular band thus formed by these double origins was about an inch and a half in breadth; it had the same muscular character as the diaphragm itself. Proceeding from left to right, and gradually narrowing, it crossed the middle plane of the body, crossing in succession, 1st, the small portion of the left crus of the diaphragm; 2dly, the gullet; 3dly, the inner portion of the right crus of the diaphragm. Hitherto, the muscle in its course lay close to the concave surface of the diaphragm, but now, descending a little, it subdivides, at its origin, into two parts, a smaller and

larger. The smaller, which was also the descending portion, seemed at first disposed to follow the direction of the right crus, but was soon lost, for after a course of about an inch it terminated by gradually disappearing on the outer surface of the peritoneum; the larger or stronger portion, rather more than half an inch in breadth, proceeded horizontally until it reached the concave surface of the liver, terminating in that sulcus which contains the remains of the ductus venosus. To the lower edge of the obliterated duct the muscle adhered by a series of tendinous fibres, and these might be traced not only upwards to the point where the duct comes off from the sinus of the portal vein, but onwards until it also adhered to the remains of the umbilical vein throughout a considerable space. The broad end of the muscle, near its origin, was now cut through, when a series of short muscles presented themselves, arising by tendinous fibres from the cordiform tendon, and terminating in the same tendon, but something more to the right. All these muscular slips proceeded over the margin of the œsophageal opening.

Here was a new attachment, then, of the liver and its vessels to the abdominal walls.

The usual decussation of the diaphragm was next examined; a strong band of fleshy fibres passed from the left to the right crus, but were in the opposite direction, properly speaking; a small portion only of the right crus lay over the above, but descended no further than the middle plane of the aortic opening.

On examining the remains of the umbilical vein left attached to the liver, the portion more immediately connected with the vena portæ was found enclosed in a sheath of fibres, having all the appearance of muscular fibres; this extended for about 2½ inches; further than this I had no opportunity of tracing it, the parts beyond having been destroyed by a *post-mortem* examination. During the same examination, the abdominal viscera had been removed prior to my own dissection of the above structures.

Future inquiries will, no doubt, some day prove the muscle I have just described, as well as the muscular sheath of the umbilical vein, to be connected with the doctrine of "unity of or-

* Cooper on the Mammaræ; Bridgewater Treatise, *passim*.

ganization" in the animal series, or in the history of the human embryogenesis.

Varieties of Arteries.—1. *Humeral and Interosseal.* 2. *Subclavian.*

I shall first notice a variety in the relation of the humeral artery—perhaps the most remarkable which has as yet been recorded in respect to this artery.

The variety to which I allude is that deviation of the main trunk of the brachial from its usual course, to pass behind the supra-condyloid process of the human humerus, accompanied by the median nerve, and after descending for a short way in the supra-condyloid groove regaining its normal position and course near the bend of the elbow. By a reference to my memoir on the supra-condyloid process in the human humerus, published in the *Edinburgh Medical and Surgical Journal* for 1841, it will be seen, that the artery and nerve, by following this course, reproduce most exactly the normal arrangement in the arm of the tiger, panther, cat, lion, and most carnivorous animals. The authors of the *Bridgewater Treatises*, and their supporters in "Guy's" and elsewhere, are, I think, bound to offer some explanation of these varieties, seeing that they object in toto to the doctrines of "unity of organization," and, indeed, to the transcendental anatomy of Frank, Goëthe, Dumeril, and St. Hilaire. Some plausible reason should in justice to their views be offered why the humeral artery and the median nerve should in some few individuals of the human race follow the non-human arrangement; there must be some reason for this, and since they object to the doctrines of "unity of the organization" they are in justice bound to offer a substitute.*

Since writing and publishing the memoir just alluded to, I find a variety in Tiedemann's great work on the arteries somewhat analogous to the above, but affecting the course of a different vessel. In this case the interosseal artery arose from the humeral artery, about the middle of the arm; quitting the course

* When my brother discovered the curious fact, that in the knee-joint of the ornithorynchus paradoxus the synovial membrane stretches completely across it, forming a partition between the superior and inferior parts of the joint, or in other words two joints, I asked the distinguished author of the *Bridgewater Treatise* "On the Hand" what purpose he supposed such a structure could serve; he replied that he thought it must be to strengthen the joint!

of the larger vessel, the interosseal branch made its way towards the internal inter-muscular ligament, and, passing behind the supra-condyloid process, which M. Tiedemann calls an "excrecentia ossis humeri in solita," it afterwards regains its position in the bend of the elbow. No mention is made of the course of the median nerve in this instance, but it may be presumed that it followed its usual course. M. Tiedemann adds, that this variety had been seen by Ludwig, Sabatier, Monro, Hildebrandt, and Barclay.

2. The next variety affected slightly the course of the subclavian artery, but was also connected with a variety in the arrangement of the scalenus anticus muscle. This muscle, on the right side, in the stout muscular adult in whom the pre-sternal bones were observed, divided into two portions, betwixt which the subclavian artery passed across the rib: the variety seemed to me an approach to that other more important variety in the course of the subclavian, first observed, I believe, by a Parisian student, and pointed out by him to M. Cruveilhier; I allude to the reported passage of the subclavian artery altogether anterior to the scalenus anticus muscle, and close to the corresponding vein: Mr. Spence assures me that he has seen this most remarkable variety *once*; the nearest approach to it I have myself observed is the passage of the artery through the scalenus, as above.

ON THE DOCTRINE OF METAMORPHOSIS.

By HERMANN HOFFMANN, M.D.

Lecturer on the Principles of Physiology in the University of Giessen.

To the Editor of the Medical Gazette.

SIR,

At the request of my friend Dr. Hoffmann, I enclose you a translation of a paper written by him for the *Annalen der Chemie und Pharmacie*, xlv. b. 2 Heft, and regret that, in consequence of numerous engagements, I have been compelled to delay it for so long a time after receiving the proof sheets.

I remain, sir,

Your obedient servant,

GEORGE KEMP, M.B. Cantab.

Cambridge, June 14, 1843.

In consequence of the extraordinary deficiency of accurate data with reference to all those circumstances which relate to the doctrine of metamorphosis (one of the most important in physiology), it appears desirable that every one should assist according to his ability in obtaining some firm principles on which new researches as well as new theories might be founded. We possess, indeed, some observations upon the daily consumption of matter in the human frame; and even if these do not agree very well with one another, still they prove almost to demonstration, that by instituting a greater number of experiments, a satisfactory result will soon crown our efforts. As the consumption of a human being in the condition of customary quiet life has in this manner been ascertained to a certain extent, it appeared to me interesting to make some experiments in order to show the amount of consumption in a condition of considerable increased activity. The practical object of these experiments was, however, to substitute a definite idea, for the vague expressions, fatigue, exertion, exercise, &c.

In the beginning of November 1842, I undertook a journey on foot to a town twelve leagues distant. The weather was damp, cold, ($+4^{\circ}$ R.) and in the beginning of my journey a light snow fell; in the afternoon, however, it cleared up. After walking three leagues,* I was weighed, for which purpose my clothes were taken off, to avoid any error from their probable dampness. The total weight amounted to 124 pounds 6 ounces. The experiment now began. Without halting or putting up anywhere for the remaining nine leagues, I proceeded on my journey. This was by no means too great an exertion, as the road was excellent, and only rendered slightly fatiguing by gentle hills. Besides, the coolness of the weather had a sensibly beneficial influence on the sensation of strength. The quantity of nourishment taken was accurately weighed, and moreover as little, and that of as simple a quality as possible, was eaten, namely, wheat bread, altogether 9 ounces 120 grains.† No fluid was drunk during the whole time, and from the state

of the weather this was not attended by any material inconvenience. Defecation did not take place during the experiment; sensible perspiration also did not occur, a circumstance easily explained by the state of the atmosphere. The nasal mucus was carefully collected in a pocket handkerchief, the weight of which had been previously determined when dry, and was again taken at the conclusion of the experiment. The increase of weight amounted to one loth*, eighty grains. The urine was received into a vessel, the capacity of which was afterwards determined by urine of similar concentration, and the number of vessels thus filled was registered. The weight amounted to one pound, one loth, 60 grs. The first weighing took place at 8 o'clock in the morning; the experiment terminated at 5 in the afternoon, and the weight amounted to 122 lbs. 13 oz. and 28 grs. From the above data, it will be seen that the actual loss of weight is greater than that accounted for by the amount of urine and nasal mucus, the difference arising clearly from the loss by exhalation from the skin and respiratory organs.

I embrace this opportunity for inquiring into another point immediately connected with the above. The question presents itself, how far a renewal of strength can be supplied during its consumption; or, in other words, how far can repose take place without rest? Are rest, sitting, lying, in point of fact so absolutely essential for the renewal of strength as is usually supposed, or is this rule subject to limitations; and if so, what are the conditions under which the exception occurs? The influence of taking food is here also decidedly confirmed. After three hours' walking, immediately after the first weighing a wheaten roll was eaten, which in a short time satisfied the hunger which had been keenly excited by the exercise. After, however, I had proceeded on the whole about six leagues, loss of strength and spirits occurred to such a degree that I hesitated considerably as to the prosecution of the experiment. My companion, a dog, which very perceptibly lost his cheerfulness in proportion as the hungry march was pursued, found himself in the same situation,

* The Hessian league or stund = $2\frac{1}{2}$ English miles.

† A loth = half an ounce.

* 18½ loth.

only much less subject to intentional deception, of which, however, one is totally incapable under such circumstances. Nothing could be more remarkable than the effect which was now produced on man and dog by some ounces of bread. In less than a quarter of an hour I felt myself in a totally different state of mind, and did not for a moment doubt of the success of my undertaking. The dog, however, acquired so much cheerfulness and strength, that he appeared as if he had only just commenced the journey.

Precisely the same result was repeated towards the end of the experiment, only that the dog recovered himself more completely, as he was quite as cheerful at the conclusion as at the beginning of the journey,—a remark not so applicable to myself.

I felt some interest in observing the nature of the origin of the local fatigue, after I had in the manner above mentioned arrived at some conclusions respecting the general lassitude. The experiment was so arranged as to include an extreme case, that of the motion of walking continued as long as possible. Numerous experiments have in this respect completely confirmed the opinions of the Webers on the oscillation of the pendulum. A sensation of fatigue in the fascia lata, and in the thigh generally, the first and most distressing symptoms in persons unaccustomed to walking, remained from the beginning to the end of the experiment. The first was a kind of general stiffness, produced by the continuous uniformity of the motion, the consequence of which was, that motion sideways, &c. was difficult and fatiguing. About one o'clock a contracted sensation was felt in the femoral insertion of the gastrocnemii of both legs, which gradually increased, and was rather distressing. The popliteus, and especially the left, participated in this sensation. After a march of ten leagues, a strained sensation, painful even in stooping, was experienced on both sides of the spinal column, at the iliac insertions of the sacrolumbalis muscles, and which was very troublesome, manifestly in consequence of the exertion of these muscles in keeping the body in the upright, though somewhat bent-forwards position, which was obliged to be constantly preserved. I did not

remark any other sensation of much interest, yet I must observe that towards evening an insupportable chilliness overcame me, which was certainly not attributable to the atmosphere, as it remained unchanged, nor to the clothing, as this was the same as in the morning. I was, however, quite well with the exception of hunger, and I consider this as the cause of the chilliness.

The changes in the circulation and respiration which I experienced in the course of the journey, under similar circumstances, were remarkable. While I usually breathe 13 times per minute at 11 o'clock, I found in this case the number of inspirations and expirations amount to 19 at half-past 10; at half-past 1, 23; at 5 P.M. 22. The pulse, which in the normal state usually gives 80 beats per minute, numbered 105 at half-past 10; at half-past 1, 119, and at 5, 122. I took the precaution of standing still for 3 minutes before counting the pulse, and then registered the average of from 4 to 6 minutes. Notwithstanding this violent fever, I experienced no heat, and remark expressly, that the cause of this increase of the heart's action, &c. was not the ascent of the hills. At 11 P.M. after supper, the pulse was at 88, and the number of respirations 17. The urine, which was passed in the evening soon after the experiment, deposited a considerable quantity of urate of ammonia, a circumstance very unusual in this place. Should I attribute this to a quantity of wine taken previously, or to the walking? It appears from what I am about to communicate that the first supposition is the more correct.

For greater security, I repeated this experiment with my friend Mr. Sullivan. The temperature and weather were almost precisely the same as in the former case; the air, however, was somewhat drier. The experiment took place at the beginning of December 1842. The journey extended to ten leagues, which we divided by an interval of one hour's rest.

My weight at the commencement, about 8 A.M., amounted to 121 lbs. 12½ oz. The food, including a pint of light French red wine, weighed 1 lb. 1 oz. The loss of urine amounted to 1 lb. 4 oz.: the mode of measurement was the same as in the former case; that is to say, the last portion emptied

in the evening was directly weighed, and the weight found taken as the medium standard. The nasal mucus might be estimated the same as in the former experiment, 320 grs. Defecation did not take place. As the weight at 8 P.M., at the conclusion of the experiment, amounted to 120 lbs. 10½ oz., the additional loss of 14 oz. 284 grs. must be considered as the result of perspiration. At 11 A.M., the number of inspirations and expirations was 16; at 8 P.M. more than 14: the pulse, at 2 P.M., gave 85 beats; at 8 P.M. 95. Before the numbers were registered, longer pauses of rest were taken than in the first experiment, which may even be observed from the calculation, particularly in that of the evening. If, now, a man, weighing 115 lbs. perspires during motion 14 oz. 164 grs. in eleven hours, this amounts to 0·49,880 of a grain to every 100 of his weight, or 0·075,584 of a grain for every 100 minutes.

My companion weighed 140 lb. 6 oz. 120 grs. at the beginning of the experiment. The food, as above, amounted to 1 lb. 1 oz. The quantity of urine determined, as in the above case, amounted to 2 lbs. 1 oz. 54 grs.; the nasal mucus was assumed, with every appearance of correctness, to weigh 320 grs. Defecation did not take place. As now, the weight in the evening, at 8 o'clock, amounted to 137 lbs. 12 oz. 180 grs., this gives a remainder of 1 lb. 6 oz. 136 grs., which must be attributed to the perspiration.

The pulse, which usually beat only 64 times per minute, had increased to 70 at 2 P.M.; and at 8 P.M., after some rest, still remained at 70. The number of respirations, usually amounting in the morning to 13½, increased at 11 A.M. to 16, and at 8 P.M. to 19. Thus,

Amount of perspiration in a man at rest for each 100 grs. during a space of 100 minutes=0·030272 grs. (Hoffman)
 =0·1138 (Dalton*)
 =0·1581 (Lavoisier and Seguin†).

Amount of perspiration in a man in motion, reduced to the same standard of time and weight— I. II.
 =0·10119 grs. 0·075584 grs. (Hoffman)
 =0·1575 (Sullivan).

I have analysed the urine passed after the second experiment, without having taken food for some hours previously.

the 134 lbs. which Sullivan weighed, reduced to 100 grs. and 100 minutes, gives 0·1575 of a grain of perspiration.

The urine, as in all the other cases mentioned, was very saturated, of a bright orange colour, and deposited no sediment within 24 hours; it therefore did not contain any remarkable amount of urate of ammonia.

For the purpose of having a standard of comparison, I some time afterwards made the following observations on myself, respecting the consumption in a state of rest. Selecting for the purpose a day in which the temperature and hygroscopic condition of the atmosphere were similar to the above, I kept constantly in my room at a temperature of 13 R.; for the weighing merely I stepped out a few hundred paces. The day was employed in study, half of the time standing, half sitting. The first weighing took place at half-past 8, and amounted to 123 lbs. 8 oz.; nothing was taken either for nourishment or drink. The loss in urine was 1 lb. 20 grs. The second weighing, at 4 o'clock, gave 122 lbs. 7 oz. Defecation did not take place, and the nasal secretion was considered=0: the perspiration here, then, amounted only to 4 oz. 120 grs.; the urine was also much lighter than in the other cases.

The respiratory action at 11 A.M. was 13, at half-past 4, 14: the pulse at 11 A.M. was at 80, at half-past 4 P.M., 80. If we calculate this as above, we have for the 115 lbs. in 100 minutes, 0·14,529 grs.; for 100 grs., however, in the same interval, 0·030,272 grs. of perspiration.

We may sum up the results as follows, comparing the amount of perspiration secreted in 100 minutes with 100 grs. of the body.

* Calculated from Dalton, who found the perspiration in March to amount to 37 ounces Total weight, 140 lbs.

† According to Lavoisier and Seguin, who state the amount of perspiration as 51 oz. daily. Here, also, the total weight=140 lbs.

In 1000 parts, the water=977,221
 Solid matter= 22,779
 1000 parts of the solid matter gave
 Ash=539,806
 Sulphuric acid= 80,581

For the purpose of determining the quantity of sulphuric acid, the ash was dissolved in water containing nitric acid, and the sulphuric acid precipitated by means of muriate of barytes. The sulphate of barytes was now exposed to a red heat, and the acid thus calculated. This urine deposited no sediment.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

REMUNERATION IN GENERAL PRACTICE.

A GLANCE at the notices of motions about to be made in the House of Commons is calculated to make one think that the medical profession, whatever chance it may have of getting an act passed for its government, is very unlikely to receive much real attention at the hands of ministers or members of parliament. It is difficult to conceive that much interest could attach to the subject, after the energies of statesmen have been unremittingly exerted for so long a time in the altering or preserving some of the most fundamental portions of our constitution, and in discussing questions which seem to involve its very existence.

Should we from this cause be doomed to slovenly and crude legislation, there will be much matter for regret, but should we escape legislation altogether it may fairly be questioned whether we shall lose much by the omission. Physiology tells us, and experience proves, that total fasting for a time, when the mind or body are over fatigued, is preferable to a full meal, and that a

hasty one involves certain dyspepsia—it may be that the humours of our body politic suffer in the same way from exhausted energies, and that feverish, peevish dreams, without refreshment, may be obtained instead of sound repose.

It is worth considering, in the meantime, how many of our acknowledged evils, and of what kind, are capable of removal by personal and private exertions; for if the delay of public measures awaken amongst us a hearty desire, and keep up an enlightened endeavour for that purpose, the advantages gained will not be trifling.

The greatest, because the fundamental evil, from which the profession suffers, is undoubtedly a superabundance of practitioners, yet public legislation can only prevent this by making the entrance to the profession more difficult. This the Society of Apothecaries has already succeeded in doing to a great extent, by their enlarged course of study, which, however censured for its quality, leaves no doubt as to its greatly increased quantity. The young Milos of the present day have to lift their daily increasing burden for a much longer period than formerly, ere they are to be trusted as active supporters of the public health; and if some of them, in the flush of youth and pride of training, have attempted injudicious tasks beyond their strength,—if they have got their fingers pinched and themselves pilloried for their presumption, let us hope that none have been quite devoured for their indiscretion. The education of the present day is, and must be, in a great degree experimental. New wants have had to be supplied, both intellectual and social, and new means were necessarily resorted for the purpose. That in the attempt to supply what was deficient much that was highly useful was hastily abandoned, must be admitted by all

ancient languages, and their toilsome but instructive acquisition are among the things obsolete, and false quantities and misplaced aspirates are so common, that not only are the fastidious ears of old Etonians offended, but even the utilitarian who late in life has brightened his massive intellectual machinery with the high polish of literature, or covered it with a thin coating of glittering material — laying on a little Latin and less Greek — often receives a shock to his grammatical susceptibilities. These matters are in course of improvement. In medicine, as in divinity, during the last half century, gigantic energies newly aroused started into irregular and misdirected action, which sobriety and good sense have to reduce by order, method, and discipline. The far-seeing speculator may be forgiven his anxieties, lest the very great need which has so evidently existed lately for forms and methods, for order and for discipline, may not have been too hastily and actively recognized, and danger thereby incurred that formality, prescription, and the wisdom of our forefathers, may again be too implicitly relied on.

We have no such fear. In a few months, by means of the Sydenham Society, the sterling old medical classics will be in the hands of many hundreds of our brethren. Many of those who read them for the first time will pay the cheerful homage of respect to the sages of former days; a few will be tempted into a half idolatrous worship, an overvaluing of patristic authority; others will sink into a feeble and fruitless diletantism, their love of literature being fussy and fondling, but barren and unseemly as the love of old age is apt to be; but can it be doubted that to sound, active, and vigorous minds new views will be suggested, new doubts resolved, new truths begotten?

One or two of the more prominent mistakes which in their daily consequences affect the credit, the comfort, or profits of our brethren, cannot too often be pointed out, that constant efforts may be made for their correction. No greater service, indeed, can be done than directing the combative energies which have so painfully been exerted against particular individuals or bodies, as the only cause of all our evils, to the removal of the evils themselves.

Now one of the practical evils of the present day is connected with the sale of drugs. In this matter altered circumstances have converted one or two truths into fictions, and this process never takes place without great inconvenience and suffering somewhere, while the redressing the evils which have arisen is no less disagreeable, often more so, as resuscitation is more painful than drowning.

The notion that every diseased state may be cured by a particular drug, or combination of drugs, has pervaded medical practice from its earliest times. The physician has been paid for pointing out, the apothecary for preparing this drug. The exclamation, "*Hei mihi quod nullis amor est medicabilis herbis*," shews the very pharmaceutical notion which the poet had of Apollo's medical skill; and happy is the practitioner who, when asked what is the best thing for this or the other symptom, neither loses his patience at the absurdity of the question, nor contributes to keep up the delusion by naming some approved simple. One result of this rude notion of physic is, that when the public are informed of any change in the medical theories of the day, or get mystified by the pretensions of some arch quackery or medical heresy, though their confidence in the prescribers is shaken, their confidence in the drugs remains

as great as ever; they merely substitute their own prescriptions for those of the doctor. Honour, then, in due measure to homœopathy! it is doing its mission for the abolition of mere druggistry, and the inculcation of dietetic and other discipline. We were informed lately, by a reverend practitioner in a small way, that 200 homœopathic medicine-chests had been supplied lately, and are now being used by as many clergymen alone. Multiply these by their probable number of patients in the middle class, and the product, may we not hope, will represent the number of persons who are in a fair way to cease from drugs, especially of their own prescribing, and to confide in enlightened medical science whenever it shall be prepared with its proofs; or if it be insisted on that the intellectual calibre of such patients is, by their present credulity, proved to be below the average, then, at least, "fiet experimentum in corpore vili," they will work out some problems in expectant medicine which, with our present notions, we cannot conscientiously attempt. If Sir James Graham had a little breathing-time between the Irish Arms Bill, the Factory Education Bill, and other pressing matters, we would suggest that the statistics of homœopathic practice should be furnished to the Home Office. A few registrarships and commissions in this department might be handed, in the meantime, to the unemployed regular practitioners, who might thus be kept alive to note the issue of the experiment.

To the general practitioner the present state of opinion is most important, and calls for a rigorous scrutiny of principles, and a steady adherence to whatever course will produce really the best general results, even if some present personal sacrifice be thereby rendered necessary.

The practice of making a charge for

medicines should be discontinued, and that of specifying and charging for visits introduced. Two modes of proceeding, then, suggest themselves; one is, the writing prescriptions to be made up at a druggist's, the other is the supplying medicines either gratuitously or at small profits. The first leaves the main evil just where it was; the prescription, when obtained, will be valued more than the advice, and the charges being necessarily smaller than the fee of the physician, the erroneous principle will be still more widely diffused. Besides, the profits of the druggist are at present large, and were founded on estimates which have become erroneous. Until of late years, the preparation and retail of medicines was in the hands only of apothecaries, persons skilled, more or less, in the art of administering them, the price of whose education was charged on the materials in which they dealt: these materials acquired a great real value from the skill and labour bestowed upon them—an increase of value like that acquired by a pound of iron when made into watch-springs.

When drugs, too, were more rare and costly, and the supplies uncertain, much more capital was required for the wholesale market than at the present time. Enormously increased demand, and manufacturing improvements in the supply, have also contributed to lower the price of chemical products, though certainly the outlay of capital in effecting those improvements must be admitted on the other hand. Yet with all these changes, and while the price of a medical visit has virtually decreased, the charge for a draught at a good druggist's is still a shilling. This is understood to be the cost of the medicine and of the skill required in preparing it. Four of these draughts a day will be the most paid for when a medical visit is

made daily, or on alternate days. The average payment for the visit, then, is 5s., and for the medicine 3s. Surely so monstrous a disproportion cannot habitually exist without gradually warping the public feeling as to the relative value of each. The judicious and conscientious practitioner will draw the right inferences from this statement, and will so arrange as gradually to bring about a better state of matters; and this he will do, not by mystifying, but by enlightening the public: the light afforded being by his actions, not by declamatory talking. Many attempts have been made to bring the parties interested to meet and combine for the purpose of settling, and if possible enforcing, their claims for attendance; but the success of such combinations is small, and the limits within which they are justifiable are not clear. More may be done, and better done, through a quiet consideration of the subject by individuals, and by keeping in view the broad principle of remuneration for time and skill, not for medicine. We have purposely kept in view a distinction between charges and fees: a fee is a gratuity, and implies an entirely different tone of feeling in the donor and the recipient from that which it would be prudent to adopt in general practice. Let fees still be large, and still given as the reward of superior attainments: this will tend to keep the consulting practitioner in his only true and proper position—that of a person whose position makes great things to be expected of him. To this elevation all who think themselves qualified for it may now rise; if they assume it without due powers to support it—and sufficient pecuniary means are amongst those powers—the fault is theirs.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

June 27, 1843.

THE PRESIDENT IN THE CHAIR.

On the Influence of Rickets upon the Growth of the Skull. By ALEXANDER SHAW, Esq. Surgeon to the Middlesex Hospital.

THIS paper was the sequel of one by the same author, printed in the 17th Vol. of the Society's Transactions. The object of the former publication was, in the first place, to prove that, besides causing softening and distortion of the osseous system, rickets has the effect of arresting the process of growth; and secondly, to show that, owing to this interruption, the proportions of the figure peculiar to the adult are not perfectly attained by persons affected with the disease, but continue to be more or less those of the child. The figure of the child is characterised by the head, trunk, and upper extremities, being of large dimensions compared with the pelvis and lower extremities, while that of the adult has the former parts relatively small, and the pelvis and legs large and powerful. In persons deformed from rickets, the whole figure is stunted; but the head, trunk, and upper extremities together, when compared with the natural adult dimensions, are only defective to a slight degree (one-thirteenth), while the pelvis and lower extremities are defective to a great degree (one-third). This difference the author accounted for by supposing that, as the disease stops the growth, it interrupts at the same time the change then in progress of being produced in the relative proportions of the figure; and so causes the patient, when arrived at adolescence, to exhibit traces of the configuration of the child. Having referred to the importance of this view in relation to the size of the pelvis in child-bearing women deformed from rickets, and stated that by measuring numerous specimens he had ascertained that the defect of growth in this part amounts, on an average, to nearly a quarter of the natural size, he proceeded to apply the same principle to the explanation of a peculiarity in the form of the head which he had observed as a general character in ricketty persons. This peculiarity consists in a disproportion between the size of the cranium and of the face. Between infancy and adolescence, a change in the relative proportions, analogous to that which occurs in the figure generally, takes place in the skull. Near birth, its form is characterised by the cranium being of large bulk compared with the face: while at adolescence the contrast is greatly diminished, owing to the face having become much bulkier in comparison with the cranium than it had originally been. The author had remarked, and confirmed his observations by

numerous measurements, that the skull, in ricketty persons, does not attain the proper adult proportions; but, on the contrary, the cranium appears remarkably large compared with the face, just as during childhood. Thus, taking the dimensions of the face as the limit of comparison, he found that in the skull of the infant the size of the cranium is as 8 to 1; in the adult, as 6 to 1; and in the ricketty person (although beneath the standard size), as 7 to 1. He explained this disproportion by supposing that, as rickets arrests the growth, it interrupts, at the same time, the change occurring in the relative proportions of the skull between infancy and adolescence; and thus gives rise to the child-like character of the proportions. The proposition was illustrated by showing the contrary effects which an increased activity of the growth produces. In the figure generally, when the growth has been preternaturally active, as in tall persons, the effect of the unequal rate of development in the two divisions of the frame is shown by the lower extremities acquiring an undue length compared with the trunk; so, in the head, the face becomes disproportionately larger compared with the cranium: thus by measuring the skull of the giant preserved in the museum of the College of Surgeons, the author found that the dimensions of the cranium (although above the standard size) are, to those of the face, only in the proportion of 5 to 1 in this skull. Having next shown that the orbits always preserve a uniform size, whatever be the dimensions of the face, in skulls of different proportions, and accounted for this fact by referring to the anatomical relation of the frontal and maxillary sinuses to these cavities, and showing that the two sinuses vary in capacity according to the rate of growth, he passed to the consideration of the growth of the maxillary bones. After dwelling on the difference in the mode of formation of the teeth as compared with the jaw bones, and the importance of an exact relation being preserved between the development of both parts, and referring to the observation of Hunter regarding the different rates of growth in the anterior and posterior divisions of the maxillary bones, he concluded by showing that, as rickets has the effect of interrupting the growth of the jaw bones, it deranges also the process of evolution of the teeth.

An Account of a Case in which a Foreign Body was lodged in the Right Bronchus.
By SIR BENJAMIN C. BRODIE, Bart.
F.R.S. Sergeant Surgeon to the Queen,
&c. &c.

The author's object in this paper was to describe a case in which a half-sovereign was lodged in the right bronchus of the patient for a period of thirty days, and in which

certain novel measures adopted for its removal proved successful. It was on the 3d of April, while the patient, Mr. B., was amusing some children, that the coin which he had in his mouth accidentally slipped into the trachea. The symptoms which succeeded were principally occasional severe fits of coughing, and a sense of pain referred to a part of the chest corresponding to the situation of the right bronchus. No particular sounds were detected by the use of the stethoscope. The patient was able to pursue his usual avocations, and made two journies into the country. On the 19th of April, having placed himself in the prone position, with the sternum resting on a chair, and his head and neck inclined downwards, the patient had a distinct perception of a loose body slipping forwards along the trachea; a violent convulsive cough ensued, and, on resuming the erect posture, he again had the sensation of a loose body moving in the trachea towards the chest. An apparatus of the following kind was now constructed. A platform, on which the patient could lie prone, was made to move on a hinge in the centre; so that on one end of it being elevated the other was equally depressed. On the 25th of April the patient was laid on this apparatus, with his shoulders and body fixed by means of a belt, and his head was lowered to an angle of nearly 90 degrees with the horizon. His back was then struck several times with the hand, but violent fits of choking were brought on each time, and it was not deemed prudent to continue the experiments. On the 27th it was agreed in consultation to make an opening in the trachea, between the thyroid gland and the sternum. In proposing this, the object was two-fold: 1st, that an attempt might be made to extricate the coin by the forceps; 2d, that if relief could not be obtained in this manner, the artificial opening might answer the purpose of a safety-valve, and the experiment of inverting the body on the platform be repeated without the risk of causing suffocation. The operation having been performed, several attempts to extricate the coin were made, but without success; and, on each introduction of the forceps, paroxysms of convulsive coughing of such a violent kind were brought on, that it was plain that the attempts could not be persevered in without danger to life. On the 2d of May, a renewal of these trials was followed by the same results. On the 13th, the wound in the trachea having been kept from closing by the occasional introduction of a probe, the patient was placed on the moveable platform as described before; his back was then struck by the hand; two or three efforts to cough followed, and presently the patient felt the coin quit the chest, striking, almost immediately afterwards, against the incisor teeth of the upper jaw.

and then dropping out of the mouth. No spasm of the muscles of the glottis took place; a small quantity of blood was ejected at the same time, apparently coming from the granulations of the external wound. From this date the patient proceeded rapidly to get well.

The author concluded by making observations on the following heads:—1st, on the influence of the size, weight, and form of a foreign body introduced into the wind-pipe, in modifying the symptoms; 2d, he referred to experiments which showed that a heavy body, like the coin in the present case, was most likely to drop into the right bronchus; 3d, he adverted to the want of success attending the use of the stethoscope in this and in some other cases of the same kind; 4th, he pointed out the reasons on which he had founded his opinion, that the artificial opening made in the trachea would prevent spasm in the glottis, and thereby give greater chance of success to the experiment of inverting the patient's body on the moveable platform; lastly, he dwelt on the difficulties and dangers attending the use of the forceps, when a weighty body is lodged deeply in one of the bronchi, as was the case in his patient.

Statistics of Bethlem Hospital, with Remarks on Insanity. By JOHN WEBSTER, M.D.

In this paper the author brought before the Society a few statistical tables compiled from the registers of Bethlem Hospital, accompanied by a synopsis of seventy dissections recently performed at that institution.

According to these tables, it appears that 4,404 curable patients of both sexes were admitted during the last 20 years, of whom 1782 were males, and 2622 were females—thus giving 47 per cent. more women than men. During the same period, 1446 female patients were discharged cured, that is, 55½ per cent. on the admissions; whilst only 823 male patients left the hospital convalescent, or 46½ per cent. On the other hand, the number of deaths in both sexes, although exactly equal, or 112 of each, yet calculated according to their respective admissions, the rate among the male patients was 6½ per cent. and only 4½ per cent. among the females. Similar results were likewise found to prevail among the incurable lunatics of both sexes. The author therefore concludes that insanity is not only more common among women than men, but also a more curable disease; so that, *cæteris paribus*, the prognosis may be considered as more favourable in female than male patients. The diminished rate of mortality, and the greater proportion of recoveries, are also clearly shewn by the records of the

institution; since it appears that during the three years ending the 21st Dec. 1752, the proportion of patients discharged cured was only 31½ per cent. on the total admissions; whilst for the three years ending Dec. 31, 1842, the cures amounted to nearly 55 per cent. The ratio of deaths, also, during the former period, was as high as 25½ per cent.—but only 5½ during the last named three years—that is, about ¼th the amount reported nearly a century ago.

The author next remarks on the diminished number of suicides in the insane patients admitted into Bethlem; observing, at the same time, its greater frequency among males than females.

A synopsis is next given of seventy dissections recently made by Mr. Lawrence, in which the various morbid appearances met with are carefully detailed.

The author concludes his paper with an allusion to the two sections of pathologists at present dividing the opinions of medical writers respecting the diseased alterations of structure met with in cases of insanity, viz., the “anatomists and vitalists,” the former considering them as causes, the latter only as consequences, of the previous mental affection. In his opinion the theory of the anatomists is the more rational, and most in accordance with the present state of our knowledge of the pathology of mania.

On the Presence of Spermatozoa in the Fluid of Hydrocele. By A. LLOYD, Esq. Assistant-Surgeon to St. Bartholomew's Hospital, and Surgeon to Christ's Hospital.

The object of the author was to announce that he had met with, since the last meeting of the Society, a third case of hydrocele, in the fluid of which an immense number of spermatozoa were present. The fluid was of paler colour than that of common hydrocele of the tunica vaginalis, and very much resembled water with which a very small quantity of milk had been mixed. When tested with nitric acid, and also with heat, the fluid was found to contain a considerable quantity of albumen. There was also much saline matter in it. When examined with the microscope from three to four hours after it was drawn off, there were seen spermatozoa in a living state, and also an immense number that were dead: moreover, the fluid contained a few blood-discs, transparent cysts, granular bodies of different sizes, and epithelial scales. The testis and its appendages were healthy. From the situation and form of the tumor it appeared that the fluid was contained in the tunica vaginalis. The spermatozoa were seen in a living state by Mr. F. Wood, Surgeon, of Brownlow Street, and by Mr. John Quekett, of the College of Surgeons.

Pathological Researches into the Local Causes of Deafness, based on one hundred and twenty dissections of the Human Ear. By JOSEPH TOYNBEE, F.R.S. Surgeon to the St. George's and St. James's Dispensary.

The researches of which this is a summary view, are in continuation of a previous paper contained in Vol. 24 of the Society's Transactions. The principal practical conclusion to which they lead is, that the most prevalent cause of deafness is chronic inflammation of the mucous membrane which lines the tympanic cavity; and that by far the greater majority of cases commonly called nervous deafness ought more properly to be attributed to this cause.

The pathological conditions to which inflammation of the mucous membrane gives rise are divided in the paper into three stages.

In the first stage the membrane retains its natural delicacy of structure, though its blood-vessels are considerably enlarged and contorted; blood is effused into its substance, or more frequently at its attached surface; blood has also been found between the membrane and the membrane of the fenestra rotunda, and in very acute cases lymph is effused over its free surface.

The second stage is characterised by the following pathological conditions:—

1st. The membrane is very thick, and often flocculent. In this state the tympanic plexus of nerves becomes concealed, the base and crura of the stapes are frequently entirely imbedded in it, while the fenestra rotunda appears only like a superficial depression in the swollen membrane.

2d. Concretions of various kinds are visible on the surface of the thickened membrane. In some cases these have the consistence of cheese, and are analogous to tuberculous matter; in others they are fibro-calcareous, and exceedingly hard.

3d. But by far the most frequent and peculiar characteristic of this second stage of the disease, is the formation of membranous bands between various parts of the tympanic cavity. These bands are at times so numerous as to occupy nearly the entire cavity; sometimes they connect the inner surface of the membrana tympani to the internal wall of the tympanum, to the stapes and to the incus. They have also been detected between the malleus and the promontory, as well as between the incus, the walls of the tympanum, and the sheath of the tensor tympani muscle; as well as between various parts of the circumference of the fenestra rotunda. But the place where these adhesions are most frequently visible is between the crura of the stapes and the adjoining walls of the *tympanic cavity*: this was the case in twenty-four instances out of a hundred and twenty

dissections, being a fifth of the number. These bands of adhesion sometimes contain blood and scrofulous matter.

In the third stage of inflammation of the membrane it becomes ulcerated; the membrana tympani is destroyed, and the tensor tympani muscle is atrophied. The ossicula auditus are diseased, and ultimately discharged from the ear, and the disease not unfrequently communicates itself to the tympanic walls, affecting also the brain and other important organs.

The following is a tabular view of the mucous membrane of the tympanic cavity in the 120 dissections related in this paper.

In the first stage of inflammation.

- | | |
|---|----|
| 1. With simple inflammation of the membrane, its vessels being enlarged, tortuous, and distended with blood | 10 |
| 2. Ditto, with an accumulation of mucus | 1 |
| 3. Membrane inflamed, with effusion of blood into its substance . . . | 3 |
| 4. Membrane inflamed, with effusion of serum, tinged with blood, into the tympanic cavity | 1 |
| 5. Membrane inflamed, with lymph effused into the tympanic cavity . . | 2 |
| 6. Membrane inflamed, with blood and lymph effused into the tympanic cavity | 2 |
| 7. Membrane inflamed, with effusion of pus into the tympanic cavity . | 1 |

Dissections illustrative of the second stage of inflammation.

- | | |
|---|---|
| 1. With simple thickening of the lining membrane | 5 |
| 2. The membrane thick and pulpy . . | 2 |
| 3. Ditto ditto and the cavity full of bands of adhesion. | 1 |
| 4. The membrane thick and flocculent. | 1 |
| 5. Membranous bands connecting the membrana tympani to the inner wall of the tympanum | 5 |
| 6. Membranous band connecting the membrana tympani to the promontory and the chorda tympani to the stapes | 1 |
| 7. Membranous bands connecting the membrana tympani to the incus . . | 1 |
| 8. Ditto ditto to the stapes. | 2 |
| 9. Ditto connecting the membrana tympani and chorda tympani nerve to the stapes | 1 |
| 10. Ditto connecting the membrana tympani and malleus to the promontory | 1 |
| 11. Ditto connecting the membrana tympani to the incus. | 2 |
| 12. Ditto connecting the membrana tympani and assecles to the inner wall of the tympanum | 1 |

13. Ditto connecting the malleus to the inner wall of the tympanum . 2
14. Ditto connecting the incus to the inner wall of the tympanum . 1
15. Ditto connecting the stapes to the promontory . 24
16. Anchylosis of the stapes to the fenestra ovalis . 2
17. Membranous bands, forming a network over the fenestra rotunda . 2
18. A broad membrane passing from the promontory to the mastoid cells . 2
19. The cavity of the tympanum full of bands of adhesions . 1
20. Membranous bands containing scrofulous matter . 3
21. The cavity of the tympanum full of calcareous concretion . 4
22. Ditto, full of caseous concretion . 2
23. With ridges of bone projecting from the surface of the promontory . 2

Dissections illustrative of the third stage of inflammation.

1. With ulceration and thickening of the mucous membrane, attended by the formation of pus . 3
2. With ulceration of the membrane, and loss of one or more of the *vasicula* . 3

It thus appears that of the 120 dissections there were—

- 20 Specimens in the first stage of inflammation of the tympanic cavity
- 65 Ditto in the second stage
- 6 Ditto in the third
- 29 Ditto in a healthy state.

120

DR. STÖBER ON THE DISEASES OF CHILDREN.

[Concluded from page 511.]

Acute Hydrocephalus.—In two patients out of three who were treated for this disease, on the day before their death, the author found a peculiar alteration of the cornea, which he had already observed in four other patients. It consisted of a semilunar yellowish covering at the lower edge of the cornea, without any injection of the eye. When the disease has lasted long, this covering extends towards the centre of the cornea, and suppurates; its lamellæ then appear to be separated from one another by purulent infiltration, and turned outwards, which gives the disease a different character from all ulcerations of the cornea. Of six patients, in whom the author observed it, three were suffering from acute hydrocephalus; the fourth had an ulcer on the head, which had

eaten through the skull and membranes, and attacked the brain itself, whose substance was softened around the superficial ulceration; the child died in a few days of scarlet fever. The fifth child died of pneumonia, which came on in the course of acute hydrocephalus, after which was found a serous infiltration of the pia mater. Lastly, the sixth patient was an adult, who had been treated for pneumonia with large blood-lettings, and had fallen into a state of great debility. He alone recovered.

In four of these patients the alteration of the cornea appeared one or two days before death, and remained in the state of a mere covering; in the fifth, who lay several days in a comatose condition, the alteration of the cornea increased more and more, and at last passed into suppuration. In the case of pneumonia also suppuration ensued.

In three cases the author observed that the eyes were half open, and that then the uncovered part of the cornea became diseased. In the other three cases attention had not been paid to this circumstance, which perhaps was the cause of the morbid change. The author, however, does not think that the long-continued access of the air to this part of the cornea was the sole cause of the disease, but rather that the general debility had the greatest share in the suppuration; and that the malady had been preceded by a state similar to that existing in the dogs which Magendie fed on sugar, and in whom likewise the cornea suppurated.

Accordingly, the author cured the pneumonic patient [of this disease with bark, strengthening diet, and dropping laudanum and oil into the eye.

Convulsions.—In the great majority of cases they are a symptom of other diseases; and in some instances they depend on causes which leave no trace that can be detected after death. The author quotes several such cases.

Scrofula.—In all scrofulous cases Dr. Stöber gives animal diet and wine; in slighter cases, with a lymphatic constitution, disposition to cold in the head, ophthalmia, and glandular swellings in the neck, he administers tonic remedies, such as tr. gentianæ c., Hoffman's elixir vitæ, and baths of hay flowers or hazel-leaves; and employs iodine externally and internally for swelled glands of long standing. He treats scrofulous ulcers with red precipitate ointment; if they are very flabby, he avoids all fat substances, sprinkles them with red precipitate, and employs a dry bandage. For swellings of the nose and upper lip, he uses a white precipitate ointment. In scrofulous affections of the bony and fibrous system, caries, white swellings, &c., cod liver oil was very useful; but had no effects in swelling of the glands.

The author confirms this by several cases, so that it appears that the efficacy of this remedy does not depend on the iodine which it contains, as iodine is known to be very efficacious in diseases of the glands.

In scrofulous inflammation of the eyes, general and local treatment are equally necessary. Among general remedies, iodine and cod liver oil are too slow; mercurials and antimonials are more active. The author gives one or two grains of a mixture of equal parts of calomel and *sulph. aurat. antim.* three times a day; he continues this for three or four weeks, and then administers a purgative. If the scrofulous symptoms continue after an interval of eight or ten days, he gives the remedy again for three or four weeks. It produces stools several times a day, but rarely salivation. He rightly rejects antiphlogistics, especially the abstraction of blood, in this disease; but recommends blisters to the back of the neck, particularly in old cases, where the inflammation and intolerance of light are violent; or where the former is combined with a considerable morbid secretion; or in relapses.

Among external remedies, the most efficacious were the following: a collyrium containing corrosive sublimate and laudanum, or *lapis divinus* and laudanum, or the *extr. lactucæ vir.*; a red precipitate ointment; Rust's ointment; or an ointment containing nitrate of silver. The last was of special service in *blepharitis glandulosa*, as Rust's was in inflammation of the conjunctiva alone, or of the cornea and conjunctiva together. When the cornea is ulcerated, one drop of laudanum is dropped in once or twice a day. When the intolerance of light is very great, and does not yield to a stimulating and revulsive treatment continued for several days, Dr. Stöber has recourse to belladonna fomentations. He has seen no benefit from the application of cicuta and the tincture of *rhus toxicodendron*. [Nor the German translator neither.]

Polypus of the rectum seems to be more frequent in children than adults.

Abscesses of the hairy scalp always arise in consequence of eruptions on the head, such as impetigo; rarely from *tinea mucosa*, never from *tinea favosa*.

OVARIAN DROPSY.

Our correspondent, Mr. Walne, has recently removed, with success, another drop-sical ovarium, in its entire state, by the large abdominal section. It weighed sixteen pounds and three-quarters. Some circumstances having occurred in the course of the patient's recovery, giving a fresh interest to the subject, the particulars will shortly be submitted to the profession. Mr. Walne's former case has been too recently before our readers to have escaped their recollection (*MED. GAZ.* Dec. 24, 1842.) The patient, we are informed, now enjoys excellent health and spirits, walks long distances, and experiences no kind of inconvenience as a consequence of the operation performed in the early part of November last.

LECTURES
ON THE
**THEORY AND PRACTICE OF
MIDWIFERY,**

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXXIV.

*On labours complicated with uterine
hæmorrhage, occasioned by detachment
of the placenta from the superior part of
the uterus.*

FLOODING may take place in the latter months of pregnancy, and during labour, where the placenta does not adhere to the neck of the uterus, but to the body or the fundus, and is detached by some external or internal cause. The separation of the placenta from the upper part of the uterus may be produced by violence, as blows, falls, pressure over the hypogastrium, and shocks of various kinds; but it arises much more frequently from internal causes, of which, morbid states of the placenta, and twisting of the umbilical cord once or oftener around the neck of the child, are the most common and obvious. This variety of hæmorrhage, though usually termed accidental, can rarely, however, be referred to accident. Sometimes the flooding occurs to a great extent without any assignable cause; a large portion or the whole of the placenta, when in a healthy condition, being suddenly detached from the uterus, when the patient has been exposed to no external accident, or injury of any kind, and when no symptoms of increased determination of blood to the uterus have preceded the attack. When this happens a large quantity of blood is poured out between the placenta and uterus, a small portion of which only at the time usually escapes from the vagina, to indicate what is going on within the uterus. There may be a great internal hæmorrhage, accompanied with the ordinary constitutional effects resulting from loss of

blood—as faintness, sickness, or vomiting, coldness of the extremities, rapid feeble pulse, hurried breathing; when there is little or no discharge from the vagina to excite alarm, or to point out the source of danger, when it is extreme. It is from the general symptoms of exhaustion, and by the disagreeable sense of uneasiness, weight, or distension of the uterus experienced, and not from the quantity of blood which appears externally in these cases, that we are led to discover the true state of the patient—to suspect that internal hæmorrhage is going on. But much more frequently only a small portion of the placenta is at first detached, and the greater part of the blood which is extravasated between it and the uterus separates the membranes, and descends by its weight to the orifice, and escapes through the vagina. In all cases, however, of uterine hæmorrhage in the latter months, the danger cannot be so accurately estimated by the quantity of blood which appears externally, as by the general symptoms. The portion of placenta which is detached never reunites to the uterus, but when expelled it is usually seen covered with a dark coagulum adhering to the uterine surface.

When the blood escapes in small quantity, and there are no labour pains present, and no disposition in the os uteri to dilate, and the constitutional powers are not impaired, an attempt should be made to prevent a return of the discharge, and the occurrence of labour pains. For this purpose, if the pulse is full and frequent, some blood may be taken from the arm, and the patient should be kept in the horizontal position surrounded by cool air, cold applications made over the hypogastrium, and acetate of lead and opium, mineral acids, and other remedies that diminish the force of the circulation and promote the coagulation of the blood, should be taken internally. The plug is here totally inadmissible; it can only convert an external into an internal hæmorrhage. But where the flooding occurs at first profusely, and is renewed even in a mode-

rate degree, in spite of our efforts to check it, the continuance of pregnancy to the full period cannot be expected; it will be of no avail to bleed and administer internal remedies, except for the purpose of checking the discharge, and thus averting the immediate danger until the uterus is emptied of its contents.

The operation of turning, which is required in all cases of complete placental presentation, is very rarely necessary in uterine hæmorrhage where the membranes are felt at the orifice. In a great proportion of these cases, where, on making an examination, you can feel the smooth membranes extending across the neck of the uterus, the flooding will be arrested, and the labour safely completed, if the membranes are ruptured, the liquor amnii discharged, and contractions of the uterus excited by gentle dilatation of the orifice, and other appropriate means. The only cases in which this treatment fails are those in which it has not been had recourse to sufficiently early, or where the whole or a large portion of the placenta has been suddenly separated from the uterus, and a great internal hæmorrhage has taken place. The uterus will not contract effectually in these cases after the membranes have been ruptured the pains, instead of becoming stronger, become more and more feeble, return at longer intervals, and during these the blood flows more profusely, and death would take place before delivery, if the child were not extracted by the forceps, crochet, or by the operation of turning. In all cases, then, of uterine hæmorrhage in the latter months of pregnancy, and in the first stage of labour where the placenta does not present, and the quantity of blood discharged is so great as to render delivery necessary, where it appears improbable that the pregnancy can go on longer with safety, or to the end of the ninth month, rupture the membrane with the nail of the fore-finger of the right hand, evacuate the liquor amnii by holding up the head of the child, dilate very gently the os uteri with the fore and middle-fingers expanded, and occasionally make pressure with the fingers around the whole orifice; apply the binder, give ergot and stimulants, and the uterus will, in all probability, contract upon its contents, and expel them without further trouble. If the hæmorrhage should, however, continue after employment of these means, delivery must be accomplished by the forceps, craniotomy, or by turning, according to the peculiarities of the case. In women who are liable to attacks of flooding after the expulsion of the child or placenta, rupture the membranes at the commencement of labour, even before the os uteri is much dilated, if the presentation is natural, and you will often succeed in entirely preventing hæmorrhage.

A TABULAR VIEW OF THIRTY-SEVEN CASES OF SEVERE UTERINE HÆMORRHAGE, OCCASIONED BY DETACHMENT OF THE PLACENTA FROM THE SUPERIOR PART OF THE UTERUS.

		Recovered.	Died from uterine inflammation.
1	June 28, 1824	Uterine hæmorrhage, with slight pains; many coagula had passed; os uteri slightly dilated, and little affected by the pains; membranes were immediately ruptured; hæmorrhage instantly ceased, and pains became regular; child born alive; hæmorrhage followed, but was arrested on removal of placenta.	
2	October 29, 1827	Hæmorrhage at the eighth and a half month, preceded by rigors and pains in region of uterus; much blood lost; os uteri soft, and little dilated; pains produced no sensible effect on it; membranes were then ruptured; strong pains followed; hæmorrhage ceased; head descended; in two hours the pains ceased, and the hæmorrhage was renewed; great exhaustion; craniotomy was performed, and the child easily extracted; severe hæmorrhage after expulsion of placenta, which was controlled by cold.	

3	Nov. 5, 1828	Membranes gave way on the 4th, after great fatigue; liquor amnii discharged without pain; on the 5th, faintness came on, with slight oozing of blood from uterus, which continued for some hours, gradually increasing in quantity; exhaustion; os uteri fully dilated; head low in pelvis; insensibility; forceps applied; hæmorrhage more formidable; labour completed by craniotomy; hæmorrhage continued after expulsion of placenta; hand introduced to make uterus contract, but without success; flow of blood continued in spite of cold, pressure, and stimulants.	Died soon after delivery.
4	March 23, 1829	Uterine hæmorrhage during the first stage of labour; os uteri widely dilated; pains gone off; membranes unruptured; finger was immediately forced through membranes, and head held up whilst liquor amnii escaped; stimulants administered; pains became strong, and labour completed without return of hæmorrhage.	Recovered.
5	April 16, 1829	Severe flooding during eighth month, at intervals; os uteri soft and dilatable; no portion of placenta could be felt; presentation natural; membranes were then ruptured, the os uteri was dilated, and pressure made with the binder; pains came on for a time, but hæmorrhage was renewed with violence; turning easily performed; child born alive; extreme exhaustion and death threatened.	Recovered.
6	October 24, 1829	Profuse uterine hæmorrhage at the end of ninth month, which had commenced two days previously; os uteri fully dilated; head presenting; syncope; strength was supported by stimulants for a time, but the head not advancing, and the prostration increasing, the forceps was applied, and child extracted; hæmorrhage ceased.	Recovered.
7	Nov. 18, 1829	Uterine hæmorrhage ninth month, without exertion, after a hearty dinner; sickness; vomiting; syncope; os uteri dilated to size of half-a-crown, thick, and rigid; membranes were immediately ruptured, and liquor amnii discharged; hæmorrhage ceased, and pains became strong; in an hour the hæmorrhage returned, and the pains ceased; exhaustion; os uteri still very rigid; turning unable to be performed; craniotomy employed, and hæmorrhage arrested; gradually sank	Died three hours after delivery.
	May 13, 1830	Uterine hæmorrhage at the end of ninth month; pains feeble, and recurring at long intervals; os uteri slightly open; dilatable; no portion of placenta felt; membranes were immediately ruptured, and the hæmorrhage ceased: child born alive	Recovered.
9	May 1830	Sudden and alarming uterine hæmorrhage during the ninth month; faintness, with laborious breathing; os uteri but little dilated; the smooth membranes were felt all round; the membranes were then ruptured with the finger, and the hæmorrhage ceased; orifice of uterus gently dilated; child dead; hæmorrhage renewed with violence after expulsion of placenta; arrested by cold and stimulants	Recovered.

10	Nov. 29, 1833	Uterine hæmorrhage at the eighth month; two quarts of blood had been discharged; great prostration; os uteri dilated to size of a shilling, soft and thin; membranes tense, and felt all round; membranes were ruptured with the finger, and pains came on, which expelled the child without hæmorrhage; the placenta followed in two minutes, accompanied by a great discharge of florid red blood; alarming prostration; ice into vagina, and stimulants administered	Recovered.
11	Sept. 4, 1834	Uterine hæmorrhage at the ninth month, which had come on after a violent quarrel; os uteri rigid, and slightly dilated; membranes felt all round; vagina had been plugged, and doses of ergot given without benefit; membranes were immediately ruptured, and all terminated well	Recovered.
12	July 12, 1835	Uterine hæmorrhage commencing at the eighth month, but arrested for ten days by cold and rest; os uteri high up and closed; hæmorrhage again came on, with pain in abdomen, like cramps; membranes were then ruptured with difficulty, and pressure made over uterus; pains very feeble; strength supported by wine, &c.; child expelled dead, after some hours, by natural efforts; placenta diseased	Recovered.
13	Nov. 15, 1835	Slight uterine hæmorrhage at the seventh and a half month; no great effect produced until Dec. 17, when it was renewed in a formidable manner; vagina filled with coagula; placenta supposed to present; os uteri soft, thin, and dilated to the size of half-a-crown; membranes felt all round, and no placenta at orifice; membranes ruptured with difficulty; pains came on, and child expelled in two hours; cord around the neck; slight hæmorrhage continued; alarming exhaustion for some days	Recovered.
14	June 4, 1836	Membranes ruptured at the commencement of labour in a patient who had always suffered from hæmorrhage; labour completed with but slight discharge; pressure and cold employed	Recovered.
15	Sept. 9, 1836	Uterine hæmorrhage at the eighth month, after an accident, which continued nearly a whole day; placenta was thought to have presented, but the membranes were felt all round without placenta; os uteri much dilated; membranes were ruptured with finger; the binder applied, and the orifice gently dilated; child born dead, with cord twisted tightly around neck; flooding was renewed; placenta was extracted; hæmorrhage arrested by cold and pressure; alarming prostration	Recovered.
16	June 22, 1837	Profuse hæmorrhage soon after commencement of labour, which increased when pains went off; great faintness and yawning; no part of the placenta felt; vagina filled with clots; membranes were then ruptured, and the hæmorrhage ceased	Recovered.
17	June 30, 1837	Uterine hæmorrhage in the ninth month; os uteri very little dilated; placenta could not be felt; membranes were immediately ruptured; child was expelled dead, followed by the placenta, which had been wholly detached; syncope followed	Recovered.

18	Aug. 24, 1837	Hæmorrhage after a fall during the eighth month; arrested for a week by rest and cold; renewed at which time, when the membranes were ruptured, and the hæmorrhage completely arrested	Recovered.
19	Aug. 1837	Hæmorrhage during first stage of labour; membranes were ruptured, and the child born alive without return of hæmorrhage	Recovered.
20	Nov. 11, 1837	Uterine hæmorrhage near the ninth month; a quart of blood escaped in about one minute; disposition to syncope; os uteri soft, dilatable, but little opened; head presented; no uterine contractions; cold was applied, and the hæmorrhage ceased; labour came on soon after, and was completed without assistance	Recovered.
21	Nov. 20, 1837	Violent flooding at commencement of ninth month; os uteri soft, and but little open; no pains, but a sense of weight in the region of the uterus; membranes were immediately ruptured, and the hæmorrhage ceased; child born dead, with cord twisted around neck	Recovered.
22	Nov. 14, 1838	Uterine hæmorrhage at eighth month; os uteri half dilated; membranes unruptured; syncope; membranes were immediately ruptured; pains became strong; child expelled in an hour, putrid; hæmorrhage was arrested; placenta in a diseased condition	Recovered.
23	June 22, 1839	Ninth month—awoke in night with sickness and pain in abdomen, followed by syncope; symptoms supposed to arise from indigestion; soon after, hæmorrhage took place from uterus; os uteri thick and slightly open; membranes were then ruptured, and the orifice gently dilated; hæmorrhage still increased; alarming exhaustion; craniotomy was performed; no blood lost after extraction of child; gradually sank; placenta expelled without assistance	Died soon after; uterus soft and uncontracted; large dark clot filled the cavity; the coats of uterus so soft that the fingers could be easily pushed through them; decidua found adhering to part of lining membrane of uterus.
24	Jan. 12, 1840	Profuse hæmorrhage in the seventh month; first attack five weeks previously; renewed again after three weeks, and a third time at the present date; os uteri high up, and directed towards sacrum; could feel with difficulty the anterior lip; continued in this state for three days, when labour pains came on; os uteri dilated; membranes were ruptured, and labour safely completed	Recovered.
25	May 29, 1840	Uterine hæmorrhage for three weeks in the sixth month; os uteri slightly dilated; pains feeble; pulse very rapid; membranes felt all round; head presented; membranes were ruptured with finger; hæmorrhage ceased	Recovered.
26	July 5, 1840	Sense of weight preceding uterine hæmorrhage without discharge; blood discharged the next day, which at last became very violent; os uteri dilated to the size of a crown, membranes felt through it; liquor amnii discharged by rupturing the membranes; hæmorrhage ceased; child dead	Recovered.
27	Aug. 31, 1840	Uterine hæmorrhage in the eighth month; placenta thought to be adherent to cervix uteri; vagina filled with coagula, but when they were removed the smooth membranes were felt beyond, but no placenta; membranes were ruptured; child born dead without hæmorrhage	Recovered.

28	Dec. 1, 1840	Violent flooding at the eighth month; os uteri high up, thick, and little dilated; placenta thought to present; membranes at last felt all round, but no placenta; membranes were immediately ruptured, and a great quantity of liquor amnii evacuated; strong pains followed; hæmorrhage ceased; labour completed safely in six hours	Recovered.
29	Dec. 18, 1840	Profuse flooding in the first stage of labour, which ceased on the membranes being ruptured; dead child expelled, with funis twisted three times round the neck	Recovered.
30	June 1, 1841	First labour; membranes ruptured spontaneously; funis prolapsed during the night, twelve hours after labour began; a great flooding took place, which produced exhaustion; os uteri half dilated; head above brim; craniotomy performed; child extracted; many coagula followed; exhaustion succeeded; no further hæmorrhage	Died a few hours after delivery.
31	July 1, 1841	Profuse uterine hæmorrhage in the eighth month; os uteri dilated to size of half a crown; placenta thought to be adherent; os uteri rigid, membranes felt, but no part of placenta; liquor amnii discharged with difficulty; hæmorrhage continued slightly for three hours, when a dead child was expelled, followed by a great discharge of blood.	Recovered.
32	Sept. 19, 1841	Dangerous uterine hæmorrhage in the seventh month, occurring suddenly, and accompanied with constant vomiting; restlessness and delirium; membranes were ruptured with difficulty; hæmorrhage immediately ceased; dead child soon expelled	Recovered.
33	Nov. 27, 1841	Alarming hæmorrhage at ninth month, nearly proving fatal before medical relief was obtained; os uteri dilated; membranes unruptured; hand was passed into uterus and turning performed; the whole placenta was detached; an immense gush of blood followed.	Extremities became cold; faint; restless; died in half an hour.
34	Dec. 8, 1841	Uterine hæmorrhage at ninth month, referrible to no accident; child dead; membranes ruptured with finger; hæmorrhage ceased; dead child expelled, with cord twice around neck	Recovered.
35	June 19, 1842	Flooding in the eighth month, which had continued two hours; os uteri widely dilated; membranes unruptured; blood flowed, and uterus not acting; ergot had been given without effect; stimulants were given; pains came on; discharge ceased; child expelled alive; funis unusually short	Recovered.
36	July 10, 1842	Sudden and profuse hæmorrhage in the eighth month; had been exposed to no accident; pulse quick, and feeble; os uteri dilated so as to admit two fingers; head presented; membranes ruptured with the finger; hæmorrhage ceased; two hours, the labour was completed	Recovered.
37		Profuse uterine hæmorrhage during the eighth month, which continued until she fainted and fell down insensible; hæmorrhage was arrested for a time, when the pulse got full and frequent, accompanied by a sense of weight in the hypogastrium; V.S. was employed; cold, and rest employed; she went to the full period, and was delivered of a living child; hæmorrhage took place after the expulsion of placenta	Recovered.

In the preceding table of 37 cases of uterine hæmorrhage in the latter months of pregnancy, occasioned by detachment of the placenta from the upper part of the uterus, four of the women died soon after from loss of blood, and one in several days from inflammation of the uterus. Twenty of these occurred in the ninth month of pregnancy, or at the commencement of labour; 14 in the eighth; 2 in the seventh; and 1 in the sixth month. Edmund Johnson, Esq. also constructed this table, which presents an outline of the cases in a small space.

It is to Mauriceau that all the honour must be awarded, and not to Puzos, or any subsequent writer, of having first pointed out the efficacy of rupturing the membranes, where the placenta does not present. He was undoubtedly the first who fully established the important practical distinction between the cases of uterine hæmorrhage in which the placenta is attached to the neck of the uterus, and those in which it has adhered to the fundus or body; and been separated by some external or internal cause. Guillemeau, as you already know, recommended immediate delivery by turning in cases of placental presentation, and in those cases of uterine hæmorrhage in which the placenta did not present, but had been detached by some accidental cause from the upper part of the uterus, he had likewise recourse to artificial delivery, and for the knowledge of this practice he states that he was indebted to Ambrose Paré. The same plan of treatment was therefore employed by him in all the varieties of uterine hæmorrhage in the latter months, and in the work of Portal there is no proof, as far as I can discover, that he made any difference in the treatment of cases of unavoidable and accidental uterine hæmorrhage. Mauriceau has recorded the history of 37 cases of uterine hæmorrhage, in which the placenta did not present, but had adhered to the upper part of the uterus, and been accidentally detached. Twenty-one of these cases occurred before the year 1682, and in almost all of them he delivered artificially, by passing the hand into the uterus, rupturing the membranes, and turning the child. The treatment he employed, therefore, in these cases, was precisely the same as that which he had employed in the seventeen cases of placental presentation alluded to in the last lecture, and differed in no respect from that recommended by Paré and Guillemeau. But in the year 1682, his case 307 occurred, and in the treatment of this he deviated from his former practice, and instead of delivering immediately by turning the child, he ruptured the membranes, and left the labour to nature with the happiest result. Mauriceau gives no account of the circumstances which induced him to make this important change

in the treatment of cases in which the placenta did not present, and to adopt that method of treatment which was at a later period so strongly recommended by Puzos, and considered by himself, and almost all later authors, as his own discovery. From a case of accidental uterine hæmorrhage which occurred in 1685, and another in July 1686, where Mauriceau had recourse to the operation of turning, it is probable he was not convinced of its perfect safety before the month of August 1686. His case 450 then occurred, and the pains being feeble, and the hæmorrhage great, he ruptured the membranes, by which means the infant he says could advance into the passage *without pushing the membranes before it, and further detaching the placenta, as it had previously done, and increasing the hæmorrhage.* The liquor amnii having escaped after the rupture of the membranes, the labour pains, which before had been feeble and inefficient, speedily became strong, and the patient was happily delivered of a living child in half an hour, and the mother recovered favourably. Case 429 occurred in 1687, and in this also he ruptured the membranes, which, he observes, should be done in all similar cases. Cases 480 and 496 occurred also in 1687, and the membranes were ruptured in both, and the labour left to nature. The reason of this practice is again clearly stated in the history of the last of these cases. Case No. 542 took place in 1688. The patient was in the 7th month of pregnancy, and the feet presented, and he ruptured the membranes and extracted the child by the feet. In case 585, which occurred in 1690, he also ruptured the membranes as soon as they became tense, and again states the ground upon which he did this. In case No. 624, which happened in 1691, the hæmorrhage took place in the eighth month of pregnancy, and here he also ruptured the membranes with the happiest effect. Case No. 633 also occurred in 1691. The patient was in the seventh month, and there was both external and internal uterine hæmorrhage. He states that the membranes were ruptured with the happiest result. The same practice was adopted, and with a similar effect, in case 633.

Mauriceau's 52d aphorism proves that he was likewise fully aware of the importance of rupturing the membranes in the first stage of labour, when hæmorrhage occurred.

In the second volume of the *Memoirs of the Royal Academy of Surgery* (1743), Puzos recommended puncturing the membranes, as Mauriceau had done, gently dilating the os uteri with the fingers to excite contractions, and leaving the expulsion of the child to nature. This, he says, is a safe and middle course, between natural labour and artificial delivery by turning, which he knew was

always accompanied with danger, and often followed by fatal consequences. Giffard, Chapman, Roederer, and Levret, appear to have placed little or no reliance on the practice of rupturing the membranes in cases of accidental uterine hæmorrhage. Smellie was, however, fully aware of its importance, and likewise knew that the practice did not invariably succeed.

“On the first appearance of flooding, the patient ought immediately to be bled to the amount of eight or twelve ounces, and venesection repeated occasionally, according to the strength of the constitution and emergency of the case. She ought to be confined to her bed, and be rather cool than warm: if costive, an emollient clyster must be injected, in order to dissolve the hardened fæces, that they may be expelled easily without straining; internally, emulsion with nitre must be used, and mixtures of the tinct. rosar. rub., acidulated with spirit of vitriol, as the cooling or restringent method shall seem to be indicated; but above all things opiates must be administered to procure rest, and quiet the uneasy apprehensions of the mind. For her diet let her use panada, weak broth, and rice gruel; she may drink water in which a red hot iron has been several times quenched, mixed with a small proportion of red burnt wine. She must abstain from all the high-seasoned foods, and even flesh meats or strong broths, that will enrich the blood too fast and quicken the circulation. But if, notwithstanding this regimen, the flooding still continue and increase, so that the patient become faint and low with loss of blood, we must without further delay attempt to deliver her, as in book iii. chap. ix. sect. 3, though this is seldom practicable, except in the last months of pregnancy; and this will be the easier performed the nearer she is to her full time, unless labour pains shall have assisted or begun a dilatation of the os internum. It is happy for the woman in this case, when she is so near the full time, that she may be sustained till labour is brought on; and this may be promoted, if the head presents, by gently stretching the mouth of the womb, which being sufficiently opened, the membranes must be broke, so that the waters being evacuated, *the uterus contracts, the flooding is restrained*, and the patient safely delivered. At any rate, if the hæmorrhage return again with great violence, there is no other remedy than that of delivering with all expedition, according to the method described in book iii. chap. iv.” &c. “If in time of flooding she is seized with labour pains,” adds Smellie, “or if by every now and then stretching with your finger the os internum, you bring on labour, by which either the membranes or head of *the child is pushed down*, and opens the os

internum, the membranes ought to be broke, so that some of the waters may be discharged, and the uterus may contract and squeeze down the foetus. This may be done sooner in those women who have had children formerly, than in such as have not been in labour before. If, notwithstanding this expedient, the flooding still continues, and the child is not like to be soon delivered, it must be turned immediately; or, if the head is in the pelvis, delivered with the forceps; but if neither of these two methods will succeed, on account of the narrowness of the pelvis or the bigness of the head, this last must be opened, and delivered with the crotchet. In all these cases let the parts be dilated slowly and by intervals, in order to prevent laceration.”

The following is the account of the practice recommended by Dr. Rigby of Norwich, in cases of accidental uterine hæmorrhage. “If, on the contrary, it be clear from a careful examination of the uterus, made in the way above mentioned, that the placenta is not at the mouth of it, and that the coming on, or increase of labour, will not of necessity increase the discharge, provided it be not very profuse (for let it be remembered that I am supposing the examination to be made early, and before any very considerable quantity of blood has been lost), it certainly will be proper to wait for the natural pains, and in the meantime to use such methods as are likely to restrain the flooding, which are, admitting a free circulation of cool air into the room, keeping the patient in a horizontal posture, giving her anodyne, tinct. rosar. &c., and supplying her frequently with such cool and simple nutritious drinks as will support her, without quickening the circulation. From pursuing this method it will often happen that the discharge goes off entirely; and if the woman be not arrived at her full term, and she be kept very still and calm, that it does not return before labour comes on; but if it should continue, or return frequently, it will be right, if possible, to bring the uterus into a state of contraction, by exciting some pain, which may often be done by gently irritating the os uteri with the finger; if this succeed, and the mouth of the uterus be thereby so far dilated that the distended membranes may be felt, they must immediately be pierced by passing a probe along the finger, as upon the discharge of water thus produced the womb necessarily contracts to a certain degree, and the flooding proportionably abates; this is for the most part soon succeeded by slight pains, which, if the child present fair, have very soon an effect upon it, and push it down. But if, notwithstanding the mode of treatment above recommended, the discharge should not lessen, if the evacuating the waters

should not abate it, and if, moreover, labour pains sufficient for expelling the child should not succeed, and the flooding should still increase, so as to endanger the life of the patient, I should imagine it hardly necessary to say, that even in this case, as well as when the placenta is fixed to the os uteri, the only certain method of stopping it should be used, namely, the delivery of the child by turning; for though I have never yet met with a case that, under such circumstances, has required it, and believe such very rarely happens, yet I would not be supposed to say such a one cannot occur, as the separation of the placenta may, for instance, be produced by such violence done to the abdomen, and the hæmorrhage may be so profuse, that nothing but a speedy delivery by art will put a stop to it; I only mean, that when we are called in early to flooding cases, if we judge only by the quantity of blood that has been lost, which may be small, and the present strength of the woman, which may be considerable, we must frequently be deceived in our judgment of the cases, and be in danger of using a wrong method of treatment, but that the knowledge of the causes which produce them will, in the one case, for the most part justify our waiting, and, in the other, will invariably prove the propriety of turning the child."

Of the 106 cases of uterine hæmorrhage related by Dr. Rigby, of Norwich, he states that 64 were owing to a separation of the placenta from some accidental cause. Of these, he says, "it appears that though many were very alarming cases, as the patients lost large quantities of blood, and were extremely faint, *not one proved fatal, not one but terminated safely, by waiting for the efforts of nature to expel the contents of the womb.*" Dr. John Ramsbotham relates 16 cases of accidental uterine hæmorrhage, seven of which proved fatal. Ten cases of accidental hæmorrhage, says Dr. Collins, "occurred in the Dublin Lying-in Hospital during Dr. Clarke's residence. Four had delivery forced, of whom one died. One had a defective pelvis; the head was perforated, the mother died. One had a cross presentation; the foetus was turned and the mother died. Two had the membranes ruptured at an early stage of the labour; both recovered. Two were left entirely to the efforts of nature; one died. Hence it is evident, Dr. Clarke observes, that of the ten cases, four proved fatal under very different modes of treatment, which result is entirely at variance with Mr. Rigby's experience." Thirteen cases of accidental uterine hæmorrhage occurred in the same hospital, during the residence of Dr. Collins as master; in four of which the membranes were successfully ruptured; *three were delivered by the natural efforts; three by the crotchet; two of the*

children were turned, and in one the feet presented; one only of the children was born alive; four were putrid. Two of the thirteen women died; one where the child was turned, and one where the head was lessened. "In my own practice," observes Dr. Merriman, "upwards of 30 cases have occurred of accidental hæmorrhage during parturition, in which I have adopted the method of rupturing the membranes as a means of lessening or suppressing the flooding, and as yet have had no reason to be dissatisfied with the plan, for in every instance the discharge has entirely ceased, or has been so much diminished as to secure the safety of the patient; and yet there were some among these patients whose cases, from the profuse hæmorrhage, were abundantly alarming. Dr. Merriman has informed me that since the publication of this statement he has witnessed three cases in which the hæmorrhage was not arrested by rupturing the membranes." Dr. Hamilton states that during the last thirty years he has met with only two cases where he has adopted this practice, and on both of these occasions he has resorted to it with great reluctance. Except in cases where the os uteri is rigid, and where the operation of turning is opposed by the patient or attendants, he says the practice must be the same as in hæmorrhage from the attachment of the placenta over the os uteri; that is, whenever danger threatens, the operation of turning must be had recourse to. "The proposal of M. Puzos," observes Professor Burns, "is very limited in its utility. Its simplicity gave me at first a strong partiality in its favour; but I soon found cause to alter my opinion. I consider that we are only warranted in trusting to it in those slighter cases which would almost do well without it. I must not, however, conceal, that many eminent men are still favourable to the plan, yet, so far as may be judged of by cases recorded by these high authorities, a larger proportion of women die in this species of hæmorrhage than in that where the placenta is attached to the cervix uteri."

If you compare the two preceding tables, you will see how much greater the danger is, both immediate and remote, when the placenta presents, and when it does not. I cannot avoid expressing my entire dissent from the doctrines inculcated in the following passage by Dr. Burns, and repeating what has already been stated, that in all cases of uterine hæmorrhage in the latter months of pregnancy, and first stage of labour, where the discharge is great, that the plug is inadmissible, and that the best practice is, even if the os uteri is rigid and undilated, and there are no labour pains, to rupture the membranes, evacuate the liquor amnii, and excite the contractions of the uterus, or wait till they commence spon-

taneously. In no case should an attempt be made to dilate the os uteri with the fingers before the membranes are ruptured.

"The old practitioners," observes Professor Burns, "not aware of the value of the plug, endeavoured to empty the uterus early; but it was uniformly a remark, that those women died who had the os uteri firm and hard. It was the fatal consequence of this practice being sometimes prematurely and rashly resorted to that suggested to M. Puzos the propriety of puncturing the membranes, and thus endeavouring to excite labour. His reasoning was ingenious; his proposal was, in one respect, an improvement on the practice which then prevailed. The ease of the operation, and its occasional success, recommended it to our notice: but experience has now determined that it cannot be relied on, and that it may be dispensed with. If we use it early, and on the first attack, before any tendency to labour exist, we do not know when the contraction may be established; for even in a healthy uterus, when we use it on account of a deformed pelvis, it is sometimes several days before labour be produced. We cannot say what may take place in the interval. The uterus being slacker, the hæmorrhage is more apt to return, and we may be obliged, after all, to have recourse to other means, particularly to the plug. Now we know that the plug can, without any other operation, safely restrain hæmorrhage until the os uteri be in a proper state for delivery. The proposal of M. Puzos, then, is, I apprehend, inadmissible before this time. If, after this, there be occasion to interfere, it is evident that we must desire some interference which can be depended on, both with respect to time and degree. This method can be relied on in neither; for we know not how long it may be of exciting contraction, nor whether it may be able to excite effective contraction after any lapse of time. If it fail, we render delivery more painful, and consequently more dangerous to the mother, and bring the child into hazard."

CONTRIBUTIONS

TO

ANATOMY AND PHYSIOLOGY.

By ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 532.]

THE anatomy of the osseous pelvis and its connecting articulations has naturally been very frequently brought under my notice during the last twenty years, both as a teacher of human and

of comparative anatomy. To the human pelvis chiefly has my attention been directed, without altogether neglecting that of other mammals, and to it the following remarks will chiefly, but not exclusively, apply.

The observations I have already published on the form of the pelvis as predisposing to hernia in certain persons; on its want of symmetry in connection with the same subject, and as determining the hernia on one or other side: these observations I need not here allude to, further than referring the reader to the Edinburgh Medical and Surgical Journal, in which he will find them: the memoir bears the title of "Observations on the Statistics of Hernia." The memoir was criticised by M. Malgaigne in a memoir published by him in the Annales d'Hygiène: I presume he meant to be fair enough, and therefore I do not intend replying to his memoir further than by referring those who understand the language in which my observations were written, to the observations themselves, where they will readily enough discover, 1st, that M. Malgaigne has mistaken my meaning in all the essential points; 2d, that he has given me no credit for exposing first, I believe, the fallacy at that time exceedingly prevalent, that hernia was a very common disease*; 3d, and (this I complain most of, if it were worth while,) that he has appropriated to himself an idea of mine with such dexterity, as to make it quite his own. The idea was a very simple one, but I do not remember having met with it in medical works; it was simply this, that different races of men may be liable in varying ratios to the surgical disease—hernia. Having got hold of the idea, new to him no doubt, and therefore "*piquante et nouvelle*," it is incredible how long and loudly he dwells on the chime. But to return.

Variety in form of the human pelvis.

Scarcely any part of the skeleton presents a greater variety in its form than the pelvis; admitting, however, that every part of the skeleton does present its own deviations from the usual or more ordinary form. Yet in the pelvis these deviations are extremely frequent. As these varieties in form, however, are

* This fallacy was supported by Monro, A. Cooper, and a host of the first names in the profession: I believe I was the first completely to expose the error.

not necessarily hereditary, and are checked by intermarriage with different families, they never proceed to the length of establishing any permanent variety, either in regard to the general form, or in regard to a specific form of any particular part; moreover, against the perpetuating of such varieties, otherwisethan by their so frequent reappearance, there exists the great physiological law of species, or of regular formation, by which all the more serious deformations are at once checked in the non-productiveness of the individual. Thus, whatever the varieties in the form of the human pelvis may be, of this we may be assured, that as yet they have failed in establishing any permanent deviation in form from the human specific form; the *law of species* is the antagonistic force to the "deforming powers or laws."

Weber's theory, that in the various races of men the *female pelvis* presents a specific form bearing a fixed relation to the form of the head of the child and the future adult, is a theory based on a final cause, and not on transcendental anatomy and physiology. It comes from a quarter (Germany) where we should least expect it, and involves another theory not chiming in with it, viz. that there are four or five specifically distinct races of men. I shall leave Weber to answer these objections, for they are so; the doctrine of final causes being unphilosophical when employed as a substitute for a philosophical theory, and it is not proved that there are four or five distinct races of men and of women whose heads and pelvises are specifically distinct, remaining so throughout all ages. The few specimens we possess in those European museums I have examined of the female pelvis in the various races of men, do not furnish at all any positive grounds in support of Weber's theory, and the varieties specified by him will I think be found to occur in all the races indiscriminately. The crania of the mingled European family have almost every form; so also has the shape of the female (European) pelvis: the rounded pelvis of the Japanese female, with all its dimensions nearly equal, is not peculiar to that race; nor do we find in the negroes that peculiar elongated form which this theory would lead us to anticipate; not at least so frequently, or so exclusively, as to warrant us in ascribing it to that race as a specific form.

Varieties in the form of the pelvis, and its component parts.

The most important in a practical point of view are the *sexual* differences; but these have been so well described by so many anatomical writers as to render my saying anything regarding them here almost unnecessary. I allude to the sexual differences when fully established, that is, in the adult: what I have to say on these points will arrange better with some other sections. Not unfrequently specimens are met with which at first sight are difficult to be decided on in respect to the sex; but attentive and careful observation will, I believe, always enable the anatomist to do so, particularly if he applies the foot-rule. I have seen some good practical anatomists puzzled for a moment when they attempted a hasty decision.

The different parts of the pelvis follow their own laws and formation, that is, they are not necessarily made in absolute dependence on each other: the true pelvis or excavation (cavum) may be ample for all sexual purposes, as in so many of my country-women, both English and Scotch, and yet the haunches appear remarkably narrow; this is owing merely to the fact, that the true pelvis and the false pelvis not being necessarily developed in the direct ratio of each other, but often the opposite, the false pelvis may be narrow, wall-sided, and its walls nearly upright, giving a remarkable want of breadth to the haunches; whilst the true pelvis or cavum may have, and generally has, the dimensions required by nature for the due performance of the sexual functions. The opposite form to this sometimes takes place; it gives a false appearance of breadth and capacity to the female haunches, and may lead the accoucheur into error.

Transcendental and other physiological laws as applicable to the pelvis and its varieties.

A portion of the pelvis, a single bone, a section, a half, mesial or horizontal, may all, or any of them, be fully developed, and not the rest. Its pubic portion, which may be viewed as the pelvic sternum, may be wanting, and this coincides with deeper malformations, affecting the bladder and genital organs; but the laws of whose application I mean here to speak more particularly are, 1st, the law of unity of

organization in the animal kingdom, and the coincidences of that law with the embryonic or rather foetal structures and forms. There will be no occasion for my following any systematic order in describing the facts, or stating what they illustrate.

The posterior wall of the pelvis is formed by a continuation of the vertebral column; the mere anatomist describes the pelvic portion of the column as composed of sacrum and coccyx, not venturing to give them other names to the student, lest, what is most likely, the student should misunderstand him: all true anatomists know that this section of the column comprises at least two regions, sacral and coccygeal: that these vertebræ, nine in number, which ought, perhaps, to be differently classed, are even by the coarsest physiologist considered as distinct; as divisible, in fact, into vertebræ of two distinct classes, namely, sacral and coccygeal. But may there not be here three classes of vertebræ, of one of which the first coccygeal bone may be the representative, confined in man to one, but in most mammals extended to many bones? Or has a class of vertebræ been struck out altogether? In the neck of man and of mammals generally there would seem to be three distinct classes of vertebræ, of which, in man, the first comprises the atlas and dentata; the second comprises the 3d, 4th, 5th, and, as I think, 6th; and the third class in man has in it only one vertebra, namely, the 7th, or proeminens; whereas, in the sloth, this same region comprises two or three vertebræ carrying ribs, as the 7th in man so frequently does. Now it is by no means unlikely that the same may happen in regard to the pelvic portion of the column; a whole class of vertebræ may be left out, or represented by a single one—the first coccygeal.

Of these vertebræ I shall consider, first, the varieties in form of the three inferior, or the 2d, 3d, and 4th coccygeal. These probably belong to a class; in early life they are perhaps comparatively large, and even may be observed to deviate to one side or other from the mesial plane; this deformity takes place very early. They vary in shape and in number, and in the muscles attached to them: twice only, in all my life, have I observed the presence of a distinct *sacro-coccygeus muscle*; but in these it was large and

distinct, and admitted of no sort of doubt*. Their variety as to number must be rare; I do not remember having met with an instance of it. Of the varieties of the first coccygeal vertebra I need not dwell: they refer principally to size, to its osseous union with the adjoining vertebræ, and to the greater or less development of its pedicle and arch. It partakes a little in that "arrest of development" of the half of the pelvic portion of the vertebral column connected with the pelvis oblique ovata of Naegele, of which remarkable deformity, and its explanation on the principles of transcendental anatomy and physiology, I shall speak presently.

[To be continued.]

ON THE
SENSIBILITY OF THE GLOTTIS
AFTER THE PERFORMANCE OF
TRACHEOTOMY,
WITH THE DESCRIPTION OF A NEW
INSTRUMENT.

To the Editor of the Medical Gazette.

SIR,

IN the course of the discussion that took place at the Royal Medical and Chirurgical Society, on Tuesday, the 27th ult., on the very highly interesting and most instructive paper communicated by Sir Benjamin Brodie, the question was raised, as to whether the sensibility of the glottis to the presence of a foreign body is diminished by an opening previously made in the trachea. As much discrepancy of opinion seemed to exist on this question, which involves a point of considerable practical importance in the treatment of those cases in which foreign bodies have gained admittance into the air-passages, the following observations, made with the view of determining it, may not be uninteresting to your readers.

It appeared to me that the only way to answer this question satisfactorily would be to note, on one of the lower

* In 1821, whilst dissecting in the practical rooms of La Pitié, I accidentally met with a perfectly distinct case of a tendinous intersection of that portion of the orbicularis palpebrarum which lies over the temporal aponeurosis and external angular process of the frontal bone; it divided the muscle into two equal parts. I have never met with this tendinous intersection since, and regret the not having preserved it, as I find its occurrence denied by M. Cruveilhier.

animals, the effect of the irritation of the glottis by the introduction of a foreign body under the different circumstances of the trachea being entire and incised. The following experiments were accordingly made.

Experiment 1.—The trachea of a dog having been exposed, a puncture, about a line in length, was made in it, about midway between the sternum and larynx. The animal continued to respire through the glottis, the opening in the trachea being so small that scarcely an appreciable quantity of air escaped by it. A small bent probe was then introduced upwards; the presence of this foreign body seemed to excite no irritation until it reached the larynx, when, as was to be expected, violent cough, with convulsive action of the muscles of respiration, and of those of the neck, the larynx being forcibly moved up and down, was induced. The animal foamed at the mouth, and struggled violently, having all the appearance of one in the earlier stage of asphyxia, the tongue becoming livid, and the eyes strained. On the probe being withdrawn, these phenomena soon ceased, but recurred whenever it was re-introduced. I found that although coughing was induced when the probe was passed downwards into the lungs, it was not of so intense a character as when the instrument was directed upwards, nor were the struggles so violent. On the employment of moderate force, it was easy to push the probe through the rimæ glottidis, but when this was done the appearance of distress was so much increased, and the danger of inducing asphyxia so great, that it was obliged to be speedily withdrawn.

This experiment was made with the view of determining the natural sensibility of the larynx and glottis of a dog when irritated from within. In order to introduce the probe, it was, of course, necessary to make a puncture in the trachea, but this was so small as not to interfere in any way with the action of respiration; which function was carried on, as usual, through the glottis.

Experiment 2.—The trachea being exposed, as in the first experiment, an incision, commencing about half an inch above the sternum, and extending upwards for nearly an inch, was made in it. The edges of this were held apart, so that respiration might be

carried on through it instead of through the glottis; the animal was therefore in the condition of a person on whom tracheotomy has been performed. The probe was then introduced, as before, into the larynx up to the glottis, when the same violent contraction of the muscles of respiration, and of those of the upper part of the neck, was excited, and attempts at coughing were made, which, however, could not take place perfectly, as the air was not forced through the glottis. There was one remarkable difference between the phenomena attending this experiment and those of the former one: to wit, that although the evidences of laryngeal irritation, and the consequent reflex muscular actions, were equally great, yet there were none of those symptoms of asphyxia observable in it which were so strongly marked in the preceding one. The reason of this difference was obvious: for although, in both cases, the irritation of the foreign body produced the same spasmodic action about the glottis, yet this could only give rise to asphyxia when there was no other opening through which respiration could be carried on; the tracheal aperture acting, as Sir B. Brodie observes, as a safety-valve.

Experiment 3.—The trachea being exposed as before, I introduced, and firmly tied, a wide pipe into the lower portion of it, so that respiration might proceed uninterruptedly: I then cut it completely across, immediately above the point where the pipe was introduced, about half an inch from the sternum, so as to separate the larynx and glottis from any direct connection with the rest of the respiratory apparatus. On introducing a probe as before, precisely the same phenomena ensued as in the second experiment; the muscles of respiration, and of the neck, being thrown into strong action, and imperfect attempts at coughing being excited, which usually terminated in convulsive expiratory efforts.

As these experiments have been repeated on five different dogs, and several times on each animal, with, as nearly as possible, the same results, I think they may be looked upon as accurate.

On reviewing the details of these experiments, it will be seen that the phenomena presented by them are divisible into two classes. In the first may be comprised those reflected movements which usually proceed from

irritation of the larynx and glottis—such as attempts at coughing, violent spasmodic closure of the glottis, and convulsive action of the muscles of respiration and of the neck, which were common to all the experiments, whether the trachea had been previously opened or not. In the second class may be placed those symptoms of incipient asphyxia which occurred in the first experiment only, and which cannot happen except in those cases in which, the trachea being entire, spasmodic closure of the glottis will necessarily, by arresting the respiratory changes, occasion the symptoms and sensations of impending suffocation.

We are then, I think, warranted in concluding from these observations, that the existence of an opening in the trachea, sufficiently free to allow of respiration being carried on through it, or, indeed, complete division of that tube, does not materially, if at all, diminish the sensibility and contractility of the glottis. And this, it appears to me, is nothing more than we should *a priori* have expected, for it would have been a solitary instance in physiology if the suspension of function in so highly sensitive and contractile a part had at the same time entailed a loss of its perception of, and power of contraction on, the application of a stimulus. When a foreign body, therefore, accidentally introduced into the air-passages, escapes through the glottis without exciting spasmodic contraction of its muscles, or reflex movements in those of respiration generally, after an opening has been made in the trachea, it probably does so in the same accidental way that it entered; the sensitive parts through which it passes being as it were taken by surprise, whilst the attention of the patient is directed to the artificial opening, or to the circumstances in which he is placed. It would probably be as difficult for a patient (whether his trachea were opened or not) to expel a foreign body through his glottis, if his attention were fixed upon that part whilst he made the attempt, as it would be for him *voluntarily* to introduce it into the air-passages through the same aperture. There is, however, this most important difference between the presence of a foreign body in the larynx, or at the glottis, before and after *tracheotomy has been performed*, that, *although the sensations of local irrita-*

tion, and the reflex movements consequent upon them, may in both instances be the same, yet danger from asphyxia can necessarily only occur in those cases in which the glottis is the sole aperture through which respiration can be carried on.

The point of treatment involved in the question that has just been discussed is nothing less than the object with which the opening in the trachea should be made—whether tracheotomy should be performed in order to facilitate the passage of the foreign body through the glottis, by diminishing the sensibility of that part, or, whether it should not be had recourse to, in order to allow it a free exit through the artificial opening. It has been shown that the natural actions of the glottis are not interfered with by the performance of tracheotomy, and the consequent suspension of its function by the passage of the air in respiration through another opening; we cannot therefore expect, as a probability, the expulsion of a foreign body through the *rima glottidis*, although the case that has lately occurred to Sir Benjamin Brodie has shewn the possibility of such an occurrence taking place. Tracheotomy, therefore, should not be performed with the expectation of, by any such procedure, diminishing the sensibility of the larynx and glottis; but should be had recourse to, as was, I believe, done by the very eminent surgeons who attended the patient in the case just referred to, with the intention of affording the foreign body a free passage through an opening not endowed with so extraordinary a degree of sensibility.

There is yet another practical consideration flowing from the preceding ones, and which was mooted by Mr. Quain. It is, whether in those cases in which a coin or other heavy foreign body has found its way into the air-passages, it would not be advisable, after the performance of tracheotomy, and before putting the patient into a prone position, to introduce some instrument into the opening in the trachea, so as to prevent the foreign body from being thrown, during the change of position, into the larynx, or against the glottis, and thus occasioning much distress to the patient and embarrassment to the operator. This appears to me, as the sensibility of the parts is not materially lessened after the trachea has been

opened, to be a sound piece of advice.

We have already the sanction of the very highest surgical authority in Great Britain for the employment of the prone position in those cases in which heavy bodies have found their way into the bronchi, in order that, after the performance of tracheotomy, they may be brought by their own gravity to the artificial opening in the trachea. Now I would suggest, in accordance with Mr. Quain's proposition, that, after the windpipe has been opened, an instrument of such a construction as would arrest the passage of the foreign body into the larynx should be passed into the incision in the trachea at its upper angle. The patient might then be placed in the prone position, and the head and shoulders being lowered, the coin, if dislodged from the bronchus, would either fall out of the tracheal aperture, or else, against the instrument; whence it might be readily removed either by means of a common pair of forceps, or by using it (the instrument) as a scoop.

With the view of thus occluding the trachea above the aperture, I have had an instrument constructed by Mr. Coxeter, of Grafton Street, of which an engraving is annexed.

It consists of a pair of cross-action forceps, the blades of which terminate in branches $2\frac{1}{2}$ inches in length and

slightly bowed at the extremities; within the bowed part is inserted a piece of delicate but strong net. The forceps open to the extent of three-quarters of an inch, which will be sufficient to obstruct all passage through the windpipe in the ordinary situation for tracheotomy. These forceps should be introduced edgewise in a direction corresponding to the longitudinal diameter of the tracheal incision; they may then, the patient having been turned on his face, be opened transversely; and the foreign body will, if dislodged, necessarily either fall out of the artificial opening, the sides of which will be kept widely separated by them, or against the net of the instrument; whence, as has already been stated, it may either be removed with a common pair of operating forceps, or else by using the tracheal forceps as a scoop. At all events, the great object of the instrument, that of preventing the foreign body from falling into the larynx, or against the glottis, and thus exciting irritation and distress, would be accomplished.

In conclusion, I may be allowed to say, that, although I have in this paper had occasion several times to refer to the case that lately occurred to Sir Benjamin Brodie, I have done so merely in illustration, and in no spirit of criticism, which would but ill become me; and that I should not have taken the liberty of mentioning a private case at all, had not the publicity that has already been given to all its circumstances, in the political as well as medical journals, made it to a certain extent public property.—I am, sir,

Your obedient servant,

JOHN E. ERICHSEN.

48, Welbeck Street.

REMARKS
UPON
SOME OF THE PHYSIOLOGICAL
OPINIONS OF PROF. LIEBIG*.

By JOHN BOSTOCK, M.D., F.R.S., &c.

(For the London Medical Gazette.)

It is unnecessary for me to make any remarks upon the value of Professor Liebig's treatise on Animal Chemistry, its merits and importance being so

* Read before the Royal Medical and Chirurgical Society.

generally acknowledged. But, in a work which contains so much that is new, both in fact and in opinion, it is to be expected that there should be certain parts of it which are less firmly established than others, and, with respect to the opinions and speculations more particularly, that some of them should be, at best, questionable. Under this impression, I shall offer to the consideration of the Medico-Chirurgical Society a few remarks on certain physiological doctrines that are advanced by Liebig, trusting that it will not be supposed that I can have any desire to throw discredit upon the work; but on the contrary, by candidly discussing some of what I regard as its most doubtful parts, that I may contribute to the just estimation of its merits as a whole.

One of the positions, which lies at the foundation of all Liebig's physiological theories, is the existence of a specific principle, "vital force, *vis vitæ*, or vitality," which is regarded as the immediate cause of all the phenomena, physical and chemical, which are manifested by the living animal; and, in the same category, are also included all the vital phenomena exhibited in the vegetable kingdom. That the phenomena of vitality, both in animals and in vegetables, cannot be referred to physical or to chemical laws, appears to me most evident; but, I conceive it no less so, that it is not possible to refer all these phenomena to one principle; that there are at least two principles concerned in the process of vitality, which are distinct from each other in their seat, their laws, and their effects: I refer to the contractility of the muscular fibre, and the sensibility of the nervous filament.

It may be said, that this point is one of little importance, as being almost entirely verbal, and turning more upon the definition which are given to certain actions or objects, than upon our knowledge of the actions or objects themselves. And this remark is to a certain extent true; but when we reflect how much the mind is influenced by the terms employed in philosophical discussions, and how frequently an inaccurate term or definition leads to inaccuracy in ideas and in reasoning, we must admit the great importance of correctness in our language, and more especially in that which *is employed in scientific discussions.*

I shall next notice, what I consider as an erroneous opinion, which is implied, if not directly asserted, in various parts of Liebig's treatise, that a knowledge of physiology, that is, of the vital actions of the system, is not to be gained by observing these actions, by classifying and generalizing them, but by chemical experiments on the constituents of the body, and by ascertaining the chemical changes which these constituents experience under various circumstances. That these experiments and observations are of prime importance in our researches no one can deny, but their importance is subservient to a knowledge of the effects produced by the appropriate powers of the living body, and are only valuable in so far as they tend to explain the operation of these powers. I may illustrate the position by the state of our knowledge of digestion, to which knowledge Liebig himself has so eminently contributed. It may be regarded as a well-ascertained fact, that articles of food which do not contain nitrogen are not adapted to the support and growth of a system into the composition of which nitrogen enters as an essential ingredient. This might have been assumed on general principles, and experiment has fully justified the assumption. But this fact throws no light upon the mode in which the articles of food are decomposed in the stomach, or upon the mode by which the elements are re-composed, so as to form the various structures of the animal body.

In connection with this subject, I may notice the principle, which, if not formally announced by Liebig, may be considered as the basis of a great part of his reasoning, that physiological action necessarily involves a change of chemical composition. That there is an intimate connexion between chemical composition and physiological action, that a specific chemical composition is essential to physiological action, I regard as an established principle. But the Professor extends his views beyond this point; he conceives that no action can be performed by any structure, without a coincident and corresponding change in its chemical composition. He conceives, that when a muscle contracts, or a nerve conveys a perception, a chemical change is produced in the part; thus resolving every action, which the living

system performs, into a mode or modification of elective attraction.

One of the most startling positions in Liebig's treatise, and one which, at first view, would appear to contradict all our established opinions, is, that the same chemical elements, and combined in the same proportion, may produce a number of different compounds. This proposition is said to be the unequivocal result of careful experiment, and, in the abstract, we may conceive its possibility, while there are few chemists to whose authority on such points I should feel more disposed to defer than to that of the Professor of Giessen. But were the position proved to demonstration, I do not conceive that it would contribute materially to the explanation of any of the changes that are going forward in the living body. We may rest assured, that no action, either vital or chemical, can absolutely create or annihilate chemical elements; the body can only be composed of the elements which it receives *ab extra*, and it can only part with those elements by some process of secretion or excretion. Our object is actually to trace out the progress which the elements pursue, from their entrance to their exit, and it can be no disparagement to the general merit of Liebig's treatise to say, that to bring forward the doctrine in question, as an explanation of any of the vital phenomena, is to substitute a verbal for an efficient solution of the problem.

There is no part of the animal economy which is more adapted to excite our curiosity, and to raise our conception of the wisdom displayed in the formation of the living body, than the mode in which the lungs are furnished with the necessary supply of carbon, and the carbon made subservient to the extrication of caloric. The function of respiration was one of the first which engaged the attention of modern physiologists, and it is one in which the science of chemistry has most materially contributed to elucidate the operation of the vital organs. There is, however, some difference of opinion respecting the source whence the lungs receive their supply of combustible matter, and of the relation which they bear to the other parts of the system. On this subject I shall venture to offer a suggestion, which may, perhaps, contribute to throw some light upon this process, as well as upon

some other of the operations of animal economy.

It is generally admitted, that the materials which enter into the constitution of the body are undergoing a perpetual change; from various causes they become unfit for continuing their office, and are, consequently, discharged, while new matter is received to supply their place. Now it is necessary that there should be a sufficient supply, not merely for all the *ordinary*, but for all the *extraordinary* demands of the system, and that, consequently, in the usual course of things, there will be a surplus quantity, for which there must be some appropriate mode of discharge, as well as for the matter which has become effete and useless. The elements of which the animal body is mainly composed are carbon, hydrogen, nitrogen, and oxygen; we must therefore inquire, what are the channels by which these several elements are carried off, when a greater quantity of them has been received into the system than is required for preserving it in a healthy and perfect state. Now there would appear to be three organs, which may be termed *depurative*, as being especially appropriated to this purpose—the lungs, the liver, and the kidney—by which the superfluous and effete carbon, hydrogen, and nitrogen, are respectively removed from the system. With respect to the first of these, the carbon, not to insist upon the injurious effects which would be produced by its retention in the system, we find that, by the mode which is adopted for its removal, an operation is effected which is essential to animal existence, the evolution of caloric. In the case of the liver, by which we have a portion of hydrogen and carbon removed from the blood, there is a new substance produced, which is probably useful in perfecting the process of assimilation; while, in the kidney, the discharge of nitrogen would appear to be the principal, if not the sole, object of its function. We have no specific organ for the removal of oxygen from the system, but this is effectually provided for by the necessary formation of the carbonic acid and the water which are discharged from the lungs and the kidney, and also by the proportion of this element which enters into the formation of the appropriate secretion of the liver. As to the mode in which the

blood obtains its elementary constituents, it may be sufficient for my present purpose to consider this fluid as the great receptacle in which all the constituents are received in the first instance, and from which they are separated, as it circulates through the system, depositing, in the several organs, those elements which each of them requires for the supply of its appropriate demands.

Another point on which, I conceive, that Liebig has advanced a position which is at least doubtful, if not incorrect, is, that each of the structures of the body requires an appropriate organ for its formation. It is obvious that no substance can be produced without an apparatus specifically adapted to the purpose; that the requisite elements must be provided, and that there must be a certain disposition of the vessels by which these elements may be deposited in their proper position and their due proportion. This state of things implies the existence of a system, the various parts of which are adapted to each other, in order to produce the ultimate effect. But it does not imply the existence of that arrangement to which the term *organ* has been usually applied. We conceive that the blood contains all the elements which enter into the composition of the muscles, the nerves, and the bones, and the other parts; and that where each part is produced there is a certain state of the contiguous vessels, which enables them to deposit, in due proportion, the elements which enter into the composition of each structure. But to style this disposition of the vessels an organ would be to use the term in a new, and, as I conceive, a less correct mode than that which is generally employed.

In concluding these remarks, I shall again express my hope, that while I venture to criticise any portion of Liebig's Treatise, I do it from my desire to remove even the smallest imperfection from a work of so much value, and by this means to contribute, in some degree, to the advance of a science in which I feel so deeply interested, and to which, for nearly half a century, a considerable portion of my time and attention has been devoted.

Upper Bedford Place,
Feb. 1st, 1843.

MISCELLANEOUS CONTRIBUTIONS TO PATHOLOGY AND THERAPEUTICS.

BY JAMES RICHARD SMYTH, M.D.
London.

(For the Medical Gazette.)

Rickets—Question of the ancient or modern origin of the disease—Opinions of Glisson, Bate, some Italian physicians, and others, on this point—History, description, and morbid appearances of the disease—Observations on the pulse and circulation.

It is the opinion of many that the malady of rickets first made its appearance, as an evil of the human race, in England, and that such took place somewhere about two hundred years ago. Glisson, Bate (physician to Charles the First, to Cromwell, and to Charles the Second), with six other eminent physicians of the time, who joined observation and experience in investigation of the origin, nature, and treatment of this disease, coincided in opinion that it was a new distemper, and not known to the earlier inhabitants of this island, or of the Continent, or to the Greeks or Romans. Glisson was an able and learned physician, and Regius Professor of Physic during forty years at Cambridge University, and might be considered well qualified to give an opinion on such a statistical point in medicine. Boerhaave and Van Swieten also would appear to favour the opinion of the modern origin of rickets. Glisson is the first, we believe, who has fully and accurately written upon the disease; and it is a little remarkable that its name (of Greek derivation, from *ῥαχίς*, spine, or chine) was not the suggestion of that author, but was the common appellation by which the complaint was known and spoken of at the time he wrote his treatise upon it (Glisson, *De Rachitide*, published about the middle of the seventeenth century.)

Not a few writers, with whom we are much disposed to agree, are of opinion that the disease of rickets, in a mild or aggravated form, existed at all times, and was comprehended and recognised in the general morbid state of cachexy. The following is a description of a morbid condition of a boy, given by a physician of Bologna,

Johannes Baptista Theodosius, in 1554, a century before the rickets was noticed by any writer in this country; and if a similar case were to come under our observation to-morrow, we would have no hesitation in pronouncing it, with full confidence in the correctness of our diagnosis, to be rickets:—"Ejus temperamentum declinat ad frigidam et humidam, ex quo color totius pallidus redditur ita ut ad cachexiam tendere videatur, et multæ in eo cruditates generentur. Affectus est debilitas virtutis motivæ, ita ut, cum mensium jam septendecim sit, non possit ullo modo se movere, nec stare, et, cum in ulnis à nutrice deferatur, vix caput potest erectum tenere. Symptoma aliud omnium sævissimum est vertebrarum trium in costis notis ad exteriora declinatio, et est modus gibbositatis, et in modum arcus costæ etiam incurvari videntur." "The temperature of him (the boy) declines to cold and humidity, by which the colour of all the skin is rendered pale, so that he seems inclined to a cachexy, and many crudities are engendered in him. The complaint is a weakness and inability to move, so that this child of seventeen months old can in no manner move itself or stand; and when it is carried in the nurse's arms, it can scarcely hold its head upright. Another symptom, the most cruel of all, is, that three of the vertebræ of the true ribs bend outwardly, and form a kind of hump-back, and the ribs appear to be arched in the manner of a bow."—(Theodosii, Epist. Medic. p. 250.)

The protuberance of the abdomen, and enlargement of the epiphyses of the joints, and irregular inordinate appetite and digestion, symptoms somewhat diagnostic of rickets, are not here mentioned; but there is little doubt that, with those which we find enumerated, these were also associated. A celebrated Italian physician, Zaviani, and some German and French writers of good authority, have argued for the antiquity of the existence of rickets. But if this disease and that of scrofula be of similar natures and kindred pathology, as we believe they are, the fact of the antiquity of the existence of the one, namely, of scrofula, and the opinion of the modern origin of the other, are somewhat contradictory and incongruous. Was not the "bottled spider," the "hunch-backed toad," Richard the Third, not the subject of

rickets at birth and during infancy? There is little doubt, we think, but that he was. The description of that monarch's person by our great dramatic poet, and the representation of it which we have seen by Kean, the present genius, is exactly that which those individuals generally present throughout adult life who have suffered from the malady of rickets in childhood:—

"But I, that am not shaped for sportive tricks,
Nor made to court an amorous looking-glass;
I, that am rudely stamp'd, and want love's majesty;

* * * *

I, that am curtail'd of this fair proportion,
Cheated of feature by dissembling nature,
Deform'd, unfinish'd, sent before my time
Into this breathing world, scarce half made up,
And that so lamely and unfashionable
That dogs bark at me as I halt by them;
Why I, in this weak piping time of peace,
Have no delight to pass away the time,
Unless to spy my shadow in the sun,
And descant on mine own deformity."

At the time that Glisson wrote his treatise upon rickets the distemper was frequent in London, and seemingly endemic in other parts of England, but more particularly in Somersetshire and Wiltshire. It was afterwards observed to prevail in Holland, France, and other parts of the continent, where it was commonly denominated the English disease (*morbus Anglicus*, *maladie Anglaise*, &c.)

Rickets has by some writers been divided into *perfect* and *imperfect*. From the enlarged state, and knobbed or knotted appearance of some of the joints, the Germans have designated the affection *articuli duplicati*, doubled joints; the French, *enfants noués*, knotted infants. When the disease comes upon a child after it has begun to walk, and while the epiphyses of the wrist and ankle bones are only observed to be increased in size, and the flesh generally some degrees softer than natural, and the little patient can still exercise the powers of locomotion, it is called *imperfect rickets*. When the malady is more severe, and the child cannot walk without falling, or is compelled to spend its time either creeping from place to place on its hands and knees, or sitting or lying, it is termed *perfect rickets*. The case of Kates, given in our last paper, is a good example, we consider, of perfect rickets. The time during which a child is most liable to be attacked by this deforming disease is from the commencement of dentition, or from the period at which that process of organic development

usually makes its appearance above the gums; that is to say, the seventh month until the age of two years. After this epoch, the disease, it is true, may still invade the system of the child, but it is observed to be a circumstance of very rare occurrence. The adult individual is subject to, and sometimes labours under, an affection similar or analogous to that of rickets in the child, termed *mollities ossium*, or *malacosteon*; from *μαλακος*, soft, and *οστέον*, a bone.

The disease of rickets, as we have observed, most frequently attacks the infant about the time of teething; and the symptoms that characterize the indisposition which often accompanies that critical process are not unfrequently those which usher in this malady. The child, previously in good health and temper, is observed to droop and to be irritable, to be fretful and disinclined for the breast; its sleep is disquiet; the skin is hot and dry; the pulse is quick, but not strong; the bowels are disturbed; there is a slow continued fever present, that has a morning remission and evening exacerbation, which soon produces severe emaciation. After the continuance for some time of these more acute symptoms, the child becomes languid, solitary, and listless; its countenance is pale and dejected; the skin generally is pale and anæmatus; a remittent, slow, suppressed feverishness is still present, which would appear to be gastric, and to expend its forces chiefly internally; the appetite is abnormal and irregular, most frequently voracious; the functions of the bowels, and the entire operations of the digestive economy, are disordered and deranged; the alvine excretions are sometimes dark, but more frequently light-coloured, and altogether devoid of bile; the renal secretion is morbid, sometimes clear and rather copious, but most commonly turbid and scanty; the flesh becomes soft, and emaciation progresses. When the disease proves fatal the emaciation is extreme, with frequent diarrhoea and convulsions preceding dissolution. Occasionally, however, as we have witnessed in a few instances, there is little or no emaciation, but the flesh is exceedingly soft and flabby. The osseous system manifests signs of participation in the general disorder and error of assimilation; the bones soften, and bend in various

ways, and different deformities are produced. The spinal column exhibits curves posterior, anterior, and lateral. The posterior curve most frequently occurs in the upper dorsal vertebræ, forming the common deformity of hump-back; the anterior curve in the lumbar region, which has the effect of throwing the abdomen forward, and thereby causing progression to be unsteady and feeble. The clavicles become more bent, and of a sigmoid shape, which allows the shoulders to approximate, and the arms to press upon the sides of the chest, which is thereby flattened, the ribs becoming less convex, and the sternum more so, causing the chests of those individuals to resemble in some degree the breasts of birds; from which circumstance persons with such deformity, which generally continues through life, are usually said to be "pigeon" or "fowl-breasted." The pelvis also changes its form, by undergoing a sort of twist, and its antero-posterior diameter is diminished, which, in the female, frequently causes the process of parturition to be difficult, and sometimes impossible, without mechanical aid. The limbs, both upper and lower, become bowed forwards or outwards; most frequently the latter. Sometimes both lower limbs are bent in the same direction, as if the feet had been pressed against the ground at the same point, and the limbs bent by some external force, in a similar manner as one would bend a young green tree. Sometimes the knees come almost in contact, and the legs greatly diverge, placing the feet upon the ground much apart, like the extremities of an equal-sided cross. In some cases the entire skeleton is so variously curved and deformed, that it is futile to attempt, and impossible, indeed, to give, a correct description of it. The joints, particularly the knees, wrists, and ankles, become enlarged. This enlargement of the wrists and ankles, and general softness of the flesh which accompanies it, are often the first symptoms of rickets that attract the attention of the parents or medical attendant. The abdomen is protuberant; there is more or less enlargement of the liver; in some cases the increase in bulk of this viscus is very great, and can easily be felt by percussion, or pressure of the hand on the right hypochondriac region. The size of the head is increased, and the

Vertex becomes flattened from greater or less spreading of the bones of the cranium; in consequence, in a great measure, we consider, of the atonic relaxed state of their integuments, and of the absence of that brace and support which they receive from these when the system is in health and the soft parts in full tone. The anterior fontanelle and the sagittal sutures remain open. To this condition of the bones of the cranium dropsical effusion in the ventricles of the brain is frequently united. Dentition is generally delayed, and sometimes the teeth are deficient in number for life, and often they early become dark-coloured, and decay. The breath, too, is at times found to be exceedingly foetid: cases are mentioned by authors in which the breath was so foetid and deleterious as to destroy young birds exposed to its influence. The development of the mental faculties of rickety children is irregular, and a thing of uncertainty: sometimes we find precocity of intellect, and premature quickness of the power of observation and remark; at other times just the reverse obtains—the intellectual faculties of the rickety child are plunged in abstraction and stupor. A great many rickety children are, in fact, more stupid than intelligent; and they all appear to be rather stunted and weak in their feelings and affections.

When the distemper of rickets comes upon a child after it has begun to walk, and is beyond a year old, it will be observed to be chronic, and slow in its progress; it steals upon the young sufferer insidiously. The child's habits and disposition are perceived to be changed; from having been an animated active child it has become dejected, and disinclined to exercise or motion of any sort; the countenance is pale; the eyes dull and decolourised; the skin generally pale, and diminished or irregular in temperature; the flesh soft; the knees and the extremities of the radius and ulna at the wrist, and also the tarsal extremities of the tibia and fibula, enlarged. The child, previously of pretty stout and active progression, now stands infirmly and walks slowly, waddling and tottering till it falls, if not supported. The abdomen is protuberant and more resisting than natural, and, on examination, the liver may be found in a greater or less de-

gree increased in bulk; there is increased frequency of the pulse without any real disturbance or acceleration of the circulation;* the appetite is irregular, generally inordinate; the alvine and urinary excretions unhealthy; the former are deficient in bile, and occasionally exhibit appearances of blood. Such are the symptoms which, in the majority of cases, will be found to characterise the first stage of rickets when this affection invades the system of the child that has begun to exercise its power of locomotion and perhaps speech. The symptoms of the further progress of the malady are similar in all respects to those of the disease as it occurs in the infant of a few months old, which have been already described.

With regard to the prognosis in rickets, it may be stated that the earlier the disease makes its appearance in the system of the child, the greater is the difficulty of its cure, and the danger of its proving fatal. The older the child is before being attacked, the greater is the hope of its recovery from the malady. Few are attacked after five years of age, and the recoveries all, or the great majority of them, take place previous to this epoch.

Let us here quote a case of rickets as the disease exhibited itself in the system of a female infant, described in the Commentaries of Van Swieten, which must be considered instructive and worthy of note, as affording a good example of this malady in a state of great aggravation and severity, with its signs of amendment, and process and progress of recovery, and restoration to sound health. All diseases, observes Hippocrates, or some other ancient high authority, and the observation is founded in every-day fact, terminate in health, death, or transition to another affection: and if it be a matter of practical consideration and utility attentively to observe the gradual development of the signs of death or of morbid change, when a disease is about to terminate fatally, or to assume a new nature, it is certainly satisfactory, much more pleasing, and not less useful, to note the appearances of returning health, and mark the gradual manner in which the characters of disease thereupon become more faint, and finally erased. Speaking of this case, Van Swieten

* See paragraph at the end of this paper.

goes on to state—"She was born very healthy, and had so good a colour during the first months that every body hoped she would totally escape the calamities of her brothers: she was hardly a year old when she began to grow pale and ill; the abdomen swelled; the wrists, knees, and ankles, protuberated; the thorax was raised; the ankles were incurvated; the back-bone became crooked; all the bones of the head were enlarged, as if they were affected with an exostosis; the structure of all the bones of the body was vitiated: she also laboured under a complication of diseases, the scurvy, dropsy, a bloody diarrhoea, a scarcity of urine, a fever, a violent cough, attended with vast anguish, and a dread of suffocation. She lived in this miserable condition for above two years. The same remedies (crocus martis et ens veneris — sulphate of iron and muriate of copper), which cured her brother, were applied to her during thirty months in vain, so that their application was almost given over, as there appeared no hopes of a cure from them; but the tender mother, unwilling to spare any pain or cost, the same method was still indefatigably persevered in. The anguish and cough began at length to diminish, and the fever ceased; the flesh looked of a better colour; the tumor of the abdomen was diminished; the incurvated spine grew straight; the joints protuberated less; the elevated sternum grew flatter; the arched figure of the clavicle decreased; the bones of the head subsided: she first began to stand and then to walk; at last no trace of so severe a disease remained, and she became equal in health and strength to other children of the same size. The muscular strength also began to be restored without the assistance of any artificial means; and the bones recovered their due form, which had been so very imperfect during thirty months." (Van Sweiten's Commentaries, Vol. 17, pp. 436 and 437.)

When rickets proves fatal, the emaciation is general and extreme. The subcutaneous cellular tissue has completely disappeared; the muscles are wasted, flabby, and decolourised; the deformed bones soft, and more cellular than natural, and deficient in their *solidifying* constituent of phosphate of lime. The deficiency in this distinc-

tive osseous element has been found to amount to one half the quantity which usually goes to the composition of healthy-formed bone. The medullary matter in the cavities of the bones is sanguineous and jelly-like; and the entire substance of the bone is spongy and more vascular than ordinary. The bones of the cranium, besides being softer, are generally larger than natural, and separated at their sutures, and the brain is frequently distended with dropsical effusion. The cerebral mass, as we have seen, appears large, and inclined to be pulpy. The abdomen is always increased in size, and its parietes wasted and thin. The increase in the bulk of the abdomen is owing chiefly, according to the testimony of Glisson, Hoffman, and others, to greater or less enlargement of the liver. The spleen is occasionally found enlarged. The mesenteric glands are sometimes quite sound, and at other times they are observed to be increased in size. The pancreas and kidneys are pretty healthy, and so also are the stomach and intestines, except that these latter are frequently observed to be more distended than natural. The thymus gland is sometimes greatly enlarged; we have seen it, in a boy between eight and ten years of age, the subject of scrofula and rickets, projecting fully three inches above the sternum, and pressing so upon the trachea as to cause severe dyspnoea. The heart and lungs are sometimes found diseased; the former enlarged or hypertrophied, the latter the nidus of tubercular deposit: but such conditions of these viscera are more adventitious and accidental than properly included in the morbid appearances of rickets. The blood is in a dissolved watery condition, and deficient in all its higher constituents. The causes and treatment of rickets we shall take up in another contribution.

We will here take the opportunity of observing, that, in the examination of disease, there are few symptoms less fully to be relied on than those furnished by the morbid pulse, and it requires a clear comprehensive general knowledge of physiology, with much practical experience, and close acquaintance with clinical pathology, viz. the live and active disease in the person of the patient, to obtain accurate and true information of the state of the system in many cases. The

phenomena of the pulse, in the study and treatment of disease, are more serviceable to the physician in the matter of *prognosis* than of *diagnosis*, and in affording frequent useful delicate indications of the necessity for the administration of general therapeutic agents. Often, as may be observed, when the pulse is beating rapidly, and from this, with other relative symptoms, one might be led to infer that the circulation was in a state of hurry and acceleration, it is not so, but just the reverse obtains—the blood is moving slowly, while the heart and arteries, the containing vessels, are acting inordinately. Such discordance in the motion of the blood and its active circulatory apparatus constitutes a condition of disorder frequently met with of *false excitement*—*excitement with debility*. It is more hardness or resistance, we conceive, in the pulse, together with fulness, and not a high number of beats in a given time, which indicate and announce a rapid strong circulation. And the best ordinary method of nicely appreciating these qualities in the circulation is, when the fingers, in feeling the pulse, have remained for some time upon it, to slightly raise them and gently repress the vessel. In this way we have thought that the most accurate estimate and information of the strength and velocity of the current of the blood, and of the amount of *true excitement* of the circulation, is practically obtainable. It is only the pulse of real or true circulatory excitement that, for the most part, warrants *general blood-letting*: all others, with a few exceptions perhaps, forbid it. Notwithstanding the knowledge of the general circulation which has been obtained by the discovery of Harvey, there is still “ample space and room enough” in this department of physiology for further investigation. We believe there is still much to be learned respecting the ultimate distribution of the blood. The nutritive circulation of every organ, like the structure of the organ itself, we are much of opinion is more or less individual and particular; and the motion or movement of the blood in its most minute and vital diffusion through the tissues of the economy is a thing, like the shades and colour of a summer landscape, of the utmost variety. This, it is obvious, involves, in some degree, a practical point of

some importance, namely, the *duration* of disease, inflammatory in particular, as it occurs in the different parts and structures of the system. We have an unsettled opinion, too, that the motion of the blood in the child is considerably slower than in the adult, although its pulse is always much more frequent. The pulse of the child at birth is double that of the adult. In old age the pulse is always slower than in youth and early manhood, but in old age the pulse is slower also.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

The Transactions of the Provincial Medical and Surgical Association.
Vol. XI. London, 1843.

THE present volume consists of three parts:—

1. A retrospective address by Dr. Black of Manchester, which contains a lucid and interesting summary of all the important facts connected with medicine which had been recorded during the preceding year.

2. A paper on the medical topography of Sidmouth, including the geology, natural productions, and statistics of that district, from the pen of Mr. Jeffrey.

3. Essays and cases, illustrated with numerous engravings.

The first of these is, Experimental and practical inquiries into the structure and functions of the corpuscles of the blood—on inflammation—and on tubercles, by Mr. Addison, of Malvern. This is an interesting paper, but the details are so much connected with the engravings as to render it impossible to give any adequate account of them without the figures.

4. Some cases shewing the advantage of powerful counter-irritation, especially the long issue on the calvarium, by Dr. Wallis, physician to the Infirmary, Bristol.

The author states that he first became aware of the value of this remedy from Mr. R. Smith, the present senior surgeon of the Bristol Infirmary, and he has used it extensively since 1828, when he became physician to the esta-

blishment in question. The following is his account of it:—

“I have used this remedy in a great variety of cases of organic disease of the brain, both chronic and acute; in paralysis, impending effusions, convulsions, erysipelas of the head and membranes of the brain; in fever in the very advanced stages; in one case of hysteria, with very great advantage; and also in a case or two of mania. The general result of my experience of its use has been such as to confirm my favourable opinion of it, as being the most powerful and efficacious of all our remedies of the class of counter-irritants. Its effects are more permanent and its disadvantages are fewer than those of any other remedy now in use. The friends of the patient will occasionally object to it, from that misapplied feeling of affection which converts every energetic effort to save life, if the use of the scalpel be required, into an act of cruelty. This is an objection urged against many of our best, nay even our ordinary remedies, such as a blister or issue of the common kind. The resistance of the friends, however, is generally overcome by remarking quietly, that ‘It is only intended to make an issue;’ an insignificant trifle compared with the distressing effects of disease.”

Mr. Smith does not, however, as a general rule, adopt this remedy at the first onset of disease, but keeps it in reserve until the ordinary remedies have been tried and found wanting. The circumstances necessary to attend to in carrying the remedy into effect are these:—

“Let the head be shaved entirely, and have the patient brought near to the right side of the bed; raise the head by a hard pillow, and put a towel round his neck to receive the blood; let an assistant keep the head steady; at the same time draw the scalp downwards in all directions, so as to strain the calvarium as much as possible; the scalp will divide with so much more ease. In this, your own left hand will materially assist, by placing it at the upper and back part of the head, commencing the incision between your thumb and fore-finger as far back as the lambdoidal suture; press the scalpel sufficiently down so as to divide the scalp entirely through at once; carry on the incision directly along the sagittal suture as far as the hair grows on the

scalp, and which will cover the cicatrix after the issue is healed up. The length of the incision thus made will be in the adult about seven or eight inches; take care that the scalp be divided entirely and perfectly through, so that the edges of the incision will separate so far as to enable you to introduce a dossil of lint rolled up hard, as thick as two fingers, and which should be well soaked in spirit of turpentine; this answers the double purpose of increasing the effect of the incision, and makes suppuration come on earlier, and will usually assist in stopping a further loss of blood. The arteries very soon retract and cease to bleed; there is seldom more than six or eight ounces of blood lost, and this quantity may be very readily curtailed if it be desirable to do so.

“In those cases where depletion has been carried to a sufficient extent, prior to your determination to use this remedy, and the further loss of blood be inadvisable, it may be prevented in the following manner:—The instant the incision is completed, close the sides of the wound, and make pressure upon it with your hand, whilst your assistant hands the lint, well soaked in spirit of turpentine and rolled up firmly of a proper length, so as not to extend beyond the extreme length of the incision, as it would be inconvenient in strapping down the wound sufficiently to check the flow of blood; a little flour and dry lint may be superadded if necessary, but the dossil must not be made so thick as to rise much above the edges of the wound, or else the adhesive straps will not be secure, by being elevated, and thereby prevented from adhering near the edges of the incision. Should the incision be imperfectly made, that is to say, not entirely through the scalp, the arteries might be only partially divided; in which case they will continue to bleed, notwithstanding the pressure you may have made: of course the arteries will require to be completely divided, to allow them to retract and cease to bleed.”

Some good cases are given, in which the remedy proved of service in acute and chronic meningitis, apoplexy and paralysis, epilepsy, hydrocephalus, &c.

5. On the employment of extension in the treatment of fractures of the spine, by W. Hinchman Crowfoot, surgeon to the Dispensary, Beccles.

The case detailed is that of a coachman, aged 42, in whom, from an external injury, the spinous processes of the ninth and tenth vertebræ were divided from each other considerably beyond their usual distance, the body of the ninth vertebra being forced forward, while that of the tenth projected backward. There was total deprivation of the power of voluntary motion and sensation in the lower extremities. A gradual but considerable extension was applied, and gentle attempts were made with the fingers to replace the bones. The deformity was in some measure removed by these means, but without the slightest return of voluntary power in the first instance. He was placed on his back on a firm bed, where he steadily improved, and at the end of three weeks could slightly move the great toe of the right foot; in a few days more this extended to the left foot. The power of the limbs now progressively but slowly returned to such extent that he was able to resume his former occupations.

6. Case of paralysis of the serratus magnus, which caused the lower angles of the right and left scapulæ to become disengaged from the latissimus dorsi, &c. by John Banner, Esq. surgeon, Liverpool.

All the interesting points of this case are given in the "heading." The patient always had good health, and the affection was purely local; nor is mention made of any attempt at relief.

7. Remarks on matico, a styptic much used in South America for suppression of hæmorrhage, by Thomas Jeffreys, M.D.

The matico may be used externally or internally. As a local application the under side answers best. Internally the decoction or infusion (ʒss. to ʒj. in the pint) may be given, in doses of an ounce and a half.

8. Anatomico-chirurgical observations on dislocation of the astragalus, by Thomas Turner, surgeon to the Manchester Infirmary, &c. &c.

This is an elaborate and valuable paper, but one, of which, dependent as it is on engravings, diagrams, and tables, we can give no adequate notion in any analysis. We shall not, therefore, attempt to do so, but content ourselves with subjoining a list of the dislocations described:—

1. Partial, direct, and simple.
2. ————— and compound.
3. ————— simple, and complicated.
4. ————— compound, and complicated.
5. ——— indirect, and simple.
6. ————— and compound.
7. ————— simple, and complicated.
8. ————— compound, and complicated.
9. Complete, direct, and simple.
10. ————— and compound.
11. ————— simple, and complicated.
12. ————— compound, and complicated.
13. ——— indirect, and simple.
14. ————— and compound.
15. ————— simple, and complicated.
19. ————— compound, and complicated.

MEDICAL GAZETTE.

Friday, July 14, 1843.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

EMPLOYMENT OF WOMEN AND CHILDREN IN HUSBANDRY.

THE report of Mr. Austin, on which we commented in our last number but one, gives a gloomy portraiture of compulsory apprenticeship, as it exists in many of our agricultural parishes. Yet, dark as the representation is, we fear that it is not overcharged. It is drawn from the concurrent testimony of witnesses in various grades of society; and though their evidence is combated, as usual, by that of others, the probability is, unfortunately, on the unfavourable side. The state of these young husbandmen and women approaches so nearly to that of serfs, or even slaves, that it is difficult to doubt the existence of the evils which bondage always brings in its train.

"To be worse treated than a parish apprentice," says Mr. Bidwell, "is a proverb, and were not proverbs held to be founded in truth, I could support the verity of this in a variety of instances, of a *general* as well as particular character."

The system is as follows. At the age of nine, a boy is taken away from his parents, not to be restored to them during his minority. "Neither parents nor children are consulted," says Mr. Austin; "they are separated by an act of law, against which there is no appeal." This separation is continued for twelve long years, which must be sufficient, in a large number of cases, to produce the most complete estrangement between parent and child; as it is not to be supposed that in so poor a class apprentices and their parents can visit one another often enough to keep up the feelings of kindred in their original freshness. Indeed, mere distance would often make this impossible. The Stat. 56 Geo. III. which regulates apprenticeships, enacts that a child shall not be bound *more* than forty miles from its place of settlement! The apprentices are knocked about *ad libitum* by master, mistress, and all the other rulers who are put in authority over them; and though very gross cases may be carried before a magistrate, the remedy is obviously as bad as the disease. A household carried on by appeals to the 56 Geo. III. cap. 126, is in an unhappy condition. Sometimes, too, the master can make his apprentices very miserable, and yet keep within the limits of the law; at other times the apprentices are skilful in the art of worrying, and yet keep on the windy side of the 56 Geo. III.

Nor do the female apprentices escape the wild justice of the farm-house. Mary Puddicombe tells of her service at Blackiston, when no longer an apprentice; the servants used to beat *her, and her master* to bang her till she

was black and blue. But "apprentices were treated worse: two, without fathers to look after them, were beat with a stick for anything that happened. One maiden had her arm cut to the bone with a stick the young master cut out of the hedge at the time, for not harrowing right, for not leaving enough for a harrow to go back again. That went to a justice: master was fined £5, and had to pay the doctor's bill. The £5 was given away in bread to the poor. The parish did not bind any apprentices after that."

It was a broad hint to leave off, truly! Mary Rendalls informs us that when apprenticed she had a bad mistress, who used to throw her on the ground, hold her by the ears, kneel on her, and use her very ill. The witness, now 41 years of age, has still the marks from kicks upon her. Mr. Lyddon, a surgeon, has often made inquiries into the condition of apprentices, and is inclined to think that at times corrections rather too severe are inflicted.

Mr. Troode, a farmer, had an apprentice, who did not go to church though sent, and was out late at night. Mr. Troode applied to a magistrate; the boy was sent to the tread-mill for a week, and whipped twice; "but that only made him worse than before; nothing hurts a boy like punishment of that kind." The witness adds, "I had another apprentice, a girl, who stayed out all night; nothing could be worse; Mrs. Troode scolded her, and the girl threw some potatoes at her; I came in at the moment and struck her with the horsewhip. The girl's parents applied to an attorney in Exeter, and the case was brought before magistrates; I was fined £1. Upon this I ordered all my apprentices out of the house, for I found I could not have the proper control over them."

Mr. Palk, a farmer, says, "we don't let our apprentices go home to see

their parents; parents who have been apprenticed never like their children to run home much."

George Moxey, a labourer, says that when an apprentice, he was never beaten nor ill-used by his master, but that he was badly used by the other apprentices; "apprentices always beat each other, go wherever you will."

In fact, the apprentice, friendless and forlorn, is too often knocked about like the fag at a public school, but with a far longer period of slavery before him. He is among those that time lags withal, and few can feel more strongly the pungent truth of the couplet—

Slow as the year's dull circle seems to run,
When the brisk minor pants for twenty-one!

Nor are these poor drudges always consoled for their destiny on earth by the hope of a "bright reversion in the sky"; for "although they are sufficiently clothed for their work," says Mr. Austin, the reporter, "they sometimes have no better kind of clothing for the Sunday; and their masters are ashamed to let them appear at church in their ordinary dress of the week."

Indeed, one of the witnesses, the Rev. Peter Benson, affirms that the moral and religious instruction of a child commonly ceases almost entirely when he has been apprenticed. Farmers do not like to send ragged children to church; and "the rule is rags, the exception is the other way."

A master, of course, stands *in loco parentis* to his apprentice, and if habitual kindness were checkered by occasional severity there would be little or no reason to complain. But if his goodness always "wears the sterner face of love"; if authority scarcely ever melts into indulgence; if the only thing which the farmer can allege in his own favour is that his apprentices have a bellyful, can we wonder that discontent hardens into hatred, or that the despised serf grows up into the enemy

of the social frame which has crushed him?

It would be sad indeed were there no exceptions to this painful rule; we hope that there are many, and bright ones.

Mrs. Tuckett, of Dunsford, in Devonshire, who retains the farm which her husband occupied, draws a pleasing picture of the felicity of her family. Her house is conducted in the old-fashioned Devonshire way. Mistress, servants, and apprentices, mess together on the same provisions; nor are they kept under lock and key; everything is open. The apprentices have five days holiday in the year; three at Christmas, and two at Easter, and Mrs. Tuckett gives them little amusements then, and at other times. Their parents come to see them when they like, and there is always something to eat and a glass of cider for these visitors. The girls are never allowed to work in the fields, except occasionally at hay-time, and then they are kept "in a little set, away from the other people, not to hear their talk."

But Mrs. Tuckett, of whose intelligence and worth Mr. Austin speaks with due praise, is a rare exception; and we perfectly agree with the reporter that it will be well to discontinue agricultural apprenticeship for the future.

We cannot conclude this article without touching upon a point which is prominent in almost every page of the evidence; we mean the extreme privations and singular patience of our rural population. The stringent severity of the New Poor Law was built on the supposition that the poor spent their wages in luxury and dissipation, and that they ought to be compelled to save up money for old age by the prospective horrors of a Union workhouse. But, alas! the mass of evidence, unpicked and ungarbled, shows that the

labourer's wages, in general, scarcely pass starvation point; and instead of the cruel mockery of requiring the husbandman to save something from nine shillings a week, we ought rather to remind the opulent that, in the words of Rousseau, the best medicines for the poor are to be found in the kitchens and cellars of the rich. Instead of constantly reproaching husbandmen, as a class, with their occasional errors, the impartial moralist, when he peruses

"The short and simple annals of the poor,"

will be rather inclined to admire their uncomplaining fortitude, and will admit that the heroism of private life is most often to be found in a station where we should have been least likely to look for it.

In the Report before us, Dr. Greenup, of Calne, after giving in detail the necessary expenses of a labourer's housekeeping, remarks, that when he reckons these things up, he is always more and more astonished how labourers continue to live at all. The diseases which he sees among the poor almost all arise from want of proper food and clothing. At Studley, in Wiltshire, it appears, from the evidence of Mr. Henry Phelps, agent to the Marquis of Lansdowne, that the women work in the fields like men. They are employed in reaping and binding corn in harvest, hay-making, hoeing turnips, weeding, picking stones, filling dung carts, &c. For this they get 8d. a day, or sometimes, at harvest, 10d.

Mr. Bowman, a farmer, and vice-chairman of the Board of Guardians of the Chalne Union, says that, in the great majority of cases, the labourer's family has only the man's wages, 8s. or 9s. a week, to live on. It is a mystery to Mr. Bowman how a man and wife, with five or six children, can live on this. We take it for granted, therefore, that the vice-chairman does

not think it just to punish the labourer in his old age for not having bought an annuity out of the abundant income of his greener years.

Mrs. Britton, the wife of a labourer, deposes that she has seven children, all boys, varying in age from fourteen years to nine months. One of the children is a cripple, and the Guardians allow two gallons of bread weekly for him; but, although her husband is a tea-totaller, the family has not even a sufficiency of bread to eat; and they all sleep in one room.

The next witness, Mrs. Sumbler, the wife of a labourer, gives an account of the unceasing toil in a dairy, having been herself employed in one for eight years before she married. "When cheeses are made twice a day, the work is never done; the work lasts all day, from three in the morning till nine at night."

Another witness, after giving the details of her spare housekeeping, adds, "we never know what it is to get enough to eat; at the end of the meal the children would always eat more. Of bread there is never enough; the children are always asking for more at every meal; I then say, 'you don't want your father to go to prison, do you?'"

It is almost needless to multiply these details of extreme penury. Mary Haynes, a widow of Calne, does men's work in the fields, and has not even a change of clothes. She receives 5s. a week in summer, and 4s. 6d. during the other months. Besides stone-picking, weeding, and hay-making, she reaps and hoes turnips, employments which some persons suppose to be confined to men alone.

"As for work," says another practical philosopher, speaking of the farm where he was apprenticed, "why, people must work, and there was plenty of that;"—the grievous point is, that the work should be so miserably paid.

In a word, the good humour with

which our labourers in husbandry bear toil rewarded by semi-starvation is worthy of all praise; and forms a singular contrast to the distorted ingenuity with which many of their superiors find subjects of annoyance and discontent in the midst of prosperity.

BRITISH MEDICAL ASSOCIATION.

Exeter Hall, July 4, 1843.

DR. WEBSTER, PRESIDENT, IN THE CHAIR.

DR. LANDER, of Sloane Street, Chelsea, was unanimously elected a member.

A discussion having taken place on the subject of Medical Reform, in consequence of the Council having learned that Sir James Graham was disposed to advise Her Majesty the Queen to grant Charters to both Colleges, which the Council believed would be highly injurious to the interests of the medical profession—

It was resolved, 1stly, That a Member be requested to inquire, in the House of Commons, if it be the intention of Government to grant Charters to the existing Colleges of Physicians and Surgeons; and that a communication be addressed, by the President, to the Secretary of State for the Home Department on the same subject.

2dly, That it is highly desirable that the profession, at this critical period, should forward to Her Majesty the Queen addresses, praying that she will be graciously pleased not to grant any Charters to either of the Colleges until the whole subject of Medical Reform shall have been duly considered in Parliament.

3dly, That the attention of the Medical Associations be specially called to the foregoing resolutions, and to the present peculiar state of medical affairs; and that copies of the resolutions be forwarded to the Secretaries of the different Associations.

In consequence of some communications relative to the late order of the Poor Law Commissioners,

It was resolved, that all those Medical Officers who may feel themselves aggrieved by the proceedings taken in connection with the late General Medical Order of the Poor Law Commissioners, be hereby invited to forward particulars of their cases to the Secretary of the British Medical Association, Exeter Hall, in order that active measures may be taken for the removal of the grievance.

The President, in the absence of the Secretary, announced that the Petitions agreed to at the last Half-yearly General meeting of the Association, praying for Medical Reform, and that no Charters should

be granted at present to the two Colleges, had been duly presented—to Her Majesty by Sir James Graham; to the Lords by the Right Hon. Lord Campbell; and to the Commons by H. G. Ward, Esq. M.P.

The Meeting was then adjourned.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN

IN LONDON AND ITS VICINITY.

AN Extraordinary General Court of this Society, numerously attended, was held on Wednesday last, at the Gray's Inn Coffee House. Dr. Mann Burrows, Vice-president, was called to the Chair, and briefly explained the object of the meeting, which was to elect H.R.H. the Duke of Cambridge as Patron of the Society. At the last Annual Dinner, His Royal Highness most graciously signified his willingness to accept the office, and from the interest which he has taken in its proceedings for some time past, it is probable that the patronage of His Royal Highness will be actively and beneficially exerted in furthering the very laudable objects of this society. It was announced that the publication of the Laws, List of Members, &c. would be delayed for a few days.

VARIETIES OF SUGAR.

1. *Purified or Refined Sugar*.—This is met with in the shops either in conical loaves (*Loaf Sugar*), or truncated cones called lumps (*Lump Sugar*), of various sizes and degrees of purity. Small lumps are called *Titlers*. The finest refined sugar is perfectly white, and is termed *double refined*; the inferior kind has a slightly yellowish tint, and is called *single refined*. Both varieties are compact, porous, friable, and made up of small crystalline grains.

2. *Brown Sugar* occurs in commerce in the form of a coarse powder, composed of shining crystalline grains. It is more or less damp and sticky, and has a peculiar smell and a very sweet taste. Its colour is brownish yellow, but varies considerably in intensity. *Muscovado* or *raw sugar*, sometimes termed *Foot Sugar*, has the deepest colour, and is intermixed with lumps. *Bastard* is a finer kind prepared from molasses, and the green syrups.

Raw sugar contains several impurities from which it may be freed by the process of refining. Its colour is owing to the presence of *Uncrystallisable sugar* (treacle). In an aqueous solution of raw sugar lime is detected by oxalic acid. By keeping, it is well known that a strong raw sugar becomes weak, that is, soft, clammy, and gummy. This change Professor Daniell

ascribes to the action of the lime. *Sub-phosphate of lime* is another constituent of raw sugar. *Glutinous* and *gummy matters*, and traces of *tannic acid*, are also present in raw sugar. The *crystal sugar* brought from Demerara (and St. Vincent's?) is the finest and purest kind of the coloured sugars which are imported. Its colour is pale yellow, and its crystals are larger and more brilliant than the preceding varieties. It is used for sweetening coffee. On account of the before-mentioned impurities, unrefined sugar is an improper article of diet for those afflicted with calculous disorders.

3. *Sugar Candy*.—This is crystallised cane-sugar. It is prepared from concentrated syrup. The crystals deposit themselves, as the liquid cools, on the sides of the vessel and on strings stretched across. The form of the crystals is an oblique rhombic prism. Three kinds of candy are sold—the *white*, the *brown*, and the *pink*. Powdered candy is used to sweeten coffee.

4. *Aqueous Solutions of Sugar*.—*Sugar water* is frequently used at the table on the continent. *Syrup* is prepared by dissolving two pounds and a half of sugar in a wine-pint of water, by the aid of a gentle heat. If necessary, it may be clarified by white of egg. It is used for sweetening.

5. *Boiled Sugars*.—If a small quantity of water be added to sugar, the mixture heated till the sugar dissolves, and the solution boiled to drive off part of the water, the tendency of the sugar to crystallise is diminished, or, in some cases, totally destroyed. To promote this effect, confectioners sometimes add a small portion of cream of tartar to the solution while boiling. Sugar, thus altered by heat, and sometimes variously flavoured, constitutes several preparations sold by the confectioner. *Barley Sugar* and *Acidulated Drops* are prepared in this way from white sugar;—powdered tartaric acid being added to the sugar while soft, when the drops are prepared. *Hard-bake* and *Toffee* are made by a similar process from brown sugar. Toffee differs from Hardbake in containing butter. The ornamental sugar-pieces or *caramel-tops* with which pastry-cooks decorate their tarts, &c. are prepared in the same way. If the boiled and yet soft sugar be rapidly and repeatedly extended, and pulled over a hook, it becomes opaque and white, and then constitutes *Pulled Sugar* or *Penides*. Pulled sugar, variously flavoured and coloured, is sold in several forms by the preparers of hard confectionary.

6. *Molasses and Treacle*.—The brown, saccharine, viscid fluid, which drains from raw sugar when placed in hogsheads, is called *Molasses*, and is used in the preparation of brown sugar. It is imported from the West Indies in casks. Closely allied to this is *Treacle*—a viscid, dark-brown, un-

crystallisable syrup, which drains from the moulds in which refined sugar concretes. These liquids result from an alteration effected in crystallisable sugar, and do not exist in the sugar cane. Both of them contain free acid.

7. *Burnt Sugar*.—When sufficiently heated, sugar becomes brown, evolves a remarkable odour, loses its sweet taste, and acquires bitterness: in this state it is called *Caramel* or *Burnt Sugar*, and is sold, when dissolved in water, as a colouring matter, under the name of *Essentia Bina* or *Browning*. It is used to colour soups and sauces. The high coloured brandies and dark brown sherries are said sometimes to owe part of their colour to this liquor. The brewer, it is reported, occasionally makes use of it to colour his beer.

8. *Hard Confectionary*.—Sugar constitutes the base of an almost innumerable variety of hard confectionary, sold under the names of *Lozenges*, *Brilliantes*, *Pipe*, *Rock*, *Comfits*, *Nonpareils*, &c. Besides sugar, these preparations contain some flavouring ingredient, often flour and gum, to give them cohesiveness, and frequently colouring matter. Caraway fruits, almonds, and pine seeds, constitute the nuclei of some of these preparations.

9. *Liquorice Sugar*.—An aqueous extract of the root of liquorice (*Glycyrrhiza*) is extensively imported under the names of *Liquorice Juice*, or, according to the countries from which it is brought, of *Spanish* or *Italian Juice*. *Solazzi Juice* is most esteemed. The Spanish extract is prepared in Catalonia, from the common liquorice plant (*Glycyrrhiza glabra*), but the Italian extract, obtained in Calabria, is procured from *G. echinata*. Extract of liquorice is imported in cylindrical or flattened rolls, of five or six inches long, and about one inch in diameter, enveloped in bay-leaves. Its principal constituent is *Glycyrrhizin*, or *Liquorice Sugar*, mixed with some foreign matters. If the foreign extract be dissolved in water, and the solution filtered and evaporated, we obtain *Refined Liquorice*, but the *Pipe Refined Liquorice* of the shops is a very adulterated article. The *Pontefract Lozenges* are made of refined liquorice, and are much esteemed. The *Liquorice Lozenges* are officinal in the Edinburgh Pharmacopœia, and are directed to be prepared of extract of liquorice, gum, and sugar. There is also another liquorice lozenge sold in the shops, under the name of *Quintessence of Liquorice*. Extract of liquorice is used as a flavouring ingredient. Slowly dissolved in the mouth, it is taken to appease tickling cough, and to allay irritation of the fauces.

10. *Preserves, &c.*—In addition to its dietetical and condimentary uses, sugar is extensively employed, in domestic economy,

as an antiseptic ; that is, to prevent the decomposition or putrefaction of organic substances. A variety of fruits, as well as some roots, stems, and even leaves, are in this way preserved, some in the moist state (as *Fruits in Syrup*, and *Preserved Ginger*) others in the dry state (as *Candied Angelica*, *Candied Citron*, *Orange*, and *Lemon Peels*, and *Crystallised Fruits*). In these cases sugar acts by excluding air, or by absorbing moisture, or in both of these ways. In some instances, perhaps, its efficacy may be of another kind, as when it promotes the solidification of vegetable jelly. "Latterly," says Berzelius, "sugar has begun to be more generally employed than formerly for the preservation of meat, in consequence of a much smaller quantity of it being required for preventing putrefaction, than of salt, while it renders the meat neither less savoury nor less nutritive. Fish, when gutted, may be equally well preserved by spreading powdered sugar inside them."—*Dr. Pereira, On Food and Diet.*

NEW TEST FOR ARSENIC.

THE one-hundred-and-forty-fourth part of a grain of arsenious acid was mixed with two fluid drachms of milk. The mixture was boiled with a few drops of muriatic acid, and a slip of copper was introduced. In less than a minute the metal was coated with a grey film of metallic arsenic. Several pieces were thus coated ; they were washed in water, dried in the heated current of air over a spirit lamp-flame, and introduced into a small reduction tube. On applying a gentle heat to the copper, octohedral crystals were obtained ; visible to the eye in the light of the sun, but plainly distinguishable with a lens of low power. The crystals dissolved in water gave the usual reactions with the ammonio-nitrate of silver and sulphuretted hydrogen gas. In a second experiment, the same quantity of arsenic was mixed with two drachms of porter ; in a third, a like quantity with two drachms of gruel, and the copper test was applied with similar satisfactory results. Each experiment was completed in about five minutes. Brandy, containing a poisonous impregnation of arsenic, was then tested ; and the arsenic readily separated. A few drops taken from a bottle of port wine, containing arsenic, and which had nearly caused the death of three persons about four years ago, were next submitted to the test, and the metal readily obtained. In organic solids the results were equally striking : a few grains of a cake containing arsenic, which had been used in an attempt to poison, were boiled in a small quantity of distilled water, and muriatic acid and copper added, when metallic arsenic was im-

mediately precipitated. The contents of the stomach of a person who was poisoned by arsenic in February, 1834, which had been loosely exposed, and allowed to become decomposed during a period of upwards of nine years, were next examined. A few drops of the thick turbid liquid were placed in a tube and boiled with dilute muriatic acid and water ; the copper introduced was covered with a bright layer of metallic arsenic. The contents of three other stomachs taken from persons who were poisoned by arsenic in 1835, 1838, and 1840, gave precisely similar results. In the last case, the whole of the contents, with the food at the time contained in the organ, had been evaporated to a dry solid mass ; a few grains of this were sufficient to furnish a clear demonstration of the presence of arsenic by the aid of the test. In the conversion of the metal to arsenious acid, it will at once suggest itself that if octohedral crystals should not be obtained by heating one portion of copper, several slips should be introduced together or separately. In all these cases arsenic will have been discovered by the application of Marsh's test, or sulphuretted hydrogen gas ; but the process would have occupied a much longer time, and with regard to Marsh's test the metallic arsenic could not have been so speedily converted to arsenious acid in a form convenient for the identification of its properties.

Another useful application of the copper test may be made in the following way. If the arsenic have been thrown down from an organic liquid in the form of impure sesquisulphuret, this may be dried and deflagrated with nitre, or decomposed by nitro-muriatic acid, whereby arseniate of potash or arsenic acid will result, and the organic matter will be entirely decomposed. In the case of deflagration by nitre, the surplus nitric acid should be expelled by sulphuric acid, and the arseniate dissolved out of the residue ; or if nitro-muriatic acid be used, the liquid may be evaporated to dryness. On boiling either of these products with copper and muriatic acid, the metallic arsenic will be readily procured.—*Mr. Taylor, in British and Foreign Review.*

EMPLASTRUM CERATI SAPONIS.

ALTHOUGH this plaster has for many years been extensively sold, spread on linen or calico, we have not seen any published formula for it, and the soap cerate being too soft for use as a plaster, several correspondents have inquired how they should proceed when emplastrum cerati saponis is ordered in a prescription.

The addition of one part of ceratum saponis to two parts of emplastrum plumbi,

forms a plaster which, on an emergency, might be used in such a case, the article in question not being a preparation of the Pharmacopoeia. But the most legitimate mode of reducing the cerate to the form of a plaster is to continue the evaporation until all the vinegar is expelled. This method is adopted at the Army Laboratory, where the plaster is kept, not only spread as usual, but also in rolls like other plasters.

The following is the formula used at the Army Laboratory:—

Common vinegar (No. 24)	. 8 gallons,
old measure.	
White Castile soap.	. . 16lb.
Yellow wax.	. . 20lb.
Olive oil.	. . 32lb.
Litharge.	. . 32lb.

Boil the litharge with the vinegar almost to dryness; remove from the fire and add the soap, previously scraped or cut; replace on the fire, taking care to avoid empyreuma; then add the wax and oil, melted and strained, and continue the evaporation, stirring constantly until the whole of the vinegar is expelled. The time required for completing the above quantity is three or four days.

The original recipe directed eight gallons of the residuum of distilled vinegar to be used instead of twenty-four gallons of common vinegar. The plaster thus prepared has a dark brown colour; but when the vinegar is used and the plaster has been carefully made, its colour is not much darker than that of adhesive plaster. The emplastrum cerati saponis extensum, as usually sold, is coloured artificially with burnt sugar.—*Pharmaceutical Journal.*

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXXV.

*On labours complicated with uterine
hæmorrhage after the delivery of the
child and retention of the placenta.*

SINCE the last lecture, a case of uterine hæmorrhage in the ninth month of pregnancy, occasioned by detachment of the placenta from the superior part of the uterus, which had nearly proved fatal, has occurred to me in private practice. At nine in the morning, a lady, without having been exposed to any accident, or experiencing any uneasy sensation in the region of the uterus, was suddenly alarmed with a gush of blood from the vagina. I saw her soon after, when an oozing of blood continued, but there was no faintness, feebleness of the pulse, or change in the countenance, and no symptoms of labour. The os uteri was so high up, directed so much backward, and so closed, that I could not ascertain by the usual examination whether or not the placenta was presenting. As the operation of turning was impossible, cold applications were made to the parts, an opiate was given to prevent uterine contractions, and the patient kept in the horizontal position in a cool atmosphere. The blood, however, continued to flow, and slight pains, with great faintness and sickness, commenced in four hours. The os uteri was then felt dilated to the size of half-a-crown, and no part of the placenta presenting; the smooth

membranes covered the whole cervix uteri. I immediately ruptured them, and held up the head that the liquor amnii might escape, applied a binder firmly around the abdomen, and gave some brandy and water. The pains became more frequent, the hæmorrhage ceased, and by compressing the fundus uteri, and gently dilating the orifice, though the faintness became more distressing, the child was expelled dead in about two hours, and no hæmorrhage followed. The placenta was found lying loose in the vagina, and on tightening the binder, and removing the after-birth, masses of dark-coloured coagulated blood escaped in such quantity as nearly to fill a wash-hand basin. There had been an internal hæmorrhage going on from the first attack of flooding, and though no discharge took place after the expulsion of these coagula, the patient remained for several hours in a state of the most dangerous exhaustion, with a pulse scarcely to be felt at the wrist, occasional complete loss of consciousness, restlessness, and severe attacks of retching and vomiting. These symptoms, however, gradually subsided, after the exhibition of a large opiate, and she is now recovering in the most favourable manner. In this case the operation of turning, which I am certain could not have been performed without the employment of great force, would have been attended with fatal consequences. The plug, as recommended by Dr. Burns, could have had no effect here in restraining the hæmorrhage which was going on within the uterus, and had nearly destroyed the patient; it could not have checked the flooding until the "os uteri was in a proper state for delivery," as he asserts. Had it been possible, at the commencement of the attack, to have ascertained with certainty whether or not the placenta presented, it would have been better practice then to have ruptured the membranes than delayed doing so for some hours, as it was evident from the first that there could be no safety till the delivery was completed.

On uterine hæmorrhage between the delivery of the child and expulsion of the placenta.

Flooding sometimes occurs in the most dangerous form, immediately after the birth of the child, where the previous stages of labour have been managed in the most judicious manner—where every thing has been done to quiet the action of the heart and arteries; the apartment kept cool; stimulants avoided; voluntary efforts to expel the child discouraged; the binder applied and tightened in the progress of the two first stages of labour,—in a word, where every thing that is possible has been done to prevent the uterus from being suddenly emptied of its contents, and afterwards from contracting in an irregular manner. In some women, in spite of all our care and precautions, a profuse discharge of blood immediately succeeds the delivery of the child, and they would soon die if we did not interfere; and before the placenta was expelled. A large stream of blood flows from the vagina, which collects in handfuls around the nates, thighs, and body of the patient, so that she is literally deluged with it, and soon begins to suffer the usual effects of sudden and great loss of blood. In other cases, a frightful rush of fluid blood, a perfect torrent, issues from the uterus after the birth of the child; the patient becomes in a very short space of time not merely faint, but perfectly unconscious of every thing that is going on around her; she neither sees nor hears any thing. Some women suffer repeatedly from attacks of this description, and those are peculiarly exposed who have been exhausted by very protracted labour. In many other cases the discharge of blood from the uterus after the birth of the child is gradual, in much smaller quantity, and attended with comparatively little danger.

I believe there is no difference of opinion respecting the method of treatment which ought to be adopted in these cases. As the placenta is wholly or partially detached from the uterus, and prevents its regular contraction, and the coagulation of the blood, in the exposed vessels like a foreign body, the placenta must be extracted artificially without delay, and compression of the fundus uteri and all other means actively employed, to cause the uterus to contract in a regular and permanent manner. The principles which ought to guide you here are perfectly obvious; but if you are frightened at the suddenness of the accident, and the appalling loss of blood, you may hesitate to pass up the hand into the uterus, and try by pulling upon the funis to bring away the placenta. If you do so, the uterus may be inverted, or, what is much more probable, *the cord will be broken off close to the placenta, and it will be left behind, and the*

hæmorrhage will probably continue till the woman dies, or you procure the assistance of some one properly prepared to act in such a case. Where uterine hæmorrhage takes place to any considerable extent after the birth of the child, apply the binder firmly around the abdomen, with a pad of folded napkins under it over the fundus uteri, and proceed immediately to extract the placenta. Take off your coat, put the cord upon the stretch with your left hand, and pass up the right hand along it into the uterus, dilating the cervix if it is contracted, expanding the fingers to the circumference of the placenta, and pressing the portion of the mass slowly from the inner surface of the uterus, which adheres to it, and extracting it slowly. The placenta in most of these cases is partially adherent to the uterus, when it requires to be extracted, and you must take care to separate this portion cautiously with the fingers, before attempting to remove the whole placenta from the uterus. If you grasp with the hand the detached portion, and draw it away, the adherent part will be left behind, and the patient will probably afterwards be destroyed by hæmorrhage, or putrefaction of the portion retained. It is not requisite to pass the points of the fingers between the adherent portion of placenta and lining membrane of the uterus, or expose this to be torn, but to press off this portion of the placenta from it with the points of the fingers, as you would a sponge adhering to a rock, which you do not require to touch. No man is thoroughly prepared to undertake the charge of a common midwifery case, who would hesitate to pass up his hand into the uterus and remove the placenta, whether adherent or detached, if dangerous hæmorrhage occurred in the interval between the second and third stages of labour. If you allow any woman to die from hæmorrhage at this time without removing the placenta, you will justly be considered incompetent to discharge the duties of an accoucheur, and severely censured.

Sixty-four cases of hæmorrhage between the birth of the child and expulsion of the after-birth occurred in the Dublin Lying-in Hospital during the residence of Dr. Collins; in six of the 64 the hæmorrhage continued after the removal of the placenta. In 45, the hæmorrhage was slight, at least not alarming; and in the remaining 19 it was severe. In 17 of the 64, assistance became necessary in the course of the first 15 minutes after the birth of the child; in 3 in 20; in 6 in 30; and in 7 in 45 minutes; in 12 in 1 hour; in 7 in 1½ hour; and in 8 in 2 hours. In 4 cases the time is not noted. In 13 of the 64 cases, the placenta, on the introduction of the hand, was found firmly adherent; in 8 cases the hour-glass, or irregular, contraction was present, and in 43

cases its removal was easily effected. Five of the 64 were premature labours; viz. one at the fifth month; three at the seventh; and one at the eighth month. Seven of the 64 women died; two only from the effects of the hæmorrhage; of the other five two died of puerperal fever; one of extensive disease of the vagina with laceration; one of inflammation of the uterus; and one chiefly of disease of the lungs.

At present I am unable to state the exact number of cases of this variety of uterine hæmorrhage which I have seen, or present you with a tabular view of them, and the results.

On uterine hæmorrhage after the expulsion or extraction of the placenta.

But one of the most dangerous varieties of uterine hæmorrhage is that which follows the natural expulsion of the placenta, or its removal from the uterus by art. Sometimes the blood escapes in great quantities from the uterus immediately after the removal of the placenta, and the pulse ceases at the wrist, and consciousness is entirely lost in a few seconds. There is no symptom before labour has commenced, or during its progress, to warn you of what is about to take place. The child has been safely delivered, the placenta has come away in a short time, and while you are perhaps congratulating yourself on the happy termination of the labour, the blood begins to trickle over the bed upon the floor, or the patient suddenly complains of great faintness. In such cases there may be either a want of uterine contraction, or the contractions may not be permanent, but be followed by relaxation and the effusion of a large quantity of blood, which may either appear externally, or remain to become coagulated, and distend the uterus. For several hours after delivery, in some cases, this alternate relaxation and contraction goes on, to the great hazard of the patient, and if her condition be not clearly ascertained, and the proper remedies be employed, death may unexpectedly take place.

By far the most important remedies in these cases of uterine hæmorrhage are constant and powerful pressure over the fundus uteri, the application of cold around the pelvis, and the free administration of wine, brandy, and other stimulants: ergot is indicated, but it most frequently produces no effect. The pressure and cold are always within our reach, however sudden the attack may be. The hypogastrium should be strongly compressed with the binder, and a pad of folded napkins placed under it, and in addition the hand should be firmly applied over the fundus uteri. I do not know who it was that first employed compression of the fundus uteri in cases of flooding after the birth of the child; but it has been often

recommended, and there are now few practitioners in this country who are not fully aware of the importance of the binder and pad, in exciting permanent and regular uterine contractions. Dr. M'Keavor states, that in 1815 it was recommended by Dr. Labatt in his lectures, and for a number of years before this Dr. Labatt was accustomed to recommend a thick firm pad, or compress, over the pubes previous to the application of the ordinary binder, where in former labours uterine hæmorrhage had taken place. Dr. M'Keavor states, that of 6665 women delivered during the years 1819 and 1820, only 25 were attacked with hæmorrhage after the birth of the child. Of these, 15 occurred before the expulsion of the placenta, ten afterwards, and in all the result was favourable. He saw only two fatal cases during the time he was in the Dublin Lying-in Hospital, and he attributes this small mortality to the entire process of parturition being understood; to the unassisted gradual efforts of the uterus; partly to the patients having been kept cool and quiet, free from all sources of disturbance and irritation; but, above all, to the careful application of the binder immediately after delivery, by which means the expulsion of the placenta, and the permanent contractions of the uterus, are most effectually secured, and whenever any tendency to hæmorrhage did occur before the removal of the placenta the first point invariably attended to was to tighten the binder, and in the event of this not succeeding, a thick firm compress, made by folding a couple of large coarse napkins into a square form, was placed over the region of the uterus, and the binder again adjusted. In the great majority of instances, these, with the admission of cool air, checked the discharge; if not sufficient, additional pressure was made with the hands.

At the same time that you efficiently compress the fundus uteri with the binder and pad, cold should be vigorously applied to excite the contractions of the uterus. The best mode of doing this is to plunge a large napkin in a pitcher of cold water, and dash it suddenly against the external parts, the nates and thighs; and this should be repeated till the uterus contracts and the violence of the hæmorrhage is controlled. I am satisfied that this is the most efficacious method of applying cold to excite uterine contractions; it is far less formidable than pouring water from a height over the naked abdomen, but it is not less efficacious, and it possesses these decided advantages over the other method, that while the application is made to the external parts, nates and thighs, the pressure of the binder and pad is not withdrawn from the hypogastrium, the position of the patient is not changed from the side to the back, the bed is not inundated with water,

and the application can be repeated as often, and continued as long, as the urgency of the symptoms may require. The abdomen may be exposed once, and cold water poured over it from a height, and the uterus made to contract, and the flow of blood be arrested for a time, but relaxation of the uterus may follow after a short interval, and the hæmorrhage be renewed again with equal violence as at first, but we cannot with propriety expose the abdomen a second time, and empty over it from a height the contents of a great decanter or kettle. Besides, by adopting this practice, we sacrifice the whole of the effects derived from pressure on the fundus uteri. The application of a napkin soaked in vinegar and water to the parts is often sufficient, along with the binder, to restrain the hæmorrhage where it is not very profuse.

I have very seldom introduced a plug of any kind into the vagina in these cases, but when there has been a draining of blood from the uterus, after the practice now described has been employed, a large soft sponge passed into the vagina, and pressed up against the os uteri, has appeared in some cases to promote the coagulation of the blood. The sponge, however, cannot be employed with safety after the expulsion of the child and placenta, unless the uterus be firmly compressed above the brim of the pelvis to prevent its becoming distended with blood. More frequently I have had recourse, with good effect, to the introduction of several pieces of smooth ice into the upper part of the vagina, and allowing them to remain here, in contact with the os uteri, and be dissolved—or pieces of ice have been inclosed in a bladder and laid over the pubes.

Other means besides those now described have been recommended in cases of flooding after the expulsion of the placenta. It has been proposed to inject cold water into the cavity of the uterus by means of the stomach-pump, and favourable reports have been given of the practice. The effect, I think, would be similar to directing forcibly a stream of cold water against a stump soon after amputation; the coagulum in the cavity of the uterus and in the orifices of the vessels would be all washed away: nevertheless, it might perhaps be advantageous in some desperate cases. Port wine and water as cold as possible, Dr. Collins says, injected into the rectum, has been of service. Some of the earlier writers on midwifery, and many in the present century, have strongly recommended the introduction of the hand within the uterus for the purpose of removing the coagula accumulated within the cavity, and to excite the uterus to contract. But it is not necessary to pass the hand into the uterus for the removal of coagula, because if the *binder has been properly applied, and strong pressure made over the fundus uteri, clots*

cannot accumulate within the uterus, and if they have been permitted to collect in consequence of neglect, then expulsion will immediately follow the use of proper compression of the hypogastrium, without the introduction of the hand. Nor do I consider it necessary, to excite uterine contractions, that the hand should ever be introduced into the cavity of the uterus after the removal of the placenta. I am fully convinced, from repeated observation, that this practice, which is so common as to be almost universal in this country at the present time, is often not only ineffectual for the purpose, in the worst cases of flooding, but that it is often followed by the most pernicious effects; the coagula which nature has formed have been displaced by the hand, and the uterus has not been excited by the stimulus of it to secure a permanent contraction. In the greater number of fatal cases of uterine hæmorrhage after the expulsion of the placenta which have come under my observation, the hand had been introduced into the cavity, and the closed fist had been pressed for a longer or shorter time round and round against the lining membrane, to make the uterus contract. I do not recollect a single fatal case, where the unfortunate result could be fairly attributed to the want of the introduction of the hand into the cavity of the uterus, and the friction of the knuckles against the lining membrane. I have repeatedly passed the hand into the uterus to produce contraction, but it has refused to obey the stimulus of the hand; it has remained like a soft flaccid bag, more like a piece of intestine than uterus, and the blood has continued to pour down the arm, until the hand has been withdrawn, and more efficient remedies employed. Leroux was well aware that the stimulus of the hand would not in all cases excite the uterus to contract, for he observes, “where the os uteri is contracted, the means indicated by Levret are very efficacious, and remove the hæmorrhage as if by a charm. But it is not so in complete inertia of the uterus; often it is widely dilated, and offers no resistance to the introduction of the hand. The introduction even of the whole hand excites little sensation, and the woman will promptly perish from the hæmorrhage, if other means more active and certain are not employed to prevent it.” The tampon or plug is the remedy Leroux recommends in cases of flooding after delivery, and he affirms that it will often succeed in stopping the flow of blood when all other means fail. Dr. Dewees observes “that he has not found it necessary to introduce the hand for the purpose of stopping an hæmorrhage after the expulsion of the placenta, during the last five-and-thirty years, and he regards the practice as always frightful, and oftentimes unnecessary and

pernicious. But it is difficult to subvert an established mode of practice, however unsound, and probably some of you, without much reflection, because you have heard this recommended, will pass up the hand into the cavity of the uterus after the expulsion of the placenta, on the very first occasion that you have an opportunity of doing so, remove all the coagula, and rub the inner surface with the fist till you are tired, without effect. I have seen cases repeatedly where this had been diligently performed by those who had neglected to apply the pad and binder, and all the other means now described. If you pass the hand at all within the parts, which I strongly suspect you will do, let me entreat you to carry it no further than the os uteri, which you may with much less risk and with greater effect press and rub with the fingers and irritate, than the inner surface of the body and fundus of the uterus.

Another reason has been assigned for passing the hand within the uterus in cases of flooding after the expulsion of the placenta, and which is the least satisfactory of all; it is, that the part of the uterus where the placenta was attached, from which the blood is flowing, may be compressed like a tourniquet between the hand in the uterus, and the other hand over the hypogastrium.

"My belief now is," says Dr. Gooch, "that when hæmorrhage occurs after the removal of the placenta, the quickest way to stop it is to introduce the left hand closed within the uterus, apply the right hand open to the outside of the abdomen, and then between the two to compress the part where the placenta was attached, and from which chiefly the blood is flowing: when the hand is introduced merely as a stimulant, there is an interval of time between its arrival within the uterus and the secure contraction of this organ, during which much blood is often lost. By directing the hand to the very vessels from which it issues, and compressing them as I have described, this quantity is saved. If I may judge by my feeling, the blood stops, in a great degree, even before the uterus contracts; the hand acts first as a tourniquet, then as a stimulant. It is true we cannot tell with certainty where the placenta was attached, and consequently where the pressure should be applied; but as it is generally attached to or near the fundus, if the pressure be directed there, it will generally be right. Besides, after the child is born it is often several minutes before the placenta separates and descends: if, during this interval, we pass up the finger along the cord, and observe, at its entrance into the uterus, whether it turn towards the point, the back, the right or left side, or straight up to the fundus, we shall form a tolerably exact idea of the spot to which the placenta has been attached in this individual

case." Without passing the whole hand into the uterus, it is impossible to know where the placenta adheres. Most frequently it is to the posterior part of the body and fundus; the hand, therefore, if introduced like a tourniquet, as here recommended, would compress the anterior wall, or that part of the uterus where there were no bleeding vessels. Mauriceau recommends that women who are subject to flooding after delivery should be bled twice or thrice from the arm during pregnancy, and once, or oftener, after labour has commenced. There are cases of uterine hæmorrhage after the delivery of the child and expulsion of the placenta unconnected altogether with plethora, or an excited state of the heart and arteries, and where bleeding and low diet do not prevent the accident. Rupturing the membranes at the very commencement of labour is by far the best remedy, the only thing indeed upon which any dependence can be placed.

I have had no experience of the effects of transfusion of blood in cases of uterine hæmorrhage. Some have been published in support of the practice, but, as Dr. Merriman observes, they are far from conclusive. Few women, if any, have been saved by it. Dr. Blundell has given an account of six cases in which injection into the human veins was attempted. A woman had lost a large quantity of blood after the expulsion of the child. She had ceased to respire, when sixteen ounces of blood, procured by venesection, were thrown into the bleeding vein of the arm. No signs of resuscitation were observed. In a man who had lost a large quantity of blood by the bursting of an artery, it was not more successful. In a third case it was equally unsuccessful. No effect was produced by it in a woman dying from puerperal fever and loss of blood. In a case of scirrhus of the pylorus it was employed, and the man died fifty-six hours after the operation. Dr. Ashwell has related a case of labour with placental presentation, where transfusion was twice performed without success. Ten ounces of blood, which flowed copiously from a healthy young woman, were injected by Dr. Collins into the median vein of a patient dying from uterine hæmorrhage, but it did not seem to have any more effect than causing the woman to mutter indistinctly; the circulation was not improved, and she expired a few minutes after the operation. Other cases have been recorded with equally unsatisfactory results, which it is unnecessary to quote.

After attacks of uterine hæmorrhage, the patient should not be raised from the horizontal position for several hours, and the strength should be supported by wine, beef-tea, and light nourishment. Brandy in gruel sometimes agrees when wine is rejected.

A good large dose of the liquor opii sedativus often produces the most decided benefit after the hæmorrhage has ceased; there are few cases before this in which opium does good, though it is constantly given in all the varieties of flooding, even when the great object is to excite uterine action. Where recovery is to take place after uterine hæmorrhage, says Dr. M. Hall, the pallor of the countenance, the disposition to syncope, the coldness of the extremities, the feeble state of the pulse, and interrupted respiration, pass gradually away. Where the case is to terminate fatally, the symptoms gradually assume a more alarming aspect, the countenance becomes pale and sunk, the respiration stertorous, and the pulse cannot be felt at the wrist. There is great restlessness, and before death one or more fits of convulsions sometimes occur. Where recovery takes place, in some women it is astonishing how little permanent inconvenience is felt from the great loss of blood which they have sustained. In the course of ten days or a fortnight the effects have entirely disappeared; and this is the most common result. In some women, a violent determination of blood takes place to the brain, marked by heat, strong pulsations of the carotid and temporal arteries, intolerance of light, and all the symptoms of inflammation of the brain or its membranes. A strong febrile attack is also sometimes experienced without an increased determination of blood to any particular organ. These affections of the brain and nervous system are aggravated by depletion. The patient should be kept in a cool, dark room, and mild cathartics, anodynes, and antispasmodics, occasionally given. Where there is much headache and throbbing, a few leeches should be applied to the temples, and a cold lotion to the scalp.

On retention of the placenta.

Atony, inertia, or want of uterine contraction, spasmodic or irregular contraction of the uterus, and morbid adhesion of the placenta to the uterus, are the three causes usually assigned for retention of the placenta beyond the usual period. Retained placenta from inactivity of the uterus occurs most frequently after protracted labours; the uterus remains so soft that it can be distinguished with difficulty from the other viscera in the hypogastrium. It does not form a hard defined body, as it does when thoroughly contracted. There are no pains, or only feeble pains, after the birth of the child, and there is no lengthening of the cord. In these cases the uterus should be firmly compressed, and the ergot of rye and stimulants given. *At the end of an hour after the birth of the child, if the uterus does not contract and expel the placenta, pass up the hand and*

remove it. Where retention of the placenta arises from contraction of the cervix uteri, which is the condition termed hour-glass contraction, the fingers in a conical form should be introduced, the dilatation of the part effected, and the placenta removed. Sometimes it is possible to extract the placenta when only the fore and middle fingers can be introduced through the cervix, as in cases of placental presentation with rigidity of the os uteri. Occasionally, the cervix is so closely contracted that it is impossible to remove the placenta, and it remains in the cavity of the uterus till putrefaction takes place, and the patient is destroyed by the absorption of putrid animal matter. The best means of obviating the effects of these is to inject into the uterus and vagina plenty of tepid water, solutions of chloride of soda and lime, and decoction of oak bark. Where the placenta is retained by morbid adhesion, it should be removed as already described.

The best method of preventing accidents arising from retention of the placenta, as has already been repeatedly stated, is to apply the binder immediately after the birth of the child, to make pressure with the hand over the fundus uteri at short intervals, and slight traction upon the cord downward and backward in the direction of the hollow of the sacrum. By these means the upper part of the uterus usually goes on contracting till the placenta is detached and pressed down through the os uteri into the vagina. In all cases, whatever the cause of the retention may be, if the placenta at the end of an hour is not detached from the uterus and expelled, it should be withdrawn artificially. The difficulty of removing portions of placenta adhering with more than natural firmness to the uterus, or retained by contraction of the cervix, is only increased by delaying to interfere after an hour has elapsed from the delivery of the child. The seventh report in my Clinical Midwifery contains the histories of thirty-one cases of retained placenta. I am indebted to E. Johnson, Esq. for the following abstract of these cases, and for all the other tables which will hereafter be employed to illustrate the different varieties of complicated labour.

Dr. J. Ramsbotham relates 11 fatal cases of retained placenta. 66 cases of retention of the placenta requiring the introduction of the hand occurred to Dr. Collins in the Dublin Lying-in Hospital; 37 from want of proper uterine action; 19 from spasmodic or irregular action; and 10 where the placenta was adherent. In 24 of the 66 there was slight hæmorrhage; 6 of the women died. Dr. Churchill states that in 259,250 cases of labour, retention of the placenta occurred 392 times, or about 1 in 661½. In 186 cases where the result to the mother is given, 36 died, or about in 5.

A TABULAR VIEW OF THIRTY-ONE CASES OF RETENTION OF THE PLACENTA.

1	March 4, 1826	Labour at six and a half months; cord very soft, and torn away by midwife in attempting to extract the placenta; four hours after os uteri firmly contracted; much force employed to pass the hand; placenta left in uterus, and expelled next day without any unfavourable symptoms	Recovered.
2	Autumn, 1826	At Odessa. Placenta retained, and, in removal by the midwife, uterus completely inverted; great hæmorrhage; uterus soon after replaced; convulsions	Died.
3	Jan. 4, 1828	Great hæmorrhage before expulsion of placenta; hand could not be introduced, from firm contraction of cervix; funis broke off near placenta; placenta left within uterus; soon after placenta easily removed	Recovered.
4	Jan. 4, 1828	Placenta retained three hours; child born dead at seven and a half months; cervix uteri rigid and undilatable; the resistance gradually overcome by the tips of the thumb and two fingers introduced, and placenta, which was lying loose in the uterus, easily extracted	Recovered.
5	Sept. 22, 1828	Retained placenta four hours; the umbilical cord and portion of placenta extracted; vagina filled with coagula of blood; os uteri closely contracted; placenta extracted with difficulty by two fingers	Recovered.
6	March 2, 1829	A portion of placenta left within the uterus; hæmorrhage three days after, and pain in region of uterus; pulse and respiration quickened; skin of a dusky hue; pains in the joints; vomiting	Died; portion of placenta found adhering to fundus of uterus in a putrid condition; veins of the part distended with pus; ulceration of cartilages of knee.
7	July 7, 1831	Morbid adhesion of placenta, and a part left behind which could not be removed; ninth day after delivery; giddiness and beating of the temples; offensive dark-coloured vaginal discharge; os uteri open, and a portion of placenta felt, but could not be extracted; injections with solution of chloride of soda; retained portion of placenta at last expelled	Recovered.
8	August 30, 1831	Portion of placenta left in uterus; three days after foetid dark-coloured discharge, vomiting, delirium, feeble pulse, and haggard countenance; orifice of uterus firmly contracted; only one finger could be introduced; three doses of ergot of rye had been given, which only increased the sickness; died in two days, with all the symptoms of an animal poison having been introduced into the system	Died; large portion of placenta and membrane found in uterus in a black putrid state; coats of uterus healthy; no morbid adhesion of placenta.
9	October 20, 1832	Retention of placenta two hours after delivery; its extraction attempted, but the cord torn away; difficulty believed to depend on hour-glass contraction; a portion of placenta found in the vagina, and the uterus firmly contracted around it; two fingers insinuated through os uteri, and placenta easily extracted; dyspnoea came on, with pain in uterus	Died; right lung covered with lymph, and hepatized; effusion into pleura.

10	June 18, 1834	Retained placenta from contraction of cervix; only a part could be removed; foetid discharge from uterus; rapid feeble pulse, diarrhoea, rigors, sickness, cough, and breathing; she became more and more feeble, and sank eighteen days after delivery	Died; pus in lungs; pleuræ inflamed; gangrene; placenta, in a putrid state, hanging through os uteri, and filling upper part of vagina; no morbid adhesion of placenta to the uterus; pus in veins of uterus; muscular coat soft. Recovered.
11	April 22, 1835	Retention of placenta from rapid contraction of cervix uteri after the expulsion of child; cord torn away near its insertion; two fingers insinuated into the orifice of the uterus, the mass seized, and extracted	Recovered.
12	July 26, 1835	Placenta left in uterus eleven hours; cord torn away; profuse hæmorrhage; frequent attempts had been made to extract placenta; 3ij. of ergot had been given during the labour; hand afterwards passed into uterus in a conical form, and placenta extracted	Recovered.
13	August 22, 1835	Hæmorrhage, with retained placenta; cord had been torn away; very little time had passed since delivery; the whole hand was passed into the uterus, and placenta easily extracted; flooding instantly ceased.	Recovered.
14	August 24, 1835	Placenta retained twenty-four hours; six months foetus; ergot of rye employed; uterus open; margin thin; point of finger readily touched a portion of hard placenta within cavity; the placenta, however, could not be seized, and it was left in uterus; purgative draught given, and during its action the placenta was expelled	Recovered.
15	October 23, 1835	Retention of placenta, with alarming hæmorrhage soon after the expulsion of the child; several unsuccessful attempts were made to extract it; a serious affection of the brain took place	Died; lymph in superior longitudinal sinus of brain, and all the veins emptying themselves into it filled with lymph, the result of inflammation; no trace of inflammation about the uterus; portion of putrid placenta adhered to the fundus; morbid adhesion of placenta to uterus. Recovered.
16	August 13, 1836	Placenta retained thirty-four hours; child dead; ergot of rye had been given, and repeated unsuccessful efforts to extract placenta; os uteri closed; discharge very foetid; the orifice of uterus at last yielded, and allowed the introduction of three fingers; with them the placenta was extracted	Died three hours after delivery.
17	Dec. 25, 1836	Placenta retained, with hæmorrhage; cord torn from placenta directly child was born, it having been twisted three times round child; severe hæmorrhage followed; attempts had been made to extract the placenta; the vagina was filled with clots an hour after delivery; placenta at last extracted; hæmorrhage continued; exhaustion	

18	Dec. 12, 1827	Placenta retained five hours, with severe uterine hæmorrhage; an hour elapsed before she was seen, when she was greatly exhausted from the discharge of blood; placenta easily extracted, which was grasped by cervix uteri; hæmorrhage restrained by vinegar and water	Recovered.
19	August 14, 1838	Placenta retained from unusual contraction soon after expulsion of child; umbilical cord lacerated; some attempts were made to extract the placenta, but the hand could not be introduced within the orifice; fetid discharge came on in a day or two; peritonitis	Died; portion of placenta firmly adhered to upper part of uterus; placenta and uterus so firmly united that they appeared one substance; peritonitis. Recovered.
20	Sept. 28, 1838	Placenta retained two days; repeated attempts had been made to extract it; dark-coloured discharge from vagina; pulse rapid; nausea; headache; a portion of placenta felt protruding through os uteri, which was easily drawn down into vagina	Recovered.
21	June 28, 1828	Placenta retained eighteen hours; cord had been torn away in the attempt to remove the placenta; no hæmorrhage; cervix uteri was found to be very contracted; by cautiously pressing the finger against the os uteri for an hour, the placenta was felt, and in a short time removed	Recovered.
22	October 10, 1838	Retention of the placenta in the vagina for three hours, on account of a broad smooth septum passing from the anterior to the posterior wall of vagina; one half of the placenta was on the left side of the septum, the other half, with cordaces, on the right side; both violently pressed down; placenta was divided with a pair of scissors, and immediately came away	Recovered.
23	Dec. 23, 1838	Placenta retained three hours; child born dead; three or four efforts had been made to introduce the hand into the uterus, but the cervix was firmly contracted; complete hour-glass contraction; the fingers slowly were insinuated into the uterus and the placenta extracted	Recovered.
24	May 4, 1839	Placenta retained twenty-four hours; cord broken from the slightest touch; child dead; no hæmorrhage, but a great disposition to syncope; neck of uterus contracted; one finger was passed after another until the whole hand entered the uterus; the placenta was extracted with difficulty; phlebitis	Died; femoral and pelvic veins all plugged up with lymph; uterus flabby, and twice natural size.
25	Jan. 29, 1840	Hæmorrhage after expulsion of child; binder applied; stimulants given; flooding continued for quarter of an hour; the hand was then introduced into the uterus, and the placenta felt adhering; the fingers were spread out towards the margin of placenta, which was pressed off from the uterus; hæmorrhage arrested	Recovered.
26	April 28, 1840	Placenta retained five hours from contraction of the neck of uterus; the whole hand was introduced into the vagina, and the fingers gradually insinuated into the uterus; placenta extracted	Recovered.

27	Nov. 30, 1840	Placenta retained five hours; violent contraction of cervix uteri; a good deal of force was required to introduce the finger into os uteri; placenta firmly adhered to uterus; with great care the whole placenta was extracted in fragments	Recovered.
28	Dec. 5, 1840	Retention of the whole placenta three hours; cervix so contracted that it was impossible to introduce the whole hand; introduced the whole hand into vagina, and inserted two fingers into uterus, and thus detached the placenta, and pressed it down into the vagina	Recovered.
29	Jan. 23, 1841	Retained placenta three hours; child born with cord twisted three times round the neck; cord was broken close to the placenta; cervix had contracted firmly after the expulsion of the child; the whole hand was insinuated into the uterus, and the placenta, which was adhering, was removed with ease	Recovered.
30	Oct. 20, 1841	Retained placenta eight hours; funis broken off close to placenta soon after delivery, and slight hemorrhage took place; the hand was introduced into the vagina, and with two fingers introduced within the uterus, the placenta was extracted	Recovered.
31	Jan. 14, 1842	Profuse hemorrhage immediately after the birth of the child; the hand was immediately passed into the uterus to extract placenta, but a portion adhered so firmly, that it could not be removed; hemorrhage continued	Died; portion of placenta found adhering.

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY.

By ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 460.]

Sacral vertebrae.

ANATOMISTS had laid down discriminating characters for the male and female sacrum as a whole, that is, after the intervertebral ligaments and soft parts had disappeared, and the five vertebrae had become united into one. They described the female sacrum as broader shorter, and more concave, than the male; and this, I think, will still prove the correct opinion as to the greater number. But I quite agree with Mr. South as to the fact of there being great varieties in all these matters.

Do the sacral vertebrae belong to all one category? it appears to me evident that they do not. The first sacral and last lumbar occasionally so strongly resemble each other, that they can scarcely be distinguished from each other; the first, second, third, and fourth, partially form alone the articulation with the os innominatum the fifth has nothing to do with it. They have different relations, then, to the adjoining structures, and moreover, it is generally understood or admitted that besides having all the elements of true vertebrae, though called false, they combine in addition a series of rudimentary ribs undistinguishably united by bony union with their transverse processes. There is every probability that, in addition to very large processes, these sacral vertebrae do carry upon the anterior surface of these processes rudimentary ribs; but still there lies a difficulty in fully coming to this conclusion. It is this. When Meckel published his work on General and Descriptive Anatomy (a translation of which, by Jourdan, shortly afterwards appeared, and from which translation into French I quote), he maintained the doctrine, that the thoracic ribs were merely the fully developed anterior roots of the transverse processes of the dorsal vertebrae. Now this theory, so soon as announced, I showed to my class must

be incorrect; in fact, there were preparations in the museum which refuted it: one, in particular, of a seventh cervical vertebra, where the transverse process was distinctly double, that is, had an anterior and a posterior root, with a considerable aperture between them for the passage of the vertebral vein; in front of the anterior root was another aperture, and then came a cervical rib; thus, there could be no doubt of Meckel being in error in respect to his theory that the ribs are merely the prolonged anterior roots of the transverse processes of the vertebræ. Now to apply this to the human sacrum, it is easy to show many specimens of the young bones where each lateral mass of each sacral vertebra is growing by *two distinct germs*; but whether these germs represent the one the transverse process, the other the rib, as in the dorsal vertebræ (in which vertebræ the anterior root has entirely disappeared), or whether these two germs on each side represent merely the anterior and posterior roots, or whether both are present and rudimentary ribs also; these are questions which the preparations I have as yet examined do not enable me satisfactorily to solve. An appeal to comparative anatomy is only one way of solving the question, and not a very satisfactory one when applied to human structure, and this for the most obvious reason in the world.

The sacral vertebræ present, as we have seen, the greatest caprice as to their form, without, however, deviating very much from the normal arrangement; sometimes, however, they do: first, as to number; secondly, as to "development" of their natural halves. Of the variety as to number I shall say nothing: six vertebræ have, no doubt, been found, but on all such occasions it would be well to look to the number of the lumbar vertebræ. Secondly, the variety in the development, or rather the non-development, of the lateral halves of the sacral vertebræ, is one of the most important deformations to which the pelvis is liable. Its explanation probably rests on a law in transcendental anatomy, or rather physiology, which I shall first state.

If the pelvis of a foetus at full term, or before or after for a short period, be examined, it will be found to differ entirely from the adult pelvis, *and most*

especially from the finely-formed European female pelvis; it resembles, also—a fact which is well known to the transcendental anatomist—the pelvis of the lower mammals, whether male or female. To them it bears the strictest resemblance in as far as the structures will admit. I shall describe the particulars of its form more minutely afterwards, merely remarking here that the introitus, and, indeed, general form of the cavity, is an elongated square rather than an oval; the sides, formed by the ossa innominata, are nearly straight; the cavity is of equal breadth throughout, and the antero-posterior measurement of the introitus is the larger; any one may recognise in this the pelvis of the lower mammals. Now, should the pelvis during its development continue of this shape, or even maintain it to a certain extent, then we have a misshapen pelvis, common enough in females both here and on the continent: the pelvis continues, to a certain extent, to maintain its foetal form; there is a kind of arrest of development; the sides are too straight, the sacrum too narrow; the transverse diameter of the introitus too small, and the antero-posterior diameter too long. I repeat, pelves of this form are exceedingly common in the male; they are also common in the female.

But let us suppose that the arrest of development has been limited only to one side, confined to the left half, say, of the sacrum and corresponding innominatum, but that the arrest of development has been here, if I may so say, much exaggerated, that is, more complete; that the bones have not only not undergone those changes as to *form* which they ought to have done, but that moreover they are positively much *smaller* than those of the opposite side; that, in fact, that has taken place here which we shall find may take place even in the ribs. Then there is produced the "pelvis oblique ovata," the discovery of which is due to the illustrious Naegele. A glance at fig. 1, pelvis of foetus; fig. 2, of mammal; fig. 3, of ill-formed female pelvis, but quite capacious enough for the passage of the child; fig. 4, the pelvis oblique ovata of Naegele; fig. 5, the finely-formed female pelvis: a glance at these figures will best explain the whole theory to the reader. Dr. F. Krammerschroff, of Dorpat, whom I

Fig. 1.

Outline of the pelvis of the human foetus at term: the pelvis at this age may be taken as the type of the transcendental law; it is more quadrilateral than rounded or oval, and its antero-posterior diameter is the longest: it has the form, in a great measure, of the pelvis of the quadruped and quadrumanous mammal, of the human male pelvis generally, and of certain ill-formed female (all human) pelves.

Fig. 2.

Outline of the pelvis of the elephant: the introitus of the pelvis of the elephant is more rounded than that of most quadruped mammals, including even that of the quadrumanus; still it does not assume the special transverse oval character of the well-formed human female pelvis.

Fig. 3.

Pelvis of the seal: this is the extreme of the type; this form occurs in the very young human foetus, and it in the adult!

It is in this pelvis, in the adult female, that a separation of the pubic articulation takes place to so great an extent prior to and during the birth of the young seal.

Fig. 4.

That form of the human female pelvis which I have called the quadruped form; it is quite common in this country, and I think in Europe generally; this is merely the foetal form persisting, the transcendental law, or law of general type, prevailing over the law of species. Beauty of form, and fitness for the due performance of function, or the law of species, when not interfered with, gives rise, in woman, to the pelvis whose outline is represented by

Fig. 5.

This is the transverse oval pelvis: when to this is added a fully developed upper or false pelvis, then the osseous girdle is considered as completely or fully developed.

The transcendental law, or law of type, may prevail on one side of the pelvis, and not influence the other; this gives rise to the pelvis oblique ovata of Naegle, as seen in

Fig. 6.

When it takes place on both sides, as is said to be the case with a human female pelvis now in the possession of Dr. Outrepoint, then the outline of the introitus will strongly resemble that of the seal—or, in other words, the transcendental of the very youngest period of the human skeleton, when, in fact, it was almost entirely cartilaginous, had continued in force to mature years, and the antagonistic law of species had, from causes unknown to us, never come into action. I should not think that the curvature of the spine in the lumbar region, seen in Fig. 6, was a necessary consequence of the non-development of the half of the pelvis.

had the pleasure to meet lately, a most intelligent observer, informed me that he saw lately, in the museum of Dr. Outrepont, a female pelvis in which the deformation now known by M. Naegele's name of "*pelvis oblique ovata*," extended to both sides, giving rise to the greatest difficulty during labour, and ultimately, if I rightly recollect, causing the death of the patient. If it were not that anchylosis or bony union of the sacro-iliac joint, so generally, if not always, coincides with the arrest of development, giving rise to this deformity, Dr. Outrepont's case was one in which the pubic section might have been attempted with some slight chance of success; to propose this operation in the round or transversely oval pelvis argues a want of mere mechanical knowledge on the part of the adviser.

The transcendental theory I have just endeavoured to apply in explanation of, 1st, the normal form of the male pelvis and its varieties; 2d, the form of the pelvis of the mammal; 3d, certain unusual forms observed in the female pelvis must ultimately rest on certain facts which it is proper to examine more in detail, or rather by direct or intuitive perception. If these be correct, then the theory is good so far as it goes: it gives us no insight, it is true, as to the *why* these things should happen so, but it shows the *manner* of their taking place. The details I shall now take the liberty of giving are taken chiefly from scattered memoranda of lectures.

The resemblance of the abdomen, pelvis, and trunk generally of the human foetus and infant to the same parts in the adult quadruped mammal, is very striking; it depends, no doubt, on the law of unity of organization. But I may as well quote the notes as they stand in my note-book.

If the principles and views just laid down be in accordance with nature, they ought to stand the test of intuitive inspection, or an appeal to individual phenomena; let this appeal, then, be made to the human and brute structure by a brief, but, at the same time, careful inquiry into a number of specimens sufficiently numerous to warrant the deductions.

1st, In the skeleton of the adult foetus now before me (not selected, but taken at random from the museum), prepared and dried in the usual way,

the pelvis presents the following appearances. In its entire outline it resembles the pelvis of the quadruped; I mean of most adult mammals. It is more like an elongated canal than the human pelvis; the iliac walls are comparatively upright, the false pelvis contracted and narrow, falling exceedingly within the limits of a perpendicular line descending from the shoulders; a straight line directed horizontally from the symphysis of the pubis towards the vertebral column strikes the lowermost part of the coccygeal bones. The conjugate or antero-posterior diameter is $1\frac{3}{4}$ inch; the transverse, where widest, about 1 inch, and nearly of the same width throughout; in other words, the pelvis is no longer, or rather not yet, a transverse oval one, but quadrilateral, its greatest diameter, as in the brute, being from before backwards, and precisely the reverse of what it ought to become (to give it a strictly human form) in the adult. Already, in this foetus, the coccygeal bones are twisted or curved towards the right side, and the area of the abdominal strait, or entrance, if divided into halves by a line passed across it as mesially as possible, gives to the right side of the area a capacity greater than the left; the left wall is straighter, and already the tendency to the *pelvis oblique ovata* of Naegele is established. Now, we have only to suppose the persistence of these forms, to a certain extent at least, to the adult age, and we then have the exact description of the ill-formed female pelvis so common in this country, and, I have no doubt, also in England; and if what travellers say of the Esquimaux be true, it would seem that the false pelvis is seldom or ever in them properly developed, so that the breadth of the haunches is nearly equal in both sexes; and this is quite possible, for the false pelvis has an entirely different and independent development from the true pelvis.

It would appear already, from the examination of a single specimen, that the more common of the malformations and peculiarities in the adult male and female pelvis are merely the persistence of the foetal, infantile, or juvenile forms, and of consequence repeated in the pelvis of many of the mammalia. The obliquely oval pelvis of Naegele is comprised in the same law, with the addition of an extremely imperfect deve-

lopment of one side. But there is nothing new in it; nothing unexpected—nothing which might not, *a priori*, be foretold by an inspection of the foetal skeleton.

I have already shewn, in a memoir published some years ago on the Statistics of Hernia, that the pelvis was very frequently more fully developed on one side than on the other, and hence the predisposition to hernia on the more fully developed side, be it right or left; but from the slightest shade of difference to the most deformed of the pelvis lithographed by Naegele one law prevails; the persistence of the foetal form on one side; the regular development of adult human form on the other. Again, the quadrilateral-formed pelvis is the type of most mammals (if not of all) when adult, and, by the law of unity of organization in the embryo, it is also the type of the early human pelvis. Whatever form, then, the pelvis assumes, must flow from the agency of these causes, and be connected with, and dependent on, these laws. Obliquely oval pelvises are not *lusus naturæ*, no more is the occasional quadrilateral form of the same girdle in the European female.

2. Another human foetus at full term is put before you: the measurements and form of the pelvis are as nearly as may be those of the preceding: still there are differences: the iliac portion or false pelvis is broader, and although the whole length of the skeleton be less than the preceding one by at least an inch, the false pelvis is broader by nearly half an inch; confirming what we already know so frequently to happen, that the future grown man or woman may be shadowed out in the infant.

3. Another foetal pelvis gives a conjugate diameter of an inch and $\frac{3}{4}$; the transverse diameter where widest scarcely measures an inch.

4. Here is the pelvis of an infant seemingly about a year old; the antero-posterior diameter of the pelvis exceeds the transverse by nearly half an inch.

Let us now examine a few adult female pelvises from amongst those whose dimensions and general form offer no obstacle to the ready passage to the child through their cavities: the first I take up gives a conjugate diameter of $4\frac{1}{2}$ inches: its transverse measures 6, and yet this pelvis is not equally de-

veloped: but it is a large and capacious pelvis, and the true as well as the false have very fully assumed the human character; it is the very reverse of the infantile and brute pelvis in every respect, in its form, its dimensions, and inclination.

The next I examine is different, and yet a sufficiently capacious pelvis; first, the false pelvis is narrow and the walls upright; the woman, therefore, wanted breadth of haunches. No proof, however, of a want of capacity in the true pelvis itself, as this follows different laws in its development. The conjugate diameter measures $4\frac{1}{2}$ inches, the transverse $5\frac{1}{2}$, or nearly so, being at least half an inch less than the preceding pelvis: but still it is a good pelvis compared with some which are to follow. The next measures $4\frac{3}{8}$ and 5, and is becoming more and more at its abdominal entrance (I mean the introitus) of an elongated square form. The next is as nearly as may be 4 inches each way, without any appearance of rickets, and the same precisely may be said of another standing close to it. Now all these are female pelvises presenting no appearance of any disease or deformity; I have so far selected them on this account. But here are others which shew these phenomena equally, or even more so, but being complicated with other peculiarities, had better follow the more simple ones.

The sacrum, I now examine, shews the following peculiarities: it is that of a female: the right half of the sacrum is nearly half an inch narrower than the left; the right half of the introitus proportionably smaller, but the iliac portion of the ossa innominata are tolerably symmetrical. Here, then, is the commencement of the pelvis oblique ovata of Naegele. The lumbar portion of the column presents an extensive curve, the cause of which curve it would be more difficult to investigate, but which probably arose from the same predisposition to a want of symmetry. A second pelvis also, in Dr. Campbell's museum, presents the obliquely oval pelvis on the left side; a large exostotic deposition on the last lumbar vertebra rendering, I should think, the passage of any living child impossible. And now I take the male pelvis, the one before me, and I find it to resemble in the form of the introitus, as nearly as may be, that of the seal, and of many other quadrupeds, although

the transverse diameter be still somewhat larger than the conjugate: a second male pelvis, now in my own museum, shews the brute form to a still more extraordinary degree. The transverse diameter of its widest part is but about $\frac{1}{4}$ larger than the antero-posterior; and, precisely as in that of the quadruped, it is greatest close to the sacrum, scarcely widening, or but very little, anterior to this. Now this is the type of the foetal pelvis, and that of the mammalia lower than man; and that this person presents a pelvis of this peculiar shape, is simply because it was the form it originally had, and from which, by a peculiarity in his nature, it had never altered.

But this male pelvis merits a further notice. The false pelvis spreads out after the fashion of the female pelvis; the true pelvis is constructed on the plan of the foetus and of the quadruped mammal. The sacrum is of such breadth that immediately in front of it, or very nearly so, we find the widest part of the introitus; that is, the edges of the abdominal entrance run nearly straight down, and then converge. The last lumbar vertebra has evidently united by its lateral processes with the corresponding parts of the sacrum, so as to become identified with it, causing it strongly to resemble the first sacral vertebra.

[To be continued.]

OBSERVATIONS AND EXPERIMENTS CONCERNING

DIABETES MELLITUS,
&c. &c.

By JOHN PERCY, M.D. (Edin.)

Physician to the Queen's Hospital, and Lecturer
on Organic Chemistry at the Royal School of
Medicine and Surgery, Birmingham.

[Continued from p. 125.]

(For the London Medical Gazette.)

WE now proceed to inquire concerning the changes which starch undergoes in the healthy stomach, and, in this inquiry, we again appeal to direct experiment.

EXP. 9.—At ten minutes past 11, a large bull-terrier bitch ate eight ounces (dry) of wheaten flour, heated with a small quantity of water to the consistence of common paste. She drank water afterwards. At 2 P.M. I de-

stroyed her by hanging. The stomach contained paste, which had a strongly acid reaction, and was not altered in appearance. To some of this paste I added water, and digested in a flask for several hours, at a temperature ranging between 98° and 120° F. On the following day the contents of the flask were dried over the steam-bath: the process of drying occupied the greater part of the day. The residuum was broken up, and treated with boiling rectified spirit. The spirituous solution was evaporated over the steam-bath, and a pale brown syrup was obtained, having a decided sweet taste, and a strongly acid reaction. A portion of this syrup was dissolved in warm water, and a small quantity of yeast was added; the mixture was then introduced into a graduated receiver over mercury. Fermentation was soon excited, and proceeded with considerable rapidity. I measured 6·7 C. In., whilst the solution was still fermenting. The fermented liquid was distilled *per se*, and carbonate of potass was added to the product, when I obtained a copious stratum of alcohol.

Now, from this experiment we do not derive satisfactory evidence of the conversion of starch into sugar in the stomach, although we learn from it that the liquid of the stomach, whether saliva or gastric secretion, is capable of effecting this conversion at a suitable temperature. During the process of healthy digestion, it is well ascertained that free hydrochloric acid is present in the stomach; and, accordingly, we find that the chyme in the preceding experiment had a strongly acid reaction. The question, then, arises, whether the sugar obtained was produced by the action of the hydrochloric acid; for we know that this acid, even in small proportion, changes starch into sugar during the process of long-continued boiling. To determine this point, it is requisite to examine whether sugar actually exists in the chyme at the time of its removal from the stomach; and, if not, whether sugar would be formed by artificial digestion, after the neutralization of the free acid. On this subject the following experiments will throw light.

EXP. 10.—At 5 P.M. a middle-sized terrier dog ate four ounces (dry) of wheaten flour, heated with water to the consistence of paste. He swal-

lowed it without mastication, and did not drink water afterwards. On the previous day he was fed on oatmeal. At 8 P.M. he was destroyed by hanging. The stomach was immediately removed. The paste was not altered in appearance, and it still had the odour of paste, and not that of chyme: it had a strongly acid reaction. I divided it into two parts, A and B.

A. I added distilled water and prepared chalk, and then evaporated to dryness over the steam-bath. The residuum was treated with boiling rectified spirit, and the spirituous solution was filtered and evaporated to dryness in a capsule. Towards the termination of the evaporation I observed a brownish yellow oil floating on the surface. I obtained a pale brown syrup of a decided sweet taste. This syrup was dissolved in water, and a minute quantity of yeast was added in the usual manner. Fermentation soon commenced; and whilst the solution was still fermenting, I measured 5 C.In. of gas.

B. This portion was evaporated *per se* on a plate over the steam-bath. The residuum was treated in the same manner with boiling rectified spirit. In both cases the solution passed through the filter turbid, and in both the turbidity was instantly removed by the application of a gentle heat. I obtained by evaporation a small quantity of residuum, of a syrupy consistence and sweetish taste. Oily matter was also separated during the progress of the evaporation, and floated on the surface: on cooling it became solid. The residuum, dissolved in water, was introduced into a graduated receiver over mercury, and the same quantity of the same yeast as used in A was added. The tubes in A and B were placed side by side. Not the smallest evolution of gas had occurred in the case of B, even after the lapse of three days.

From this experiment we learn that true sugar did not exist in the chyme at the time of its removal from the stomach; and that the sugar obtained from it was generated after neutralization of the free hydrochloric acid. The paste in A, it must be remembered, was mixed with water, and was exposed to heat for many hours; whilst that in B was dried in a comparatively *short time*. *The presence of sugar in A is inferred from the fact of the resi-*

duum fermenting on the addition of yeast; whilst the absence of sugar in B is inferred from the converse of this fact. Now the residuum of B contained a portion of free acid, which might be supposed to impede or prevent the action of the yeast. That this supposition, however, is incorrect, we discover by reference to Exp. 9, in which the residuum was strongly acid, and yet rapidly fermented on the addition of yeast. We are not justified in concluding that, in the experiment before us, sugar was not formed in the stomach; for possibly sugar may have been produced only in the immediate vicinity of the mucous membrane, and have been directly absorbed; or, according to the hypothesis of Dr. Prout, the formation of sugar may have been only a point *in transitu*.

EXP. 11.—At 11½ A.M. a dog ate eight ounces (dry) of wheaten flour, heated with a small quantity of water to the consistence of thick paste, and afterwards drank a pint of water. He was killed by hanging at 7½ P.M. The stomach contained thick paste, similar to that mentioned in the preceding experiments. The paste was dried to a brittle mass over the steam-bath. This mass was broken up, and treated with boiling rectified spirit in a flask. Two days afterwards the spirituous solution was first distilled in a retort, and then evaporated over the steam-bath in a capsule. During the progress of the evaporation a pale brown oil floated on the surface. The residuum reddened litmus. I added water and yeast in the usual manner.

April 17, Potash apparatus, after	= 635.400
April 12, Do. do.	before = 634.887

•513

In this case the increase is so small, that it may be altogether neglected, and we may infer the absence of true sugar. The residuum, on the addition of water, appeared like pearl white dextrine precipitated by alcohol.

EXP. 12.—At 10½ A.M. a large bull-terrier dog ate ten ounces of wheaten flour mixed with water. Except a few morsels of cheese, he had not received solid food for three days previously. At 3 P.M. he was destroyed by prussic acid. During the action of the poison he vomited, and voided a small quantity of urine. Half an hour

afterwards I removed the stomach, which was much distended with liquid. The contents appeared to consist of starch, of oily matter floating on the surface, and of some lumps of cheese; the reaction was strongly acid. On the addition of tincture of iodine the characteristic blue colour was immediately produced. I evaporated the liquid contents to dryness over the steam-bath, having previously added prepared chalk in order to neutralize the free acid. On the following day the dry residuum was treated with boiling rectified spirit. By evaporation of the spirituous solution I obtained a brown mass, of the consistence of syrup, and having an odour not unlike that of osmazome. The mass was dissolved in water, yeast was added, and the mixture introduced into a graduated receiver over mercury. Three days afterwards I measured off 0·8 C. In. of gas. In this case also the quantity of gas evolved was so inconsiderable as to lead to no positive inference concerning the formation of sugar.

EXP. 13.—At 10½ A.M. a large bull-terrier dog ate six ounces (dry) of wheaten flour, heated with water to the consistence of paste. He drank about half a pint of water afterwards. He had not been fed on the previous day. He was destroyed by hanging at 5 P.M. The stomach was removed in a quarter of an hour afterwards. It contained only a small quantity of liquid, resembling common gruel, in which were two or three small lumps of paste, unchanged in consistence or appearance. This liquid had an acid reaction, but only slowly reddened litmus. I immediately proceeded to desiccate the contents of the stomach on a plate over the steam-bath. Some oily matter floated on the surface. I obtained a brittle residuum, which was broken up and treated with boiling alcohol, of specific gravity 0·834. The solution was decanted, and the spirit was distilled off in a retort, and then completely evaporated in an open capsule. I obtained a small quantity of brownish liquid, of the consistence of syrup, having a peculiar odour and taste, but not that of sweetness. I then added distilled water, and digested over the steam-bath. The solution was turbid, and had a pale brown colour. I then filtered. The filtered solution was clear, and had a pale straw colour.

816.—XXXII.

A small quantity of fresh yeast was added in the usual manner, and the mixture was introduced into a graduated receiver over mercury. Three days afterwards I measured 4·9 C. In. while the liquid was still fermenting. By distillation *per se*, and the addition of carbonate of potass to the product, I obtained a copious supernatant stratum of alcohol. The matter which remained on the filter was dissolved immediately by cold æther, and by evaporation of the æthereal solution globules of oil were separated. This oily matter had a butyraceous consistence, and stained paper. The residuum of the contents of the stomach, after treatment with boiling alcohol, was again desiccated, in order to expel any trace of spirit. Water was then added, and the whole digested over the steam-bath. By filtration was obtained a small quantity of clear solution, which acquired a reddish purple colour on the addition of tincture of iodine, and in which alcohol occasioned a copious precipitate of white matter, like dextrine.

EXP. 14.—At 10½ A.M. a large bull-terrier dog, which had received no food on the previous day, ate six ounces (dry) of wheaten flour, in the state of thick paste, and drank half a pint of water afterwards. He was destroyed by prussic acid at 3½ P.M. Twenty minutes afterwards the stomach was removed. The contents consisted of liquid like gruel, and some thick paste, which did not appear to have undergone much alteration. The liquid part was poured off, and evaporated to dryness *per se*, in the usual manner. The dry residuum was treated with boiling spirit, sp. gr. 0·834. The solution was decanted and evaporated. I obtained a brown matter of a sweetish taste. This matter was dissolved in warm water, and yeast was added. Three days afterwards 1·4 C. In. of gas was disengaged, and fermentation had entirely ceased.

OBSERVATIONS.—When wheaten flour is introduced into the stomach of a dog, we find that, after the lapse of several hours, it is reduced to a comparatively liquid state, like common gruel, and eventually completely disappears, being principally removed by absorption. Now the first step in the conversion of starch into grape sugar is the formation of dextrine, a substance which is

readily soluble in water, and which, in many respects, resembles gum-arabic. From the preceding experiments we derive confirmation of previously recorded statements concerning the conversion of starch into sugar by the agency of the liquid of the stomach, whether saliva or gastric secretion, or both conjointly. We do not, however, from these experiments obtain demonstrative evidence of this conversion being effected in the stomach; for even in Exp. 13, in which a sensible quantity of sugar was procured from the liquid contents of the stomach, it might be alleged that the sugar was formed during the process of desiccation. This process, however, was rapidly completed, and the quantity of sugar determined by fermentation, compared with the small quantity of liquid operated upon, appeared to me to be greater than could well be produced during the short period required for complete desiccation; so that in this case we should not, I think, err in concluding that a portion of the sugar, at least, was generated in the stomach. Still, I repeat, the evidence is not demonstrative; and, in all physiological discussions, we cannot be too cautious in the admission of data intended to serve as the basis of reasoning. If starch be changed in the stomach in very sensible proportion into sugar, the sugar must either undergo a further change, or be absorbed with rapidity; otherwise it would accumulate in a sufficient degree to admit of easy detection. Now we know, from what has been previously advanced, that, under certain conditions, saccharine matter introduced into the stomach quickly enters the circulation as sugar; and, if in certain proportions, is partially eliminated by the kidneys. Here I would suggest the possibility, not to say probability, that under ordinary circumstances starch, or amylaceous matters in general, may be in great measure converted into dextrine, and in this state be directly absorbed. Dextrine, as we know, is readily soluble in water, and may probably pass unchanged into the circulation. If this probability should be realized, the results of the foregoing experiments would be clearly explained. To decide this question, numerous and delicate *experiments* are required; and I hope *that, on a future occasion, I may be*

enabled to present satisfactory information upon this subject.

There is one point deserving of notice in respect to the nature of the sugar generated in some of the preceding experiments, viz. that it was found to be incrySTALLIZABLE. A portion of the syrup of Exp. 9 was left exposed to the atmosphere for a month, but not the slightest trace of crystallization was observed after this exposure. As to the manner of determining the presence of sugar by fermentation, it will be remembered that I offered some observations in a previous communication.

I have been careful to make comparative experiments, in order to ascertain the quantity of carbonic acid liberated from the yeast alone. For example: twenty, if not thirty, times the volume of yeast employed in Exp. 9 was mixed with water, and introduced into a graduated receiver over mercury. After the lapse of two days the carbonic acid disengaged amounted only to 0·7 C. In. I have confined myself entirely to the application of the test of fermentation, as I believe that test to be most decisive, as well as most practical; for a true sugar is most prominently characterized by the property of fermenting at a suitable temperature on the addition of yeast or other similar matters, with the formation of alcohol and carbonic acid.

I may here also mention, that sugar is formed in small quantity by simply digesting paste, similar to that employed in these experiments, with water at a gentle heat, over the steam-bath. In this case the sugar may probably be produced by the conjoint influence of the gluten and atmospheric air (Dumas, *Traité de Chimie appliquée aux Arts*, t. 6ième, p. 88). However, the actual quantity of sugar which I obtained in this manner was very small compared with the quantity of sugar indicated by the result of fermentation in some of the preceding experiments.

We may sum up the results of the preceding experiments as follow:—

1. That the liquid of the stomach is capable of effecting the conversion of starch into sugar, by digestion at a suitable temperature.

2. That although no demonstrative evidence has been adduced in proof of the formation of sugar in the stomach from wheaten flour, yet, in Exp. 13, it is highly probable that a portion of the

sugar obtained was generated in the stomach.

3. That if sugar be the product of the digestion of wheaten flour in ordinary circumstances, it is either rapidly absorbed, or undergoes a further change. We have, however, no direct and experimental proof of such change, while we have demonstrative evidence of the speedy absorption of sugar after its introduction into the stomach.

[To be continued.]

REFLECTIONS

ON THE

INFLUENCES OF HEAT ON THE LIVING BODY.*

By T. WILKINSON KING.

(For the London Medical Gazette.)

Five effects of heat—Delicate health—Easy play of all functions—Warm bath—Clothing—Wasting—The feeble, free, oppressed—Cases for warmth—Objections.

SOME of the more general facts of the influence of heat have been already hinted at. We may yet find particular facts deserving of notice, but our present aim will be chiefly to illustrate, by the effects of heat, the theory advanced with reference to cold, and to shew its practical importance in the treatment of different classes of disorders. We conceive that we may safely leave it to the course of our reflections to demonstrate, that of all remedial agents that which is at once the most safe, controllable, powerful, and generally applicable, is temperature.

There are certain distinct influences of heat on the body which will scarcely require much proof:—

1st. Superficial excitement.

2dly. Universal or general liberation of functions.

3dly. Superficial excitement, tending to local hypertrophies.

4thly. General freedom of actions, tending to general decline, or atrophy, or even fatal syncope; but

5thly. One or more organs being oppressed, or failing, as a distended heart or indurated kidney, the unimpeded play of the remaining functions becomes of vital importance.

The simple view that *increased warmth excites the superficial functions of the body, and tends to diminish both the nutrient and secretory supplies of internal parts*, has seemed so clear, though only partially true, that it deserved to be advocated singly both on its own account, and as a step towards the more general proposition on which we are now about to enter.

John Hunter, the most celebrated perhaps of all the investigators of the nature of life and health, meeting his friend Mr. Nicol, who had lost five children successively by endeavouring to "bring them up hardy," "Well," said Hunter, "are you going to kill this next one as you did the rest?" And he proceeded to shew how all young animals are brought to life and nourished by great warmth, until they can, by full exercise and digestion, maintain their own heat freely. Mr. Nicol found that tenderness and comfort succeeded better. His next offspring is said to be still living.

Surely we may all perceive how a hot-house, or the approach of spring—"the genial warmth of joy-renewing spring"—forces or facilitates the dormant functions of vegetables and animals; and, on the other hand, the universal expression "taking cold," is an acknowledgment of the obstruction and disturbance which the vital functions are so continually liable to experience. The happy power of endurance which the vigorous possess renders them insensible of what is needful for more tender plants. The oak may well say to the exotic, "Open the windows, and make yourself hardy;" and in return, while the exotic patient must carefully judge for himself, he may naturally envy his more robust neighbour. Thus in delicate health and old age, when the powers decline and become incapable of resisting outward mischiefs, a larger share of comfort again becomes necessary; for a great deal of the evil and aggravation of disorders, as delicate persons well know, consists in successive relapses, which are the result of negligence and exposure. A climate in which care is scarcely necessary becomes absolutely indispensable, and most particularly to those who do not rightly know how to take care for themselves.

Youth, health, convalescence, spring, and the first days spent in a tropical country, are well understood to be

* Vide recent papers in this journal on "Irritation" and "Cold."

characterized by a peculiarly happy sense of life, of ease, lightness, and vigour; and as far as science hitherto admits, we discover on all sides a decided liberation and excitement of molecular changes, chemical, botanic, and animal. We are not without pleasing evidence that, even in the tropics, the healthful balance of all the animal functions may be long sustained. Some persons of delicate constitution, and many advanced in life, are striking instances of this fact, which will be, perhaps, best accounted for, in the first place, by our investigation of the opposite train of events. Gradually, in the course of weeks, undue warmth excites the functions of the skin beyond their natural bounds, as excessive perspiration, hypertrophy of glands, and even diseases of the skin, often testify; and these cannot be unattended with deeper consequences.

The primary effect of general warmth at the surface begins without delay. All the functions are rendered freer; early puberty, and even decay, are cases in point. All the mischievous results, when examined separately, seem only so many more examples of the same thing; but we think it cannot be denied, that as the superficial organs evince by degrees the most excessive excitement, so, in the general, the disorder of the rest is subsequent to, and depending on, that excitement. Various atmospheric conditions will of course interfere with the effect of warmth to the body: it may suffice for the present, if we illustrate some of these indirectly in our course.

Mere local derivation, by means of superficial warmth, is perhaps sufficiently understood. When applied in the form of hot-bath, it is even of itself a powerful agent, although we ought to distinguish fairly between this single revulsive effect and the influence of artificial heat in the whole circulating mass of fluid. Pediluvium may produce pallor of the face, or even syncope, but not by a simple counter-irritation.

The warm-bath, as a rapid means of communicating heat to the whole body in almost any quantity, is a most efficient resource. The quantity of fluid which it abstracts from the body may be considerable, or it may be a source *of supply to the body*. The blood *itself may be in a condition to imbibe actively, without the necessity of any*

other specific means of absorption. In all cases, however, at least solids are disposed of in the way of nutrition and secretion, at the surface, by the agency of heat.

The effects of the vapour-bath are modified by the patient's being in the upright position. It would certainly appear that dry heat is less calculated to excite perspiration, and thus the peculiar eruptions of hot and arid climes may be explained. Warm clothing, by retaining the secretions about the surface, approaches in effect to the warm-bath. The problem of the effects of heat, variously combined with food, drinks, exercise, and clothing, depends in a measure on experience in any given case. Thus the state of the individual from hour to hour must in great part regulate the results; yet, on the principles already advocated, good general conclusion may be readily comprehended, as well as to the subjugation of old derangements, as to the rise of new ones.

Thirst too liberally and carelessly gratified, failing activity in the stomach, constipation, permanently declining renal secretions, muscular languor, and general wasting, comprise but a part of the disorders in warm climates or seasons which so evidently aggravate each other. The means of meeting these difficulties can only be understood by a fair consideration of the doctrine which explains their origin, course, and connection; but in this aggravated train we have a complicated case of constitutional or general irritation, which we shall reserve for future comment. It may seem at once conclusive, that if the blood possess the materials of supply, exertion will lead to increased nutrition of muscle or nerve; and so a stimulus will aid appetite and digestion.

The current hypothetical explanations of heat inducing undue hepatic excitement, do not appear to us satisfactory. The tropical coup-de-soleil we regard as only the sudden manifestation of a more gradual and general disorder. That yellow fever is an hepatitis, and that the oriental liver abscess, and chronic diseases, belong to the effects of climate, we cannot question; yet, seeing these affections are in a manner peculiar to visitors, whose varied habits, food, and drink, involve such a diversity of considerations, we may be excused for delaying to admit

conjectures, which at the best are useless. The knowledge that warmth accelerates the processes of life even to the extent of wasting the materials of support, and the certainty when such considerable disturbances are set up that the especial stimulus of each function must be supplied or subtracted unequally, seems to be the first rational part of the account where one organ or system is found excited and another quiescent. There are, besides, specific sources of disturbance to be thought of, as in the liver from drinks.

We should not be unmindful that active hepatic diseases, inflammations, and hypertrophies, are common in our own temperate region. The difference dependent on climate is materially affected by particular seasons, by which the disorders are rendered more or less frequent and severe; while the less prominent morbid changes in the liver of our clime are to be attributed to the circumstance of other organs, as the kidneys, being sooner and more fatally involved.

We admit that the summer, with its exhaustions, occupations, and open windows, may render many persons additionally liable to disorders from various modes of influence, but we are not ready to admit that these instances of its effects are against our views until the processes leading to disorder have been fairly examined; for it must appear at a glance that the case is one of a complex kind, and that cold is by no means out of the question as a means of disturbance. The general disturbance of hay-fever, for example, we may often trace to cold, combined with peculiar susceptibility. Is not the diarrhœa of autumn somewhat like the renewal of a suspended function (the bowels being re-excited as the cutaneous functions decline), with the general disturbances of cold superadded?

It has been often said that, with regard to understanding his own constitution and the management of it, a "man is either a fool or a physician at forty;" and although this does not by any means apply to the treatment of a sudden attack which is altogether new to the sufferer, it is a very just observation with respect to those who, possessing a moderate share of judgment and self-control, are compelled to be continually on the watch to keep a declining or enfeebled frame capable of daily

duty, under the influence of various kinds of exposure and exertion.

Common sense, observing that many feeble, or aged, or valetudinarian folks make a slight progress towards attaining vigour in the height of summer, concludes at once that they would necessarily be benefited by a mild and permanent tropical climate; and it is still more a matter of common observation that the delicate, or the asthmatic, or the rheumatic, prepare themselves, as well as they can, to endure and labour through (if not cut off by) the severity and variability of a great part of our year, which they have still more reason to tremble at and shun than they are really aware of.

There are constitutions so susceptible of cold as to require a *continual* summer in order that the general functions may reach even a medium share of development; and there are doubtless others to whom heat is as oppressive as the cold is invigorating; yet we think there is greater cause to wonder at the smallness of the disparity in this respect than to regard the inequality as inexplicable. The most essential fact of all is perhaps this, that a day or an hour, an injury, excess, or dose of medicine, or a fright, will, in certain states of constitution, make all the difference between severer exposure with impunity, and slighter cold with dangerous consequences.

A gentleman, who seemed never to have known sickness, complained severely of the chilly evenings on the Atlantic, when the thermometer stood at 80°. It is not to be supposed but that many persons do not continually take cold, even under the equator. Need we say, the delicate and feeble suffer as much in our summers.

We see that one seemingly strong man wears twice as much clothing as another*; we see women and children wearing habitually or irregularly almost nothing; we may see the balance of health sustained under great disadvantages, or overturned by one or a few repetitions of a comparatively slight exposure, under circumstances unfavourable to resistance. And what

* Though seemingly strong, there is perhaps some disproportion about his frame that renders him delicate, or his functions easily overbalanced; or the situation in life may render his habits unfavourable on account of some undue developments, as in the case of a muscular frame with sedentary occupation.

are we to conclude but that, although the compensatory means are great, they have their limits, which differ in different persons and in different seasons? The healthiest man, after sixty years of vicissitudes, takes cold, and is seized with the croup of infants, which, as to visceral disorganization at least, might seem among the most remote from any kind or degree of decay or general deterioration.

If any one ask what are the disorders likely to be benefitted by a warm climate, a partial answer is easily made, a complete one we deem an impossibility. All affections which are worse in winter and better in summer speak for themselves; and this is scarcely the time to advert to peculiarities and partial objections, unless it be to show by example some traits of constitution by which a judgment may be formed in practice.

We do not know a more established and neglected fact than that the cases of malformed heart are benefitted by warmth. Our own experience strongly favours the inference, that the acquired obstructions of the heart demand like facilities. When exercise is forbidden, warmth seems doubly available.

Hypertrophy of the muscle of a ventricle will never exceed the measure of the impediment on which it essentially depends (thickening of the secondary arteries, for a common example), but in the absence of due nutrition, or in consequence of extreme obstruction, the increase of muscular power will fall short of what is requisite. It is certain that if the causes of difficulty be diminished, as by superficial warmth and general facility of the functions (not copious assimilations), the ventricular hypertrophy must decline in proportion as surely as every part wastes through disuse. The chief mischief of hypertrophy of the heart is probably that it tends to operate with disproportionate violence on particular parts of the capillary system, as, for instance, on the brain; and if at any time the general state of the blood should dispose the body to inflammatory softening, the mechanical disturbance will determine the disorder to the cerebrum, just as a pediluvium may locate gout, or local cold excite erysipelas, or a stricture cystitis. We make a wide distinction between a true hypertrophy and a deteriorated tumefaction of muscle, but it

may be necessary to state that these changes are often combined. Dilatation of the heart is either the effect of failing nutrition or increased impediment, without corresponding increase of nourishment. (See an account of Angina in MEDICAL GAZETTE, 1841.) The most studious management of temperature and diet is of vital importance to ease and sustain the failing heart.

We are at a loss sufficiently to enforce our views relative to the means of oppressing or relieving a disordered viscus. We fear, too, that common practical views, as they are called, are firmly settled against us. Why should it be supposed that mercury, or any form of diuretic, can act beneficially on the kidney in any state besides that of simple inactivity? Can any thing relieve excessive action but derivation? Can any thing mend perverted action so much as a considerable attention to the due performance of all co-relative functions? Can any thing palliate the effects of settled renal induration and arrest of function so well as the unobstructed play of compensating eliminations?

Were it not for the prejudices of those who are strong and capable of free exercise, the admitted rule of practice relative to bronchitis, acute, or chronic, or variable, would need no new enforcing. How far are we from understanding that every *catarrh* is under like laws, and who will show that every kind of irritation which we have before endeavoured to analyze is not liable to be affected by the same? How many secretory disorders and structural disorganizations are the result, not of chronic disease, but of often repeated relapses, fresh attacks of *irritation* from cold and the like? And when one important function is obstructed by disorganization, what will ease the play of the rest like warmth? What will oppress the balance like cold? But we shall defer the full illustration of this great topic till we come to dwell on constitutional irritation.

The following are the particulars of a case which is in a measure the origin and ground-work of all the reflections here assembled:—

“A delicate boy, at thirteen years of age, had ague, and subsequently often experienced feverishness in chilly weather. At sixteen, after dining and

running violently, he first felt dyspnœa, and for many years from this time he rarely passed ten months without suffering from fever and suppuration near the tonsils. Between study and activity his spirits were always good. Autumn after autumn he became more subject to cold during the day, which after dinner was manifested by dyspnœa, easy cough, and some sense of fatigue. Every exposure caused a fresh attack; confined diet, relaxation, free exercise, warmth, or conium and ipecacuanha, brought relief. Severe exposure induced a week or two of bronchitis. The summer inland air of Kent aggravated the asthma, and especially with the least exposure to cold. Sitting in church never failed to disturb the health. The erect posture, maintained, governed the dyspnœa. Towards his thirtieth year, with a slight cough and expectoration, varying through several months, he continued to become more susceptible of cold and to waste in substance; his old dyspnœa was frequent and troublesome; his rustication in the country was disadvantageous as to exposures, and not successful. After exerting his voice he coughed up about 2½ oz. of blood, and his medical friends looked on his case very gravely, but he himself felt that a recess would restore him as usual.

His pursuits and habits had been a little unsalutary; his strength, appetite, activity, and sleep, were always good, and the country, or rather repose with comfort, so constantly and quickly renovated him (save sometimes as to dyspnœa), that he could not but rely on so well tried a resource. His pulse, sitting, rarely amounted to 70, and he detected no feverish symptoms except briefly after exposures; he perspired, however, somewhat at night, and too easily at other times, having been gradually obliged to increase his clothing a good deal. Still he took cold on the least exposure, and on all occasions,—in bed, at church, and finally in the parlour. Countless varied experiments seemed to prove this. Though he could but just perceive or detect the occasion in a few hours, it was proved by sneezing, catarrh, dyspnœa, or languor; he found that all late meals disturbed his breathing, and that to feed lowly and keep close, quickly set all right, though probably the regimen increased his susceptibility to derangement. Notwithstanding a long

decline by little relapses, and the evidence that the bronchi were so weak, his former ready restorations by care and air made him think that a sudden hæmoptysis without dyspnœa would still subside with sufficient care. The hæmorrhage did not last half an hour.

Though it did not disappear until the third day, it was evident that the rest of the blood had remained in the tubes, as it came away in little clots, decreasing in size, colour, brightness, and the firmness, with usual unopaque expectoration. A day or two before, he had felt a little uneasiness in the larynx; cough, with a slight sense of pricking; and fever, quicker pulse, and decline followed. No plan seemed comfortable enough but a warm bed. Flatulence, diarrhœa with blood, perspiration, and wasting followed, and a sense of having taken cold daily, or oftener, always introduced the deepest aggravations. Still, circumstances seemed to have combined a succession of unavoidable exposures and ill-ordered rooms, notwithstanding the will to avoid them for a period of two months, during which he was still declining, though by slow degrees, while living on the coast. His chief meal was reduced to three or four oysters per diem.

He embarked for warmer climates in December, and felt for the first time at liberty to take to bed and exclude all cold. He had no vomiting after the first hour on board ship, and from that time his convalescence was uninterrupted unless by too free an exposure, and the only inconvenience he experienced during five months in the West Indies was from cold, through that general absence of protection which all besides valued so much and purposely secured. On reapproaching colder regions, comparatively stout and active, every care seemed necessary; and ever since, warmth has been his friend, and cold his enemy.

We are well convinced that such cases of variable affections, and many widely different, are strictly dependent on variations of temperature and similar causes which affect the general balance of the animal functions.

A sister in the ward of a London Hospital, whose occupation and apartments are ill adapted for a delicate person, had, in the progress of many months, become asthmatic, hectic, and wasted, and only waited till forbearance could forbear no longer to be dis-

missed from her post. A new stove, listed doors, and better clothing, seem to have restored this patient to her duty; her situation, however, is trying enough to an extremely delicate frame at about 30 years of age, and much judicious care is necessary for such a case.

A gentleman of great wealth, and without mental resources, became addicted to the excesses of the table to a remarkable degree; he retired to rest late under a huge quantity of bed-clothes, and this training seems to have been for many years the means of consuming the superabundance, and renewing his appetite for dinner. He took but a little regular exercise and wore warm clothing.

Mr. E. F., of Bermondsey, about 28 years of age, of a strong lean figure, had an attack of continued fever, which wasted him for near a month. We gave him abundant counsel to avoid the causes of relapse, but at length he left his bed to sit by the fire in an ill-appointed parlour. From day to day symptoms of decline became more apparent, loss of appetite and cheerfulness, feverishness and night perspirations, cough and expectoration, all made him fearful, and he slept but little. The only remedy enforced in this case was a complete second suit of clothes, and the unhappy symptoms all rapidly vanished.

The disorders which are to be treated with warmth, as a means of facilitating the process of recovery, may be considered as comparatively simple, but those which may be advantageously submitted to heat as a kind of heroic remedy are to be regarded with yet more serious attention. The affections are serious, and the treatment may seem severe, and cannot be safely taken in hand without much knowledge and discretion. Distressing rheumatic pains, recurrent almost weekly for six or eight years, aggravated by so many winters, and perhaps by a much greater number of deliberate medical sieges and sappings, will not evacuate their strong holds with slight measures of a few days' continuance; yet we have known a lady, between forty and fifty years of age, carried on board ship, a sad cripple, and almost a hopeless sufferer from such an affection, being unable to help herself into her carriage, whose complaints were giving way before half the winter had passed in Jamaica,

and who returned to England in the summer perfectly cured.

Some vulgar proverbs point forcibly enough to the fact, that the feeble often outlive the robust, and no doubt the chief point of the explanation is, that the former are careful, and the latter careless; but can we reflect on the sources of mischief incidental to both, without concluding, that exposure to cold is the most certain and frequent danger that can be named, and which generally might be found to have been avoided on the one hand and incurred on the other?

It is surprising how frequently and easily many invalids do take cold, and often without knowing when or where, or how (not being very considerate); and it is important to reflect, that a disturbance being set up in the body, how readily the weakest or most deteriorated organ seems to become oppressed. To persons in health, it is very certain that warm apartments, luxurious beds, and undue clothing, enervate and induce languor, and thus increase the susceptibility to disease; but, on the contrary, almost every one in turn, unless prematurely cut off, comes to find the want of increasing warmth and comfort.

It is little to assert that the warmth that overpowers some is vitally essential to others. We do not scruple, at least with every month of the year, to point out the fact in a great hospital, where one or another falls a victim to ventilation—an accident, an operation, a chronic disease, is cut short by a sudden phlegmasia*; an acute affection in progress of cure is unawares fatally aggravated or supplanted by another; one patient escapes through half a dozen dangerous relapses, only to be cut off by the next. The repeated relapses of chronic, or more strictly speaking variable disorders, and the metastases and protean alternations of others, are not to be fully explained without reference to the like influences.

We defer commenting on the varying quantities of heat that air removes in proportion to the rapidity of its motion over the surface of the body in different cases; the effect of dry air on a moist surface; the probable proportions of heat in different diatheses, ages, and disorders; and also the irregular dis-

* See the account of open fractures, in the *Cyclopædia of Surgery*, and the *Causes of Strangulation in Hernia*, *Guy's Hosp. Rep.* No. 7, and *Med. Gaz.* May 1843.

tribution of heat and sensations of cold which are experienced under peculiar circumstances. The feverish man complains of cold, where a delicate female (having perhaps just dined) complains of heat. One enters the house after a walk and feels oppressive heat, when another leaving an easy close carriage finds it chilly; in the course of twenty minutes these sensations may be reversed.

It may, we hope, be now conceded that warmth like other remedies is to be employed as it is needed. More than this we would not ask; for, having indicated the general importance of our views, we grant that the disadvantages of heat, as of all medical disturbance, render it essential to employ as little as the emergency requires. The method of administering warmth, whether singly or in combination, we may yet endeavour to determine, although much must be left to experience, and a little to experiment. On the whole a warm house seems most like a warm climate. It admits of great freedom, little or no additional clothing may be needed when about to move actively out of doors. Perspiration is to be moderated, and the internal functions regulated. And all this is by no means difficult under favourable circumstances.

The practices of different nations, as the Swedes and Russians, and others, might afford many useful lessons with regard to what is safe and salutary in the application of warmth; but it is not pretended to be universally specific in its action as a remedial agent; but as an ever present means to use or to abuse, it must exert its proportionate influence on our economy.

The harmlessness of long-continued heat is forcibly shewn in the following fact. A gentleman who laboured under mild typhus, and was naturally very sensible of cold, remained from choice during two months of winter in a temperature strictly regulated, between 65° and 70° (rarely a little higher), and he was besides always well covered. When his convalescence was considerably advanced, circumstances obliged him to leave all his comforts entirely, and to expose himself in snowy weather both out of doors and in very unfavourable apartments. This was done not altogether without care, but he expresses his conviction that the warm regimen assisted very much to

enable his frame to resist the mischiefs. He endured a week of exposures and some serious difficulties, with but slight uneasiness, and to him unusual and unexpected impunity.

Some persons may ask how can it be safe to leave a warm place and to discontinue the artificial comforts? The answer is plain. Invalids are not the worse for temporary confinement to bed, or to a comfortable parlour. Those who have regained their health by going to a hot country, find it quite safe to return; and in our own country it is far more easy to obtain a warm climate without dangers, delays, or discomforts, and equally easy to try to leave it by degrees, although it is probably true that a few persons of peculiar constitution cannot live long without the constant comfort of great warmth. Accordingly we find every now and then, one who is compelled to do the best his knowledge and circumstances admit of, to form a perpetual summer about him. With judgment and care there seems to be no reason to anticipate any source of mischief, and surely it may not be too much to express a hope that we may one day see such plans in operation in a part of every great charity, in some establishments for education, and in various situations for the comfort of the feeble, and the aged of all classes.

When warmth is required strength is gained by having recourse to it, and strength being thus gained, diminished temperature becomes gradually required, and is often attended with proportionate increase of strength and benefit.

We have already in part explained how it happens that when the vigour is restored by comfort, a freer diet, more exercise, and even diminished clothing, are not incompatible with exposure even to the severities of winter. We may often return to the illustration of this observation.

The very objection to thermal comfort made by many judicious and well-informed persons is one of the most striking and general proofs of the advantages and necessity of securing feeble persons against cold.

It is constantly advanced that persons may not suddenly leave a warm climate without danger. The grand intention of artificial warmth should be simply to obviate this evil: to

guard against the constant or casual inconveniences of our own climate, to invigorate and prepare the delicate to bear them, and to enable them to take the full benefit of every favourable season or even turn of weather. It cannot be denied that one who cannot bear a favourable English summer, even with care, may return from the tropics able to endure unhurt a severe winter, and that with little or no care.

It is both foolish and false, between error and wilfulness, to contend that heat must of necessity relax or enfeeble. Why are the first days of convalescence those of confinement, perhaps even to bed? What is the chief cause of relapses? The early neglect of comfort is the evil to be feared; it represses every natural and restorative action that the infantile condition demands. What more certain advantage of the sea-side to tender subjects than mild and equable temperature? What more real and tangible in the benefit of "country air," as we say, than quitting bad habits for protracted gentle exercise, long rest in bed free from exposure, and full diet, by which a free and equal swing is given to all functions?

Artizans exposed to heat and cold in a very irregular manner, and without either disposition or judgment to protect themselves, are yet enabled, in a vast number of instances, to grow old in their employments without any material impediment or discomfort.

The solid objections to the use of warmth, and the precautions and aims to be considered with it, are like those connected with all remedial operations. The theory of general irritation, which we shall endeavour to unfold, may be the means of reflecting some light on all these points.

The opinions of Sir George Lefevre, "Thermal Comfort," lately published, appear to us well deserving attention. The perusal of these, and the retrospect of our own reflections, leave us more than ever strongly impressed with the conclusion, that a still more careful analysis of physiological processes is to be alike the main basis of pathology and therapeutics. We apply the following quotation with some confidence to the study of heat and cold.

"Be assured there is no little analogy between the duties of the military and those of the medical profession. The

physician is the general; the Pharmacopœia—using this term in a very wide acceptation—is his army; the disease is the enemy opposed to him. He has his skirmishes, as well as his pitched battles, to fight. He has his long campaigns, as well as his sudden encounters, to be prepared for. He has his outposts to look after, his guards to set, his entrenchments to fortify, his garrisons to subsist. His commissariat, as well as his gunnery and ammunition stores, must be attended to. When apparently most secure, he is liable to sudden surprises and inroads; the work of one hour may upset the exertions of a whole month; the events of one day may ruin the labour of years. And, last of all, he must be prepared for many emergencies which no human vigilance can foresee, and no human prudence can prevent. A passing storm may lay prostrate in a moment his wisest preparations; or the undermining influence of fear and despondency may render them all of no avail. No set of men surely ought to know better, or feel more deeply, than the soldier and the physician, the full force of the saying, that "the race is not to the swift, nor the battle to the strong*."

36, Bedford Square.

EVIL CONSEQUENCES

OF THE

TOO EARLY APPLICATION OF THE STARCHED BANDAGE IN A CASE OF SIMPLE FRACTURE OF THE FORE-ARM.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following be thought worthy of a place in the *MEDICAL GAZETTE*, an early insertion in its columns would much oblige the writer.

I am, sir,

Your obedient servant,

D. M'CASH, Surgeon.

July 1843.

I was called upon a considerable time ago to visit a boy twelve years of age, and of slender conformation, who had fallen from the top of an old wall to the ground, and was supposed to have

* *Med.-Chir. Rev.* No. 77, p. 167.

sustained a fracture of the arm. On arriving at the house I found the patient seated in an easy chair, with the injured arm resting on a cushion, and all his members agitated by the intensity of his sufferings. The history of the case and the appearance of the arm at once betrayed the nature of the injury, and enabled me without hesitation to come to the conclusion that the fore-arm must be broken in both its bones midway between the wrist and elbow. Manipulation detected crepitus and considerable displacement. The lower half of the fore-arm was bent in a forward direction upon the upper at an angle of nearly twelve degrees. Power of motion was completely destroyed, and a good deal of distortion existed round the fracture. Only half an hour had elapsed since the time of the accident, and no inflammatory symptoms had yet begun to show themselves. The fracture was easily reduced, but an obstacle to keeping it so until the apparatus had been applied, arose in the occurrence of violent spasmodic contractions of the flexor and extensor muscles. Had recourse to camomile fomentations to the part, and administered a dose of sulph. magnes. holding in combination a small proportion of the tartrate of antimony. A short time previous I had been reading some accounts by Velpeau of the successful application of *la bandage immobile* in cases of simple fracture newly contracted, and pleased with the nature of the details, had resolved on giving it a trial in the first suitable case that should present itself. Several circumstances seemed to me to point out the present case as adapted to my purpose, and on the strength of Velpeau's recommendation, proceeded without loss of time to have the arm encased within the folds of the starched bandage. Patient complained a good deal of pain and tightness on its first application, but being assured these unpleasant symptoms would abate as soon as the evaporation of the moisture should impart looseness to the bandage, he bore up with his difficulties for a time, and before the lapse of half an hour had sunk into a refreshing sleep. Saw him next morning, and found every thing in the condition I could have desired them to be. Pain had been very severe during the night, but had subsided towards the morning, and was now less than it had

any previous time been. A little constitutional disturbance was discoverable, but no prominent symptom existed to cause alarm. Bowels had been twice moved during the night, and several ineffectual attempts had been made to vomit. Being called away in a hurry to some distance from the scene of the accident, upwards of seven weeks elapsed before I had an opportunity again of revisiting my patient. During my absence, except a few days after I left him, the boy had continued without any considerable pain, had betaken himself to play, and favourable hopes were entertained by the parents that he would be all to rights again as soon as my return should sanction the removal of his bandage. On the eighth week after its application, I cut open the bandage and exposed the naked arm. Bones were in perfect apposition and firmly united. A glueing of callus was still discoverable around the joint. The finger and wrist joints were stiff and immovable even under the strongest endeavours of the patient to make them yield. But these disagreeable circumstances were viewed as the necessary consequences of their previous disuse, and no doubts were entertained but that their flexibility would return as the frequency of attempts to exercise them would increase. The cure seemed so complete, that only a few days were deemed necessary to allow of the parts recovering their natural condition, when the boy should be set at liberty and return to school. Fearful, however, lest the excitement of being allowed his freedom, should betray him into acts of indiscretion, and occasion untoward circumstances to his arm, I caused him to wear a splint for a time, and keep his arm suspended in a sling until the union of his broken bones should become more complete. The splint was applied along the inner aspect of the arm, and in order that he should exercise his hand, extended only from the bend of the arm to the wrist. Circumstances again prevented me from seeing him for nearly five months; when the following was found to be the condition of the arm. I may here state for my own justification, that I was only an occasional visitor at the house of a friend where the boy laid, and allowed myself to interfere with the case from the circumstance only that there happened to be no resident

medical man in the place, and of my being on the spot near which the accident occurred. The parts had previously assumed a pliant inactive condition from which they had not yet attempted to recover, but allowed themselves to be modified, and acted upon by every concurrent circumstance, for good or for evil, without evincing any tendency on their own part to regain their natural condition. The fracture was still firmly united, and the callus was nearly all absorbed. The fleshy part of the arm unusually round and firm, conveying the impression, when handled, as if the muscles were matted together. Flexion and extension, save to a very limited degree, quite destroyed. The wrist drooped over the end of the splint, and was beyond the control of the patient. The fingers were rigidly hooked upon the palm of the hand, and likewise defied all attempts on the part of the patient to make them straight. Sensation undiminished. Arm a little emaciated, and rendered totally useless as an organ of prehension. The tendons of the flexor muscles were prominent at the wrist, and resembled contracted cords passing on to the hand. On a more close examination of the case, it became perfectly evident that such an undescribable state of things depended, not upon any rigidity of the joints, but on a certain abnormal condition of the muscles whose office it was to move them; for though flexion and extension, as well as pronation and supination, were materially impaired to the patient, who required the aid of the other hand to make his fingers move, yet these motions were not so utterly suspended as to be beyond the power of being performed by the aid of a bystander; with these restrictions, however, that when the carpus was pulled up into the line of the fore-arm, the fingers hooked the more, and conversely the fingers were capable of being brought into the straight position only through the instrumentality of the bend at the wrist. Such seemed to be the permanent condition assumed by the parts. Patient complained of no pain, and seemed to have accommodated his disposition to the altered condition of his arm. When he requires to carry any weight by the affected limb, the body *requires* to be hung round upon his

contracted fingers, as upon an inert hook appended to his arm. If I were asked what deviations from the healthy condition of parts would be discovered by dissection of the arm, my answer would be—All the usual consequences of acute subjacent inflammation terminating short of the formation of pus; thickening and condensation of all the tissues; a copious deposition of organised lymph around and into the substance of muscles; morbid adhesions of one part to another, with all the other changes due to the same cause, to which alone the loss of motion of the limb was attributable. I have said subjacent inflammation, for the rigid bandage acted exactly the same part as a tense fascia over the morbid action which was going on beneath it. If the question were repeated, in how far were all these untoward circumstances so prejudicial to the walking of the patient connected with the treatment which was followed for his recovery, my reply would be in affirmation of their connection being so nearly united that the one might almost be regarded as the consequence of the other. To say unhesitatingly that the case would have terminated more favourably under the splint-and-roller treatment, would be to assume a stronger position than the nature of the premises would allow; but certainly I think there are few surgeons of the present day who would have been prepared to meet the consequences which ensued. My own conviction is that 80 at least out of 100 of such cases, treated with the ordinary remedies, would have done well. For the want of success, however, attending the present case, I would not by any means depreciate the starched bandage as a remedial means, for in my opinion it must ever be regarded as a valuable addition to our surgical *armamentarium*; but the position I would wish to see subverted is that of Sendin, the inventor, who attributes the principal share of its utility to earliness of application. Never was the invention of a useful instrument so overshadowed by wrong directions for its use, and perhaps there are few appliances from which more baneful consequences by injudicious management could be made to flow. No prudent surgeon should overlook the guidance of his own judgment in the promulgated advices of authors and inventors, however

authoritative they may seem, as to resort to such constricting measures in the treatment of fractures as the starched bandages before the inflammatory period which succeeds every accident has gone over, and the parts have subsided into their due medium of action. Such is the proper period for deriving its full advantage; but to apply it before this time is to impose a control upon nature which she will not suffer, and consequences most prejudicial to the reputation of the surgeon are almost certain to ensue; for every one but moderately versed in his profession, who, while he knows what benefit is to be derived from depletion, and the removal of tension in inflamed parts, must, at the same time, be aware what will be the nature of the results when not only these salutary measures have been neglected, but a treatment of the very adverse kind pursued. It reminds me of a commandment which would say, throw water into the fire, and you will extinguish it, while the person spoken to not only disregards the precaution but adds more fuel to the flame, with the intention in his view of accomplishing the same end, and in the blindfoldedness of his error allows the fabric to be consumed or rendered unfit for use. The case I have related, by following the directions of others rather than in attending to my own judgment, affords a vivid illustration of this figure, and if errors blindly contracted may be forgiven, I would not hesitate to affirm that the consequences which ensued were the effects of the practice employed. It may form a warning to others, and as such I give it without reserve. Three years have now elapsed since the occurrence of the accident cited; the arm continues as unserviceable as before.

ON THE FUNCTIONS OF THE LACTEALS.

To the Editor of the Medical Gazette.

SIR,

If you think the accompanying paper worthy of a place in your journal I should feel much obliged by its insertion.—I am, sir,

Your obedient servant,
SAMUEL FENWICK, M.R.C.S.

St. Albans, July 7, 1843.

After the constant discussion which the subject of absorption has of late years undergone, it seems now to be the general opinion, that whilst this property in the rest of the body is exclusively possessed by the blood-vessels, it is also shared in the intestines by the lacteals. The experiments of Magendie, and other physiologists, have clearly shown that the lymphatics of other parts never, under any circumstances, absorb, and doubtless from the similarity in their structure, and in their condition, in an empty state of the intestinal canal, the same would have been inferred of the lacteals, but that their turgid state during digestion, and an apparent analogy between them and the roots of vegetables, have misled inquirers into their functions. It is my object to show, that in the intestines, or elsewhere, the absorbing power resides entirely in the blood-vessels, and that the lacteals act only as ducts to carry away the nutritive matters taken up by the former, their existence being necessarily required on account of the impediment to the circulation through these blood-vessels (when distended with the fluids they have just absorbed), arising from the blood which has already supplied the intestines having to pass through the capillary circulation of the liver.

In attempting to demonstrate the above statement, it will be necessary first, to prove that the lacteals cannot of themselves absorb.

1st, Segallas placed poison in the intestine of an animal, and tied the vessels of the part. No symptoms of poisoning took place in one hour, although here the lacteals were unobstructed.

2d, I filled the intestine of a rabbit with milk, and isolating a portion of it by ligature, deprived it of its circulation by tying its mesenteric vessels, and returned the bowel into the abdomen. On examining it afterwards, no absorption had taken place in the isolated portion, although the lacteals of the contiguous portion of intestine were fully distended.

3d, I drew out a loop of intestine from the abdomen of a rabbit which had been previously fed (the lacteals being then distended with chyle), and tied the vessels leading to it, at the same time cutting off any vascular connexion with the contiguous portions

of gut by ligature. In a short time, on inspecting the animal, the intestinal lacteals on the isolated portion were found emptied, whilst those of the mesentery and of the neighbouring portions of the bowel were still filled with fluid.

It is evident, from the result of the above experiments, that the distension of the lacteals is in some manner connected with the circulation: they prove that the so-called lacteal absorption depends neither on simple capillary attraction, nor upon this force, assisted by the distension of their *mouths* by the influx of blood which takes place during digestion (for the blood was here retained in its vessels and no absorption ensued); and that it does not arise from any ciliary motion, or nervous influence, is evident from the third experiment, as the chyle was found to have been carried forwards into the lacteals of the mesentery—a sufficient proof that nervous influence must have continued in the intestine after absorption had terminated.

It being thus proved that the lacteals do not absorb, it becomes necessary, in the next place, to examine some of the arguments by which the opinion that the blood-vessels perform this function is supported.

1st, Delille and Magendie tied the lacteals of a portion of intestine in a living animal, leaving the blood-vessels unobstructed, and found the usual effects produced on injecting poisons into the gut.

2d, Fodera and others detected salts in the mesenteric veins after injecting them into the intestines.

3d, Tiedemann, Gmelin, and Meyer, have observed *chyle* in the mesenteric and portal veins.

4th, Absorption in many of the lower orders of animals is carried on entirely by the blood-vessels, no trace of lymphatics or lacteals having been discovered in them.

5th, I would refer more especially to a paper lately published in the *MEDICAL GAZETTE* by my talented friend Mr. Robinson, in which it is shown that the whole process of absorption depends upon physical principles, and that a current of any fluid is alone necessary to explain the phenomenon, without having occasion to call to our aid any mysterious and unknown principle of attraction to

account for what takes place in the living body.

Having seen, 1st, that the lacteals, when deprived of the circulation (even though nervous influence, and a certain degree of turgidity of the part, are maintained) cannot absorb any fluid, not even the chyle, which it is supposed to be their peculiar property to take up; and 3dly, that the blood-vessels can and do perform this function, which simply depends upon the physical power possessed by any stream of fluid; we have now to assign reasons rendering it probable that the use of the lacteals is only to convey the chyle absorbed by the blood-vessels.

1st, It has been observed, that when fluids are injected into the intestine they appear to enter equally the blood-vessels and the lacteals: thus, in the experiments of Fodera, a solution of prussiate of potassa was injected into the intestine, and on testing the fluids of the blood-vessels and lacteals with sulphate of iron, both were found to contain the same salt; and as we have before proved that the lacteals cannot, and the blood-vessels can, and do, absorb salts, it follows, that the prussiate of potassa must have entered the latter before their appearance in the lacteals.

2dly. If we look to comparative anatomy, we discover that no great development of the lacteal system is observed, until we reach that part of the animal scale where the intestinal blood has to pass through the capillary circulation of the liver; and on considering this circumstance, it will be found to afford a strong argument in favour of the theory here advanced. The heart's action being augmented in strength and frequency whilst digestion is going on, the rapidity of intestinal circulation is greatly increased, but at the same time, the vessels being in contact with a quantity of fluids, the products of digestion, they must by the physical laws above referred to commence to absorb them. They will by these means soon become gorged, in consequence of the *vis a tergo* forcing on their contents faster than they can be discharged into the general circulation, on account of the mechanical obstacles opposed by the capillary circulation of the liver. What, then, must be the natural result of this engorgement? either the fluids contained in the blood-vessels must

flow through their sides, or a complete stoppage of the circulation will take place. The porous structure of the capillaries prevents the latter, and if it were not for the distension of the intestinal tube by the digested materials, and its constant contractions, it is probable that the newly absorbed fluids would again pass into the cavity of the gut. But this being prevented the chyle oozes out of the blood-vessels into the capillary lacteals, which are placed within a net-work of vessels for this purpose in the villi of the intestines.

Viewing the whole mucous membrane of the intestines in this light, we perceive each villus to form a complete gland, agreeing with the other glandular tissues of the body in structure, as it consists of a ramification of blood-vessels and capillary ducts, (the latter being the lacteals,) the former for the separation and the latter for the transmission of its secretion (the chyle): the whole series of smaller ducts eventually uniting, as in other glands, to form one large conducting tube, the thoracic duct, and only differing from the generality of glands in use, as its secretion consists of matters lately absorbed and necessary for nutrition, and in its function being regulated by mechanical forces, uncontrolled by nervous energy.

It has been considered, that the lacteals were invested with the peculiar property of selecting the materials necessary for the nourishment of the body, whilst the blood-vessels not being equally gifted with discernment, indiscriminately took up whatever was presented to them; but the fact of the lacteals when tied still continuing to absorb, was always felt to complicate the theory of the functions of the rival vessels; it is evident, however, if the above statement of their use be correct, that this admits of an easy explanation: when a lacteal is tied, the blood-vessels being uninjured will continue to absorb the chyle, and pour it into the obstructed vessel, until, as observed by experimentalists, it appears ready to burst: the pressure of the fluids in the blood-vessels being then balanced by that in the distended lacteal, no more will enter, but as the surrounding vessels become restored to their usual degree of distension, when digestion is finished the fluid in the obstructed

lacteal will flow back again into the blood-vessels, and cause the empty state of the lacteal which is observed to take place after some time has elapsed.

The only two objections to this theory, which appear to me of sufficient force to merit notice, are the following:—

1st. The fact of the chyle being usually of a white colour, so that it is generally said the lacteals refuse to take up colouring matters. But if we reflect how little of any colouring matter is usually prepared for absorption by the digestive process, as evinced by the colour of the excrements of herbivorous animals, and when we consider how much more easy it is to detect by tests colouring matters in a clear fluid like urine, than to observe any slight change of colour in chyle, this objection loses much of its importance. Besides, many physiologists have most distinctly observed the lacteals filled with coloured fluids, which had been injected into the intestines, and there is no doubt that the lymphatics of the liver have been seen containing bile in cases of jaundice, and that those of the spleen frequently contain blood globules, which is very likely to happen in an organ so constituted, and so prone to congestion.

2d. Müller remarks that the globules of chyle are much larger than the capillary blood-vessels, and on this account an objection may be raised; but we do not yet know whether the chyle or similar fluids, when absorbed, do contain globules, indeed, I am inclined to suppose that in most cases these microscopical bodies are not formed until after the fluid has entered the vessels, for if globules of chyle, pus, &c. of so large a size can enter the pores of the lacteals, these pores should be apparent; and how do we find deposits of pus in various textures of the body, if the capillaries of these parts be too small to admit the globules?

Whether the above theory of the use of the lacteals may be extended to explain that of the other parts of the lymphatic system, we have not yet sufficient facts to determine; indeed, more experimental evidence should have been adduced in support of the subject of the present paper, but being at present, from other engagements, debarred from

pursuing the subject, and being myself fully convinced of the correctness of the theory, I deemed it proper to submit it at once to the investigation of others, who, being unprejudiced in its favour, may be able more candidly than myself to judge of its truth, or extend its applications.

HEMIPLEGIA CONSEQUENT ON SYPHILIS.

To the Editor of the Medical Gazette.

SIR,

IN the MEDICAL GAZETTE of May 27, 1842, Dr. Budd has called attention to some cases concurrent with, or depending upon, the presence of the syphilitic virus in the system. Since hearing that clinical lecture, I have paid much attention to the subject, and have been fortunate enough to meet with other cases, which, like those he records, seem fairly traceable to the same disease.

Richard Potts, æt. 32, millwright, of temperate habits, was admitted into the Liverpool Infirmary, Feb. 20, 1843, with hemiplegia. Stated that two years ago he contracted the venereal disease, and that since that he has suffered from sore-throat four several times. Soon after he was cured from the last attack (which was very obstinate), he had a trifling paralytic seizure. About five weeks subsequently he had another attack, which deprived him of his senses for a time, as well as the power of using the left side. Sight and speech he regained under the use of mercury; the muscular power by the repeated application of galvanic shocks soon after his admission: he had a venereal eruption on the skin, which was still upon him when he was discharged.

Thomas Dolan, æt. 27, admitted April 4th, states that he had syphilis three years ago, when he had chancres for nine months; during this time he had an eruption on the skin, which lasted three months. Two years ago he had sore-throat for six months; and twelve months ago, had pain in the shin-bones and ankles, which were always worse at night. He has frequently been subject to pains in his head, which became constant soon after the other secondary symptoms

were subdued, and continued till a few days before his admission, when he found that he had suddenly lost the use of the right side—his intellect not being affected. He recovered rapidly under the use of calomel and antimony.

John White, æt. 32, cooper, admitted 25th March for cataract in the left eye. States that two years ago he had syphilis, and subsequently nodes on the shin-bones during twelve months, for which he was salivated. For the last year has felt ill, but cannot describe any prominent symptom, except an occasional sore-throat. Seven weeks ago, while at his work, he suddenly lost the use of the right side, retaining his intellects entire. He recovered rapidly under the influence of mercury.

Owen Richards, æt. 30, clerk in an office, was admitted with complete hemiplegia of the right side (the face being much drawn to the left), which had occurred a few days prior to his admission. At the invasion of the attack he had been deprived of his senses for some time, and was, while in the hospital, unable to articulate distinctly. His history is therefore necessarily imperfect. He called my attention, however, to a large chancre situated on the glans, which I ascertained had been contracted at least three months before the paralytic seizure. He greatly benefitted under the use of mercury, sarsaparilla, and the iodide of potassium; but went out at his own request before he was completely restored.

Mr. R. A., whose history I have not been able to procure in detail, was subject to repeated attacks of hemiplegia, the first of which came on when he was about 33. He had been frequently before this the subject of the venereal disease, though the character of the secondary symptoms I have not been able to procure.

I may also call attention to a case which Dr. Todd, of King's College Hospital, made public; that of a young prostitute, æt. 21, who was covered with a venereal eruption at the time of her admission. It appears that she had been suddenly deprived of her senses, and on regaining them found that she had lost the use of the left side. This case subsequently proved fatal, and a *post-mortem* revealed inflammation of one cerebral hemisphere and red softening of the other.

It may, perhaps, be questioned how far I am correct in associating these cases with the syphilitic diathesis; and attributing the apoplectic attacks, to the effects of that virus. It may be urged, that instances not unfrequently occur in young subjects, for which no cause can be assigned on the most rigorous investigation; that the cases adduced may be those of simple coincidences, and that the two diseases, though contemporaneous, do not stand in the relation of cause and effect. It may be urged, moreover, that if there were such a marked association, it could not fail to have attracted the attention of some of the numerous writers who have treated on syphilis, by whom no mention is made of it. At present, perhaps these arguments cannot be altogether overthrown; but they will be strongly opposed by considering the general statistics of apoplexy. Out of 128 cases recorded by Morgagni, Andral, and Rochoux, 16 only occurred in persons below forty; in four the attack was distinctly referrible to over exertion, or excess in drinking; while in the others, no cause was assigned. This refers chiefly, however, to the graver forms of apoplexy; but when we examine into the statistics of hemiplegia, we shall find the disproportion fully as great, if not greater. In the four cases Dr. Budd records, and in those mentioned above, the patients were all under forty years of age, and we are naturally led to inquire into the cause of so unusual an occurrence. In all, we find that they have been subject for a greater or less time to syphilis: we know the formidable nature of that virus when introduced into the system, and being unable to find any other cause, naturally attribute it to that which is apparent. That the effects of mercury have no part in the matter is I think sufficiently proved, by its beneficial influence upon the disease, of which we can scarcely suppose it both the cause and cure.

As regards the way in which the virus may be supposed to act, I can add nothing to the remarks made by Dr. Budd, the only fatal case on record I have seen being that of Dr. Todd, which is shortly detailed above.

I have not, sir, troubled you with these remarks, so much to advance any speculation of my own, as to call the attention of your readers to a subject

which cannot fail to be interesting, and which, before it can be fully established, requires a much more extended series of observations.—I am, sir,

Your obedient servant,
THOMAS INMAN, M.B.
House Surgeon.

Infirmary, Liverpool, July 9th, 1843.

EARLY MARRIAGES SO COMMON IN ORIENTAL COUNTRIES NO PROOF OF EARLY PUBERTY.

To the Editor of the Medical Gazette.

SIR,

I REQUEST the favour of your giving insertion to the accompanying paper (or such an abstract of it as you may think proper), in any number of the *MEDICAL GAZETTE* that may be convenient.—I am, sir,

Your obedient servant,
JOHN ROBERTON.

Manchester, July 8, 1843.

In two papers on the Natural History of Puberty, published in the Numbers of this Journal* for October 1832 and July 1842, I have attempted to prove, in opposition to the generally received opinion, that the age of puberty is as early in the cold as in the tropical regions of the earth; and that, were marriages to take place in England at as juvenile an age as they do in Hindostan, instances of very early fecundity would be as common in England as they are in the latter.

In the papers just mentioned, I have expressed an opinion, that early marriage and early intercourse between the sexes, wherever found generally prevailing, are to be attributed not to any peculiar precocity, but to moral and political degradation, exhibited in ill laws and customs, the enslavement more or less of the women, ignorance of letters, and impure or debasing systems of religion. In proof of this opinion I expect to be able to show that in *England, at a period when some of the unfavourable circumstances just mentioned as yet lingered amongst us, early marriages were very common, if not in all ranks certainly among the gentry; and that such marriages were likewise common very recently among both high and low in Ireland.*

* Edinburgh Medical and Surgical Journal.

Before entering on the evidence for this curious and hitherto unnoticed fact,—unnoticed I mean in connection with the present subject of inquiry, it may be well to state what is the age of marriage in some European countries, lying, like England, in the temperate zone, and therefore experiencing the same or nearly the same climate, but where the mass of the people, from moral or political causes, and commonly both, are sunk in gross ignorance, or at best, with slow and doubtful progress, emerging from it.

It is to be recollected, that, though I have alluded to Hindostan by way of example, as a land of early marriages, such marriages are found in the coldest climates,—found as commonly among the Esquimaux of North America and the tribes along the shores of Siberia, as on the burning plains of the Carnatic or in the islands of the Indian Ocean,—equally in the inclement Archipelago of Terra del Fuego,* as among the tribes on the Orinoco,—among the Kirgis with their herds of Yaks, in the perpetual snows of Pamir at the fountain of the Oxus,† as in the verdant and sunny island of Ceylon. In every country, supposing the simple means of subsistence easily attainable, and even generally where it is otherwise, if the people are strangers to the Christian Scriptures, or to the civilization of the more favoured European nations, which has its root in the Scriptures, *there* the female sex remains uneducated and unhonoured, bought and sold, or bargained for in some form, like an article of merchandise; and there it is found that generally the marriage union takes place at a premature age. ‡

* "The Fuegians marry young."—Voyages of the Adventure and Beagle, Vol. ii. p. 182. Evidence as to the existence of early marriage among the Esquimaux and the Northern Asiatics will be found in my former papers.

† Journey to the Source of the Oxus in 1836-7-8, by Lieutenant Wood, p. 340. The Yak cannot live or does not thrive even in the winters of Cabul. It seems to require the region of perpetual snow, from under which it procures its food.

‡ Probably in all countries in an early stage of civilization, it has been the custom to buy and sell wives. By the laws of the Saxon Ethelbert, "if a free man lie with the wife of another free man, let him buy another wife for the injured party."—Strutt's *Manners and Customs of the People of England*, Vol. i. p. 75. There were laws fixing the price for women of all ranks as wives.—Ibid. p. 76. And Michaelis, with reference to Germany, mentions, that, in the German *Chronicles of the Middle Ages*, "we find it stated

Spain.—A recent writer has said, "The general immorality of the females is to be attributed to the prevailing system of early marriages—marriages of policy or convenience—and to the low standard of morals, rather than to extraordinary depravity of natural disposition." "In Spain, women for the most part marry first and love afterwards, and conjugal fidelity is consequently a rare virtue, especially as neither religion nor education interposes to check the fervid passions of a southern clime." "The cause of the low standard of sexual morals may be referred to the defective system of education, and the want of any proper religious principles to control the ebullition of passions." "I was amazed to discover the profound ignorance of the Andaluzas on the most common topics. The fact is, that in Spain woman is still suffering an Oriental degradation. She is still regarded in the light of a being created to contribute to the sensual gratification of man, rather than to be his companion, his friend, his counsellor."*

Sicily.—Frederick von Raumer calls "Ireland the English Sicily,"† intimating, that the degraded condition of the people of Sicily is a disgrace to the Neapolitan government, as that of the Irish is a stain on the government of England. It is when speaking of the Sicilians that an interesting writer has said, "One must not enter these huts with English ideas; cleanliness must not be expected, but he will find enough to eat and drink, and the peasants satisfied with what they have. If any proof of what I have said were wanted, it might be found in the *universally* early marriages, and the numerous broods of naked, dirty, but not ill-fed children that are everywhere to be seen."‡

Greece.—In Mr. Strong's valuable statistical work lately published, enti-

that A. B. bought C. D., that is, married her."—Smith's Translation of Michaelis's *Laws of Moses*, Vol. i. p. 450. This subject—the age and terms of the matrimonial contract in different countries, at different periods—has never as yet, with anything like an adequate degree of care, been investigated, although there are few that better deserve the trouble.

* A Summer in Andalusia, Vol. ii. p. 404-5 and 6. London, 1839.

† Italy and the Italians, vol. ii. p. 355.

‡ Letters on Sicily, by William Irvine, M.D. p. 27. In the Spanish island, Minorca, the Minorquins "are often betrothed to each other while children, and marry at fourteen."—Cleg-horn on the Epidemic Diseases of Minorca, p. 54.

tled "Greece as a Kingdom," when treating of the soil and the inhabitants, he alludes to the early union of the sexes, which he seems to attribute to natural precocity, and mentions an Athenian lady who was a grandmother at the age of 24.* Whittman in his Travels had given 15 years as about the age when the Greek women marry;† and those of the Ionian Islands, according to another writer, marry some at 11, many at 12, and most before 16; all the matches being made by the parents‡.

Russia.—European Russia may still perhaps be considered, as to the mass of its population, as lying beyond the boundary of civilized Europe; and here the age of marriage, according to the testimony of a number of writers, is allowed to be extremely early—to have been so, at all events, till within a very recent period. Thus Mr. Tooke writes, that the common sort enter into the nuptial state "as early as they can;" and elsewhere remarks, that the women arrive at maturity at their 12th or 13th year.§

Another writer has said, that the lords of the soil in Russia all take care to promote matrimony early.|| According to Archdeacon Coxe, a boy of nine or ten is often married to a woman of more advanced age, she living as his father's concubine.¶ This latter is a curious trait which was noticed by Sir Dudley North, as we learn from his Letters during a residence in Archangel as far back as the reign of Charles II. "One of the inconveniences," says he, "that lie on those who dwell in this country, is, that the people are so given to nastiness, that nothing can be eaten out of their hands; you shall have perhaps four brothers and as many sisters, with their father, mother, husbands, and wives, all dwelling in one hot-house; (*wisbie* they call it;) they have nothing but a little straw strewed on the ground to lie upon." "In this country the husband is the sole commander of the wife, who differs very little from his servant. Many will marry their sons very young to

lusty baggages on purpose to gain able servants."*

From no author I am acquainted with have we in several respects equally precise and valuable information on the customs of Russia, as the Rev. Dr. Pinkerton, some time Foreign Agent of the Bible Society, and "many years," he tells us, resident in Russia. Concerning the age of marriage he thus writes: "Before the influx of European customs, the contract for marriage was formed by the parents and relatives, and the bridegroom was never permitted to see his bride until the ceremony of betrothing took place. An ukaz of Peter the Great, in the year 1700, forbade this practice to be continued, and prohibited the priest solemnizing the marriage unless the ukaz was attended to." "At the beginning of the eighteenth century, it was the custom of the Russians of all ranks to marry their children very early, even before the age of puberty."†

We shall have again occasion to refer to the Russians in connection with the subject of early marriages: in the meantime I may remark, that every reader conversant with modern history must be aware that, if we except, to some small extent, the Russians, the inhabitants of the other countries mentioned are degraded politically, morally, and intellectually; the women sought as wives with little regard to a sentiment of affection at an age preposterously early; whilst they, ignorant of the position in the social system they are designed by the Creator to fill, exhibit the vices peculiar to the uncultivated female character—indolence, frivolity, and an abject superstition—with few of its humanizing, purifying virtues. Thus early marriage is found to be the effect of a degraded condition of society, and is again, in turn, a powerful cause of the perpetuation of that same degraded condition.

If, however, instead of supporting this conclusion, we were to concede, what has been so long and so generally contended for by physiologists, that not ignorance and moral debasement are the causes of early marriage, but that it depends upon a bodily cause; that, in fact, the Creator has fitted the

women of Andalusia and Greece, for example, to enter upon the duties of wife and mother at an earlier age than is natural to the women of England, then might the superiority of these latter over the former be considered as a thing absolutely settled; nor should we be permitted to hope that a purer religion, an improved education, and wiser laws, would avail to remove the difference. If it be asked why? the answer is, that the training of young women, the acquisition of the knowledge and the habits requisite to qualify them for wives, requires time—a period at the least of several years subsequently to the age of puberty—if the education is to be anything better than nominal; and seeing that puberty, on the hypothesis in question, is later in our favoured climate than on the shores of the Mediterranean and the plains of Russia, the women of England, by the ordination of Nature, will possess incalculable advantage in the longer space of time they will have to devote, before the period for marriage, to a preparation for the duties of domestic life. This, doubtless, is a conclusion few physiologists would *choose* to arrive at if it could be helped; but it is one that they cannot evade, except by a supposition, which I am not aware any one has ventured to make, viz. that the women of Spain and Greece, possessing greater quickness of parts than those farther to the north, are able in a briefer space of time to complete their education, the early development of the body being accompanied by a proportionably precocious display of mind.

The impediment to the work of education arising from the prevalence of early marriage in a community, has not altogether escaped the notice of observers. In a recent tour in Egypt and Candia, Captain Scott, the author, thus writes; and though his remarks have reference to Mahomedans, they are of course applicable wherever the same practice of premature marriage exists.

“An almost insuperable objection to a finished education in any Mahomedan state,” says this writer, “is the early age at which marriages are contracted: a father provides a wife for his son when he ought to be still at school; so that the youths themselves have the cares and distractions of a family upon them ere they are of an age to be removed from under the rod of the

schoolmaster; and it may be here observed, that precocity of intellect is by no means remarkable among the Arabs; so their education cannot commence at an earlier age than in northern countries.”

But by what arguments are the advocates of the hypothesis which I am endeavouring to expose (that early marriages depend on early puberty, and this latter on warm climate), to encounter the instance of the Russians, in whom this kind of influence of climate at all events cannot be alleged as the cause of *their* early marriages? I can imagine none. Moreover, there is evidence to prove that, just in that degree in which the light of civilization has, from time to time, found entrance and been diffused in Russia, has the practice of early marriage been discouraged and opposed by its rulers. A century and a half ago the inhabitants lay in a state of profound ignorance and debasement—on a level with the nomade hordes of the Asiatic deserts; and it was only when a sovereign like Peter the Great arose, with a clear perception of the better way, with wisdom to take it himself, and courage and perseverance to force his subjects into it, that Russia began to rise in manners, and slowly advance into the rank (as yet perhaps the rear-rank) of civilized nations. It was the custom of the Russians of all conditions, says Dr. Pinkerton, “to marry their children very early, even before the age of puberty; but Peter, by an ukaz of 23d March, 1714, strictly prohibited the nobles from entering the married state before the age of 20 for the bridegroom, and 17 for the bride. Catherine II., by an ukaz in 1775, reduced the legal age of marriage to 17 for the male, and 13 for the female. This custom of early marriage still prevails; and in innumerable instances, especially among the common people, it is fraught with very pernicious consequences, both to the physical and moral state of the parties. Many shocking instances have been known among the peasantry, of a breach of the laws of consanguinity in consequence of these premature marriages. By a recent ukaz of the present Emperor Nicholas (1831), the priests are forbidden to solemnize marriage unless the man be 18 and the bride 16

* Rambles in Egypt and Candia, vol. p. 185.

years old: and this edict extends also to the Uniats and Protestants in the empire.”*

Testimony such as this, concerning the age of marriage in Russia, coming from an eye-witness long conversant with the manners of the people, and a proficient in their language, must be regarded as extremely interesting and valuable. It illustrates the view which I am endeavouring to enforce, as to the causes of early marriage and early sexual union, wherever they are to be found; establishing, by an example on a great scale, that early pubescence, the effect of a warm climate, cannot be regarded as necessarily among those causes.

To proceed to the main object of the present essay: a transition, in some degree resembling the foregoing in Russia, from marriage at a juvenile to marriage at a more mature age, must have occurred in England; although, owing to greater remoteness of time, the steps of this change in respect to the common people cannot, it is probable, now be traced: with regard to the gentry the case we shall find is otherwise. In entering on this portion of the inquiry, it may be well, since we have the means, to give the age of marriage in England at the present period; by which we shall be enabled to see, in the issue, how great a change time has wrought in this particular among us.

In the Report of the Registrar-General for the year ending 1839, a table of the ages in 4858 marriages has been published, and these not being selected instances, but belonging to districts varying in situation and character, and including every marriage in those districts, may be presumed to be a fair example of the ages at which marriages occur throughout the whole kingdom.

According to this table there were under 15 years, none for either sex; of males 15, and under 20 years, there were 3½ per cent; and of females of the same ages about 14 per cent. of the whole number. The average age of marriage for men, 27 years, and for women 25 years and a few months: a result which still leaves room both for regret and improvement.†

I have already stated that, at the period when premature marriages were frequent in the country, some of those ill customs existed (or customs of like evil consequence) which are found wherever such marriages are found. Independently of the general ignorance, and the rudeness of manners in England in the fifteenth and sixteenth centuries, or even later, concerning which I shall not venture particularly to speak, there was the feudal right of wardship and marriage; a cause in itself alone of various evils, but of none greater or more hurtful than early marriage, which we shall find it absolutely necessitated in a number of instances; and thus introducing the practice in high quarters, diffused it probably through the whole mass of society. The nature and exercise of this feudal claim, which existed in all its oppressive rigor so lately as the reigns of the first two Stuarts, having been abolished only in the year 1660, it will be easy to explain and illustrate: in the course of doing which a number of facts will be mentioned indicative of a state of manners whose grossness and barbarism I had not myself an idea of before entering on this course of inquiry.

“Almost all the real property of this kingdom is by the policy of our laws supposed to be granted by, dependent upon, and holden of some superior lord, by and in consideration of certain services to be rendered to the lord by the tenant or possessor of his property.”*

All tenures of land were supposed to be derived from the king, either mediately or immediately. Those who

page 10, 8vo. From Senior's statement concerning a provision for the poor of foreign nations, 8vo. 1835, we find that in several European countries the laws against early and improvident marriages are, as appears to an Englishman, extremely strict. Thus in Bavaria the clergy are held responsible for the support of those poor persons they have married without leave from the authorities, besides being fined. In Berne no pauper can marry without the consent of his parish; in Norway no one can marry until he has satisfied the clergyman that he is able to maintain a family: in Mecklenburgh, owing to the conscription and other causes, men marry at from 25 to 30, and the women not much earlier. In Saxony a man liable to serve in the army may not marry under 21; in Wurtemberg no man is allowed to marry, unless permission have been especially obtained or purchased, under the age of 25. In Belgium the average age of marriage is for men 27, and 26 for women.

† Report of the Registrar-General for 1840,

held immediately of him were called tenants in chief; and these again in their turn were lords to tenants of a less honourable grade over whom they exercised rights.

The services rendered both by the tenants-in-chief to the sovereign for the lands they held of him, and by the inferior class of tenants to the middle lords in return for their tenures, were various; consisting, among others, of military service, aids, fines, forfeitures, and, what particularly concerns us at present, wardship and marriage.*

The right of wardship means that the lord had the guardianship of his tenant during his minority, by virtue of which right he had both the care of his person, and received to his own use the profits of the estate, excepting the ward's aliment, the amount of which lay much at the mercy of his lord. By a gross abuse of this custom in England, this right of wardship was often by the lord assigned over to strangers, or it was put up to sale, or bequeathed by will like any other kind of disposable property. But, besides the profit of the estate during the minority, the lord had another perquisite connected with his guardianship, viz. the right of disposing of his ward, whether male or female, in matrimony.

Let us suppose a tenant to die, leaving a child or children of both sexes, minors, the lord would assume the powers of guardian,† due inquiry having first been made with reference to the nature and amount of the property, and the ages of the minors; and here it may be well to mention, that the male was a minor till the age of 21, and the female till

the age of 14, though in the case of a female ward the law continued the guardian's hold of her person and property two years longer—till she was 16. If the lord did not make over, or sell his rights, he soon set about finding matches for his wards; either by uniting them, if that were thought advantageous, with members of his own family, or of the families of relatives, or by selling the marriage; i. e. if the ward, for example, were a female, disposing of her hand to the best bidder, provided he were of suitable rank, for the law forbade disparagement. When the female ward was thus married before her twelfth year, she might, on arriving at that age, repudiate the match; in which case she had to pay to the guardian *the value of the marriage*; a sum out of her property equal to what a jury would assess as the price which might have been given for the alliance. Of course all wards (I purposely confine my remarks to those of the female sex, though the same would apply with the before-mentioned difference to males) were sure to be made to marry at the latest before the age of 16, since at that age the guardian's power over them ceased, and they were at liberty to sue out their deliverance from wardship. We shall by and by see that marriage, in such cases, instead of being delayed till the age of 15 or 16, or even till the legal age of consent, which was 12, was often contracted at an age considerably earlier, with a view to its being consummated when the parties should arrive at puberty—in some cases probably even before that period.

But it might and often did happen, as has been already mentioned, that the lord, instead of exercising the right of guardian, sold it to a stranger: to use the words of Hargreave, "This guardianship, being deemed more an interest for the profit of the guardian than a trust for the benefit of the ward, was saleable and transferable, like the ordinary subjects of property, to the best bidder; and if not disposed of was transmissible to the lord's personal representatives. Thus, the custody of the infant's person, as well as the care of her estate, might devolve upon the most perfect stranger to the infant, one prompted by every pecuniary motive to abuse the delicate and important trust of education, without any ties of

* The kind of tenancy here alluded to was called tenure by chivalry, or tenure by *Knight service*,—in other words, it was a military tenure which in time came to include (or rather in some cases degenerated into) escuage or pecuniary assessment in the room of personal military duty. Socage tenure was a different thing, and did not bring to the tenant the same kind of burdens as tenure by chivalry.

† In law phrase guardian in chivalry. It is a curious circumstance that wardship and marriage is found among the Rajpoots of India. The mother, however, is generally guardian. Tod's *Rajast'han*, vol. i. page 161—3.

If any of my readers have a desire to understand fully the nature of this feudal claim I refer them to Hallam's *History of the Middle Ages*, vol. i.; Sir Henry Spelman's *Posthumous Works*, chap. xiv. and xv. folio, 1698; and especially Christian's edition of Blackstone, 4 vols. 15th edition, 1809, vol. ii. pages 67, 68, 69, 70, 71, 131, and vol. iii. page 258.

blood or regard to counteract the temptations of interest; or any sufficient authority to restrain him from yielding to their influence.”*

Before illustrating by instances the strange results of this oppressive and debasing claim, I would remark that our law in a different case appears to proceed on the assumption that early marriages were common: thus Littleton tells us that the wife shall be endowed out of her husband's lands and tenements, “whether she have issue by her husband or no, and of what age soever the wife be, so as she be past the age of nine years at the time of the death of her husband, for she must be above nine years old at the time of the decease of her husband, otherwise she shall not be endowed.”† On this passage Sir Edward Coke makes the following comment: “If the wife be past the age of nine years at the time of the death of her husband, she shall be endowed of what age soever her husband be, albeit he were but four years old. Quia junior non potest dotem promereri neque virum sustenere; nec obstat mulieri petenti minor ætas viri.”‡ “This we are told by that grave and reverend judge, without any remark of surprise or reprobation,” says Mr. Christian indignantly;” and then he adds—“It is abundantly clear, both from our law and history, that formerly such early marriages were contracted as in the present times are neither attempted nor thought of.”§

In another instance, the law concerning rape, the existence of very early marriage is indirectly recognized thus;—by the statute of the 18th Elizabeth, which makes it a capital crime to abuse a consenting female child under the age of 10, an exception seems to be left for these marriages, by its being declared that *only the carnal and unlawful knowledge* of such woman-child is felony.||

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

PRIVATE TUITION.

ADULT readers of history, and especially those who delight in autobiographies, personal memoirs, letters, and other documents, which may be called rather materials for history than history itself, cannot fail to be struck with the small motives of temporary expediency which appear to have suggested the most important measures, and the small circumstances which have contributed to develop and carry them into effect. Such readers are apt, indeed, to settle down into a disbelief of all those qualities of deep foresight and steady perseverance which the more youthful reader of summaries and abridgments is apt to attribute to the great actors of former days; and as there is, in the lives of most men, a time when such a scepticism is produced, so there are some who, seduced by a love of paradox, an indolence of habit, or other personal peculiarities, never emerge from such a state, but actually persuade themselves into the practical as well as theoretical adoption of an inert and morbid fatalism; for it is matter of deep experience that our constitutional tendencies, physical and moral, have more power to form our theories than our theories have to regulate our constitutional tendencies. But such scepticism will, in healthy and active minds, sooner or later give way to a practical belief, chastened indeed, and tempered, but not on that account less earnest, that diligent labour, and prudent conduct, are the true means placed within our reach for effecting the great purposes of life. The value which such qualities bear

amongst men, as an acute modern writer has remarked, may be considered as the exponent of two facts; first, the uniformity of the general laws which regulate the affairs of the universe; and secondly, the occasional exceptions to which those laws are subject. If either undeviating routine or blind chance evidently controlled events, there would be no room for the exercise of superior penetration, and no wisdom in superior prudence. Now the art of medicine is one which, more perhaps than any other, requires the broadest general principles to be kept in view while dealing with apparently the most inconsequent of small details. Superiority in detecting and acting upon the latter is so evidently and appreciably valuable, that it seems the most useful quality in practice, as it is certainly the most immediately profitable to its possessor; and many men of large intellectual possessions are constantly embarrassed for want of that small change which others, who are far their inferiors, seem to have always at their command.

It is most important that broad principles should be inculcated early in life, and that the mind should receive those habits of reasoning justly, and judging rightly upon whatever premises may be within reach, which, if early inculcated, and faithfully cultivated, becomes in time a kind of intellectual instinct, acting involuntarily and unconsciously without labour to the possessor, and beneficially influencing all his proceedings. It is evident that to us sound physiological and pathological views are the great foundations for technical, as the abstract sciences are for general, accuracy of judgment; they are to be matters of gradual instruction, and of personal experimental conviction. This conviction will of course vary in degree according to the talent and diligence of the pupil, and the faithfulness of the teacher. Not

even the most advanced of the former has his convictions of this kind complete on entering into practice. Much that might be matter of proof he will have believed on hearsay, and much that is mere matter of strong probability he will have adopted as unquestionable.

Those who have most experience in teaching, and especially in lecturing, are most distressed at the small amount of information which is carried away by their pupils, not only of a serviceable kind, but in a serviceable state, with its due weight of evidence, and its due bearing on practice. The lecturer is obliged by his office to lay down his subject as a whole, and though if he be a practical man, as well as a man of genius, he will so handle it by faithfulness in his general outlines, by strongly marking what is certain and important, and touching lightly on what is distant and indistinct, as to draw, in the mind of his pupils, a correct picture, full of colour and perspective—yet he must reckon on sad mistakes in his meaning, distortion in the general effect, and caricature of his details, when his pupils come to represent for themselves the pictures he has drawn for them. It is our confident hope and belief that the proportion of young men who saunter through the medical schools not studying at all, well or ill, is exceedingly diminished of late years; the distribution of prizes, the institution of clinical clerkships, and the competition amongst lecturers, have brought the students more under the personal notice of their teachers: but this is not all that is wanted; the public lecturer and the private instructor have very different offices, and the advantages to be gained from each will be increased as their respective duties are recognised and performed. Perhaps the term private instructor does not convey the exact meaning of the office alluded to. Won-

derfully little can be *taught*, properly so called, beyond general principles—the student must learn for himself, and teach himself. The capital error in the system of cramming has been the supposed power of substituting some intellectual operation done by the grinder in a short time for the long-continued study which the curriculum requires. The word *tutor* more accurately expresses the meaning; he should be really the guardian and defender of the student against his indolence, his misconceptions, and the various temptations which beset his path from within and from without. Against his indolence, not assuredly by drenching his mind with mawkish dilutions of what he has heard or read, but by taking care that the current of thought and reason is quick, not stagnating, by detecting the short-comings of his memory or his comprehension, and directing him to proper sources for supplying their defects, by observing whether the words which he has heard have conveyed correct ideas to his mind, and by scoring on his memory the level to which the tide of daily instruction has flowed.

The talents and energies of lecturers and authors should be devoted to raising the subjects treated of to the highest possible pitch, rather than exhausted in reducing their details to the level of the meanest capacity; but in proportion to the brilliancy of the master, and the admiration of the pupil, is the chance of misconception—not to mention the inherent dangers which beset those high and original endowments which are the most valuable qualifications for a teacher. Few lecturers—probably none—omit to impress upon their hearers their willingness to explain to them privately whatever points they have not understood; but this is always a disagreeable process, as it is felt tacitly to imply a defect of perspicuity in the teacher, or

of intelligence or attention in the pupil: the more youthful party is not always apt to decide against himself, and an impugment of his superior not seldom results. These matters are easily explained by a well-informed private tutor. Against his temptations from without, the student has to be defended, not by long-winded homilies and elaborate dissertations, but by giving to the habits of recreation an innocent as well as cheerful direction. Against temptations from within, no tutor who combines experience, judgment, and candour, will *profess* to do more than endeavour to practise and to promote that conduct which is a daily sermon, while an ability to give a reason for the faith that is in him will not be wanting to account for the habits of daily piety which he may adopt.

These are high and responsible duties, not to be lightly undertaken nor carelessly delegated; and this leads naturally to the best mode of selecting such a person. The sincere believers that elective purity is attainable, will of course suggest a *concours*; but a good deal of observation has destroyed our natural belief in the efficacy of this process, and almost in all very complicated “ballot-boxes, or other machines whatever,” recommended as infallible for that purpose: proportioned, indeed, to our conviction of the importance of selecting the best man for any office, will be our doubt as to the specific powers of any elective process which professes to ensure so desirable an object.

That eccentric writer, Mr. Thomas Carlyle, whose soothsayings have at least this in common with those of the Trojan prophetess, that they are not believed, thinks that on the whole we in England choose our leaders worse than any nation that he knows of; and it is a sort of comfort to find his disbelief in any specific form of election so complete. Catch the right man, he says, and you

have got all. Catch your no-man, the unfit, the pretender, and you have got all too, but the other way. We recommend those interested in this question to look out for themselves amongst their own neighbours and acquaintances, for fit men, if they are to be found, and to choose, it may be hinted, not those who promise most, but those whom they know best.

FELLOWES' CLINICAL PRIZE REPORTS.

BY ALFRED J. TAPSON.

University College Hospital, 1842.

[Continued from p. 480.]

CASE XIII. — *Enteritis, ushered in by copious discharges of blood from the bowels, and marked by the usual symptoms of a mild attack of enteritis. Cured by V.S. leeches, blistering, mercury, &c.*

WINNIFRED MORAU, æt. 45, admitted May 28th, 1842, under Dr. Williams. A thin, pale, nervous looking woman: is married, and has had thirteen children, only two of whom are living. Has been living in a very damp house during the winter, and has not been able to get enough food for some months; is temperate.

She states that she is naturally of a strong constitution, and was formerly much stouter; she never had any illness till last July, when she was in this hospital under Dr. Williams' care for an attack similar to the present, but much more severe, and ever since then her bowels have been habitually constipated, sometimes not being opened for a whole week, obliging her to take aperient medicine frequently.

The *present attack* commenced on the 21st instant, after she had been ironing for some hours on the floor, and was a good deal fatigued. A sudden pain came on in the small part of the back, and she felt very weak: the pain in the back was much worse on the 22d, and she had also severe pain over the pubes and sacrum, with headache, anorexia and thirst, and she passed about a pint and a half of fluid, bright-coloured blood when her bowels opened; on the 23d she passed fully a pint of blood in the same way, and nearly a pint on the 24th; about half a pint on the 25th, and this was clotted and almost black. Since then she has not passed any. (She never had any such discharge of blood before; has never had piles, and menstruated rather more copiously than usual the week before last, and is not aware

of any cause that could have produced it.) The pain in the back and lower parts of the bowels has never ceased since it first began, but is much increased at intervals, and at these times her abdomen is covered with perspiration; she has not been sick, but has scarcely eaten anything, and has got very thin and weak.

Present symptoms.—She lies on her back with the knees drawn up; the countenance is pale and has a depressed expression; the breathing is quick; pulse 96, sharpish, but weak. She complains of a severe pain across the lower part of the bowels, increased by a deep inspiration, and much worse sometimes than others; considerable tenderness on pressure all over the abdomen, but especially in the right iliac region; the abdomen is enlarged all over, is tympanitic over the situation of the cæcum, but dull on percussion over the less iliac region. The lips and tongue are dry, and the latter covered with a coarse white fur; is thirsty; breath has a disagreeable smell; the bowels were opened a little this morning; the urine scanty, and causes her much pain and difficulty in passing.

Abdomini admov. Hirud. xij. et postea cataplasma amplum.

R Hydrarg. Chloridi. gr. iv. Ext. Belladonnæ, gr. j. M. f. pil statim sumend. et post horas tres, si perstiterit dolor, repetenda pilula. Vesperi sumat. Olei Ricini, fʒj.

• Low diet.

May 30th.—The leeches removed the pain for some hours, but then it returned, and has been severe ever since; vomiting also came on, and still continues. The tenderness of the bowels is quite as great as on the 28th, especially in the right iliac region, where there seems to be a small roundish tumor; the lips are very red; tongue dry and furred; pulse 104, fuller and sharper than it was; breathing rather laboured and quick (27 respirations in a minute): last evening she took a second dose of the castor oil, and the bowels have been opened several times to-day; the stools all dark coloured, not bloody. The urine exceedingly scanty, the sp. gr. 1032, and contains a considerable flesh-coloured stringy sediment, chiefly composed of the lithates: urea is also greatly in excess.

V.S. ad fʒxij. Abdomini applic. Empl. Canth.

R Hydrarg. Chlorid. gr. iv.; Opii, gr. j. M. f. pil. bis die sumenda.

R Acidi Hydrocyan. diluti, ℥v.; Soda Sesquicarb. gr. x.; Mist. Acac. fʒj.; Aquæ, fʒj. M. f. haust. ter die sumendus.

31st.—The blood drawn yesterday is considerably cupped and also buffed; the clots

loose below ; the pain has been much less since the bleeding ; it is not constant now, and when it comes on is less severe ; the blister has risen well ; pulse 100, less full. She was sick twice in the night ; the bowels not opened since yesterday forenoon ; urine scanty and high coloured, but much clearer.

℞ Olei Ricini, Olei Olivæ, aa. fʒj. ;
Vitelli ovi. unius. Decoct. Avenæ. Oj.
ft. Enema, statim injiciendum.

June 1st.—Bowels less swollen and much less tender and painful ; sickness continues ; gums tender and tumid ; mercurial foetor evident ; the enema has not produced any effects.

Olei Ricini, fʒss. statim.

2d.—Better ; slept pretty well last night ; has no pain at all when at rest, and she can move without much pain ; there is still tenderness in the right iliac region ; bowels have opened twice ; motions copious and lumpy, not very dark.

Omittantur pilulæ. Adde haust. Creasoti, ℥j.

4th.—The sickness has ceased ; she has a good deal of pain in passing her water, which is still very scanty.

Adde haust. Sp. Æther. Sulph. ℥xx.

7th.—Has no pain in any part of the abdomen ; but there is great tenderness yet in right iliac region ; the tumors here seem much swollen ; tongue covered with a thick yellowish white fur ; salivation considerable ; bowels not opened for three days ; urine only about half a pint in 24 hours.

Statim sumat. Olei Ricini, fʒss.

℞ Sodæ Biboratis, ʒss. ; Mist. Acac. fʒij. ;
Aquæ, fʒvj. Ft. Lotio, quâ sæpe os lavatur.

Middle diet.

9th.—The bowels were freely opened by the medicine ; she has no pain anywhere, nor tenderness, and there is no swelling to be felt now in the right iliac region ; appetite returning. The skin has been itching the last day or two, and there is a slight eruption to-day, chiefly vesicular, very like that of scabies ; feels very weak.

℞ Fiat. haust. cum Infusi. Calumbæ, fʒj. vice Aquæ.

℞ Potass. Iodid. ʒss ; Aquæ, fʒiv. ft. Lotio, quâ fricentur partes prurientes.

11th.—Improving ; but the bowels are costive ; urine rather increased in quantity.

℞ Sulphuris Loti. ʒij. ; Sodæ Tart. ʒj. ft. pulvis 2dâ quâque mane sumendâ.

14th.—Feels stronger ; no rash or itching now.

Sumat. pulvis omni mane.
Full diet.

18th.—Is now quite well, only rather weak ; urine natural in quantity and appearance.

20th.—Discharged cured.

REMARKS.—In the present case a certain *diagnosis* could scarcely have been made, if we had only had the symptoms which existed on her admission to guide us, but when these were taken in connection with her previous history and the mode of attack, there was very little room left for doubt.

The more important of the symptoms might nearly all have belonged indiscriminately either to peritonitis or to enteritis—thus, the feverishness, the posture in which she lay, the situation, and in some respects, also, the character of the pain complained of in the abdomen, the tenderness, the state of the bowels, &c. might have depended on either of the above diseases : accordingly we find there was very little on which to found the diagnosis from the symptoms alone : the pain certainly had more the character of that attending enteritis than peritonitis ; it had not the sharp lancinating character that commonly marks inflammations of the serous membranes, and it came on in paroxysms, in the intervals of which she was comparatively free from pain—and this is often the case in enteritis, probably from the passage of gas, &c. from one part of the intestine to another, producing spasm. If we now refer to the previous history, and to the mode of attack, we shall not hesitate to pronounce it to have been a case of enteritis. *First*, in the history it is mentioned that she was in this hospital twelve months ago for an attack of enteritis more severe than the present, as appears from the account given of it in the hospital report-books, and since then her bowels have been habitually costive, both of which circumstances are strong predisposing causes of enteritis ; and *secondly*, we find that this attack came on with pain in the lower part of the back and abdomen, followed by several copious hæmorrhages from the bowels. It is obvious that the blood could not have proceeded from the peritoneum, and must have come from the inner coats of the intestines. The precise part of the intestine from which it came could not be ascertained, but from its colour and fluidity it evidently was from some part at no great distance from the termination. The cause of the discharge of blood was not hæmorrhoids, nor was it suppression of the menses (*vide* history), and the only other cause at all likely to have produced it was great congestion, such as accompanies the early stages of inflammation. We know, indeed, that discharges of blood per anum are by no means very rare as an accompaniment of the early stage of enteritis, just as gastritis is often ushered in by vomiting of blood. The patient had very probably ex-

aggrated the quantity of blood that she had lost, as, according to her account, it amounted to about two quarts altogether, which is a much larger quantity than a little delicate woman would be likely to lose from such a cause. Admitting, however, that there was some, it would tend to diminish the inflammation and symptomatic fever, and it may have been this circumstance that rendered the present attack milder than the former, which is the reverse of what might naturally be expected, as a severe attack of enteritis is extremely apt to produce permanent structural change in the intestines, and thus lay the foundation of future serious attacks.

As to the part of the intestinal canal that was inflamed, we may infer, from the absence at this period of both vomiting and purging, that it was chiefly the lower portion of the small intestine; and this would accord very well with the preceding remarks about the blood. Subsequently there was reason to believe that the inflammation had extended both upwards and downwards; as vomiting had come on there was more symptomatic fever; and there was a distinct feeling of a tumor in the right iliac fossa, in the situation of the commencement of the colon or termination of the ilium. From this feeling, and taking into consideration the occurrence of a former attack of the costive state of the bowels since, Dr. Williams believed that there had been some deposition of lymph during the former attack, which had produced thickening of the intestine in this situation, which was now, in consequence, more prone to inflammation, and more swelled, causing the feeling of a tumor, which went away gradually as the inflammation subsided.

In the *treatment* of enteritis, the indications are, to subdue the inflammatory action, to quiet the pain, and to procure a free passage through the intestines when these are constipated, as here, and as is usually the case when the inflammation is at all severe and deep-seated, though there may be diarrhoea when only the mucous coat is inflamed. In most cases general blood-letting is advisable, and here nature had already done that by the hæmorrhage, which, besides being in sufficient amount to produce a decided effect upon the system at large, was also from the seat of the inflammation; so that as the symptoms were mild it was thought that leeches would be sufficient, followed by calomel and castor oil, to open the bowels, and belladonna to allay the supposed spasmodic condition of the intestines, which it does without causing constipation. These measures produced temporary relief to the symptoms, but two days after there was more fever, the pain was as bad as ever, and vomiting had come on, so

that she was now bled from the arm, and calomel in combination with opium was given to affect the system, and an alkaline draught to allay the sickness. Under these means the symptoms gradually abated, and she was discharged cured on the 20th June—rather more than three weeks from the time of her admission, she having been kept in the hospital nearly a week longer than was necessary, out of charity.

Throughout the whole course of the disease the urine was remarkably scanty, often not amounting to more than a few ounces in the 24 hours, and generally was very turbid and of a high specific gravity, arising from its concentrated state. This almost suppressed state of the urine is common in gastritis.

As *causes* of the disease we have already mentioned incidentally the previous occurrence of the disease, which, in all cases, is a powerful predisposing cause, and especially so if there be any permanent thickening left, as this is a sort of nidus of a future attack; also the habitual constipation, which is an exceedingly frequent cause of enteritis, particularly when the disease has occurred before: it is sometimes a sufficient cause of itself—thus enteritis often supervenes upon colic: as a third cause must be mentioned the poor and insufficient food—so fertile a cause of various intestinal diseases; for when enough cannot be obtained from poverty, as here, that which is obtained is generally very bad in quality, thus giving rise to many acrid secretions, which, with the preceding causes, are quite enough to induce the disease.

MEDICAL REPORT

OF THE

WESTERN LYING-IN HOSPITAL, DUBLIN.

THE following report of the hospital embraces a period of two years, that is, from January 1, 1841, to December 31, 1842, inclusive; and, according to the general register of admissions and applications, relief has been afforded to 1506 women, but, owing to the irregularity with which many cases were entered in the statistical register, it has been found necessary to exclude a considerable number, in order that no facts might be adduced of the accuracy of which we are not certain. Our records will consequently be limited to the delivery of 1206 women; from these must be deducted 43 cases of abortion, leaving 1163 cases of labour at the full time.

The number of children amounted to 1175 (691 males, and 484 females), of which 63 (44 males, and 19 females) were still-born, or died at birth; of these

12	were premature.
15	„ still-born.
2	„ putrid.
4	„ footling cases.
8	„ breech presentations.
1	„ head and hand presentation.
3	„ arm presentations.
3	„ funis presentations.
6	„ crotchet cases.
2	„ forceps cases.
1	„ placenta prævia.
4	„ syphilitic.

The ages of 1067 patients were ascertained as accurately as possible :

77	were at or under	20 years of age.
296	„ between	20 and 25 do.
370	„ „	25 „ 30 do.
177	„ „	30 „ 35 do.
117	„ „	35 „ 40 do.
40	„ „	40 „ 45 do.

In 982 cases the entire duration of labour was as follows :

In 357	it was under	6 hours.
312	„ between 6 and 12	do.
214	„ „ 12 „ 24	do.
50	„ „ 24 „ 36	do.
17	„ „ 36 „ 48	do.
11	„ „ 48 „ 60	do.
15	„ „ 60 „ 95	do.
2	„ „ . .	100 do.
3	„ „ . .	121 do.
1	„ „ . .	153 do.

The extreme prolongation of some of those cases was owing to the friends of the patient deferring their application for assistance.

The period which elapsed between the commencement of labour and the rupture of the membranes, was noted in 981 cases :

In 167	it was about	2 hours.
335	„ between 2 and 6	do.
165	„ „ 6 „ 10	do.
113	„ „ 10 „ 14	do.
71	„ „ 14 „ 18	do.
33	„ „ 18 „ 22	do.
46	„ „ 22 „ 26	do.
23	„ „ 26 „ 30	do.
8	„ „ 30 „ 38	do.
9	„ „ 38 „ 40	do.
4	„ „ . .	50 do.
2	„ „ . .	60 do.
1	„ „ . .	70 do.
3	„ „ . .	80 do.
1	„ „ . .	105 do.

In 812 cases the interval between the rupture of the membranes and the birth of the child was as follows :

In 396	it was about	1 hour.
142	„	2 hours.
120	„	4 do.
50	„	6 do.
34	„	8 do.

17	it was about	10 hours.
26	„	25 do.
11	„	20 do.
9	„	28 do.
4	„	35 do.
1	„	40 do.
1	„	50 do.
1	„	120 do.

In 953 cases, from the birth of the child to the expulsion of the placenta, there elapsed

5 minutes in 98 cases.

10	„	190 do.
15	„	175 do.
20	„	166 do.
25	„	48 do.
30	„	126 do.
35	„	16 do.
40	„	30 do.
50	„	43 do.
60	„	14 do.

From 1 to 2 hours in 33 do.

„ 2 „ 3 „ 9 do.

„ 3 „ 4 „ 5 do.

The latter cases, when the placenta was retained so long, were under the care of midwives, who applied for assistance on this account.

In 1008 cases the presentation was as follows :—

In 941 the head presented ; in 13 the hand descended with the head ; in 22 the breech presented, 8 dead ; in 18 the feet presented, 4 dead, the funis prolapsed in 3 ; in 6 the funis presented, 4 dead ; in 5 the arm presented, 3 dead, 2 of them putrid ; in 2 the placenta presented, 1 dead.

There were thirteen cases of twins. In four cases the children presented naturally—six children were saved, and two, which were premature, died. In six cases one child presented the breech and the other the head—ten were born alive, two were lost. In one case one child presented footling and the other the head—both were saved. In another, one child presented the head and the funis, and the other the foot and funis—both were lost. In a third case both the children presented the feet and funis, and were lost.

In ten cases there was hæmorrhage between the birth of the child and the expulsion of the placenta ; in six of which manual extraction was necessary, but no unfavourable results followed.

In six cases flooding occurred before delivery—three were cases of accidental, and three of unavoidable hæmorrhage. The rupture of the membranes was sufficient in the accidental and in one of the unavoidable cases, and the mothers and the children recovered. It was necessary to turn and deliver the child in the other two cases—one of the mothers died and one recovered ; one of the children was saved.

Seven patients were attacked by convulsions—all recovered: One fatal case of uterine phlebitis occurred, and several slight attacks of hysteritis, which were relieved by the usual treatment.

We met with one fatal case of rupture of the uterus.

Version was performed six times (1 in 243); five times on account of presentation of the arm—all the mothers recovered, and three children were saved, the others were putrid; and once because of unavoidable hæmorrhage.

The forceps were used in eight cases (1 in 182). Seven of the mothers recovered, and the death of the remaining one was caused by disease of the heart.

In eight cases the perforator was employed (1 in 182). Six of the mothers recovered, and two died—one from rupture of the uterus, as recorded above, and one from disease of the liver.

Of the 1463 women attended during these two years, only five died, or 1 in 292. One sank from disease of the liver, another from disease of the heart, a third after unavoidable hæmorrhage, a fourth from uterine phlebitis, and the fifth from ruptured uterus.—DR. FLEETWOOD CHURCHILL, in *Dublin Journal of Medical Science*.

HYDROSULPHURET OF AMMONIA.

I HAVE within the last few days been accidentally led to try the process for hydrosulphuret of ammonia, recommended in the April number of your journal. The object apparently is to get a protosulphuret of calcium, and then to decompose it by means of sulphate of ammonia, for the ingredients are all taken nearly in atomic proportions. The reaction might, if this were the case, be thus expressed:— Ca S and $\text{N H}_4 \text{ O, S O}_3$, and $\text{N H}_4 \text{ S}$. But nothing of this sort occurs, because in boiling the lime with the sulphur, no protosulphuret of calcium is or can be formed, but (leaving out of the question a little hyposulphite of lime which is produced), the solution contains only a pentasulphuret of calcium, and consequently four-fifths of the lime are removed on filtration. The sulphate of ammonia being now added, in quantity equivalent to *the whole* of the lime, one-fifth only is decomposed, and the following reaction occurs:— Ca S_5 and $\text{N H}_4 \text{ O, S O}_3$, = Ca O, S O_3 , and $\text{N H}_4 \text{ S} + \text{S}_4$, the product thus containing not only a great quantity of sulphate of ammonia in solution, but also a large excess of sulphur, much of which precipitates on dilution with distilled water, or even on standing twenty-four hours. These results I have obtained by experiment as

well as theory, and yet the solution is described as "sufficiently pure for most experimental uses."

If this be submitted to distillation, as recommended where perfect purity is required, the sulphate of ammonia and excess of sulphur are got rid of, and the product $\text{N H}_4 \text{ S}$ in solution is obtained sufficiently pure; but this is not the same thing as that obtained by passing sulphuretted hydrogen through solution of ammonia, which is now generally allowed by chemists to have the formula $\text{N H}_4 \text{ S} + \text{H S}$. In fact, the distilled liquid is precisely similar to that produced by the well-known old process of distilling together lime, sulphur, and muriate of ammonia, and known, when concentrated, as "Boyle's Fuming Liquid," which was constantly used as a test until recently superseded by the other preparation. The processes, too, differ only in this, that the *new* one substitutes sulphate for muriate of ammonia, and employs three operations where one only is necessary.—MR. W. B. RANDALL, in *Pharmaceutical Journal*.

OPHTHALMIC SURGERY AT VIENNA.

AMONG the many pupils of Beer, five in particular distinguished themselves, Jäger, Rosas, Benedict, Bringolf, and Dr. Fischer, the venerable professor of ophthalmology at Prague. Beer was succeeded in the chair of ophthalmic surgery by the present professor, Dr. Anton Edlen von Rosas, a Hungarian physician, who holds his clinique from ten to twelve o'clock daily. This clinique is situated in the second story of the left-hand corner of the third square, near the pathological museum. It consists of a male and female wards, with twenty beds, most admirably fitted up for the comfort of persons labouring under diseases of the eyes; the beds, constructed on the principle of those for fractures, and made to raise in the upper half, are furnished with curtains, the walls and fixtures painted green, and the windows so arranged as to modify the light. To prevent the chance of contagion from the indiscriminate use of the sponges and napkins, or the vessels, each ward is supplied with a small cistern placed against the wall, about five feet from the ground, with a syphon-shaped tube attached; on turning the cock of this, a *jet* of luke-warm water plays to the height of about eight inches. To this each patient who requires ablution applies his eyes, and thus, without the fear of infection, syringes the organ in the most gentle and agreeable manner. It is an apparatus that the eye wards of every hospital should be supplied with. The annual average number of patients treated in this department is

about one hundred and fifty, all interesting cases chosen by the professor's assistant from the general wards of the hospital; and attached to it is an *Ambulatorium*, which affords relief to above one thousand persons in each year. United with these wards is a spacious and well-arranged *Auditorium*, or lecture and operating-room, at one extremity of which there is a raised platform railed off, for operating and examining patients; it is, however, at present rather too small for the accommodation of the vast number of students who crowd this clinique.

In this theatre stands a bust of the Emperor Francis I., "*Patris Patriæ*," under whose auspices and those of Andreas von Stiff — the former Protomedicus — it was erected in 1816; and around the walls are portraits of Barth, Prochaska, Rust, T. Sömmerring, Richter, Adam Schmidt, Fischer, Quadri of Bologna, Philip von Walther of Munich, Gräfe, Jüngken, Von Ammon, and our distinguished countryman Dr. Mackenzie. Attached to this clinique is a very valuable and extensive library, chiefly composed of works upon the eye, in different languages, from which books are lent out to the student or visitor weekly, on the payment of a very trifling subscription. There is a small collection of pathological specimens of the human eye in spirits, many of which are from the hands of Beer. One of the greatest objects of attraction to the foreign visitor in this school, is the magnificent collection of wax-preparations of the morbid eye, and the armentarium chirurgicum of eye-instruments from the earliest period to the present date, both beautifully arranged and in admirable keeping, — *Wilde's Austria*.

ACCOUNT OF A CHILD

WHICH WAS BORN IN THE 25TH WEEK OF PREGNANCY, AND LIVED THREE DAYS.

BY DR. HOLST.

A WOMAN, aged 30, was frightened on the 2d of August by a violent clap of thunder, and on the 5th was delivered of a living girl. The child weighed 1½ lb., and was only thirteen inches long. The skin was thin and reddish, and no pulse was perceptible in the radial arteries. The head was disproportionately large, the extremities long, and the joints very flexible. The nails were tolerably developed on the fingers and great toes; on the remaining toes there were no nails, but only roots. The apex of the head was covered with tolerably thick and dark hair, and the rest of the body with a quantity of down, which was particularly thick and long upon the face. The lobules of the ear were perfectly developed; the iris was very

narrow, while the pupils were broad, and covered by a membrane. The nymphæ, which were large, projected from the labia majora; and the clitoris was also large. The child was wrapped in cotton wool, and put in its mother's bed. It could not suck, but was slowly fed with cow's milk, water, and thin gruel. Morning and evening it was bathed in milk and water. It had natural evacuations, and slept almost continually. When it awoke it uttered a weak squeaking sound, and lay constantly quiet, almost without motion. Its strength soon diminished, and it died in 66½ hours.

The mother, who had borne eight children before, and had always menstruated regularly, positively affirmed that the catamenia had appeared for the last time in the middle of February, and that she had felt the motion of the child for the first time on the 23d of June. So that if we suppose her pregnancy to have begun on the earliest possible day, namely, the 15th of February, it lasted only twenty-four weeks and three days; and the appearance of the child, as described above, agrees with this supposition. — *Schmidt's Jahrbücher*; from the *Norsk Magazin*.

ACCOUNT OF THE OBSTETRICAL CLINIQUE

At the University of Grätz during 1837-8.

BY PROFESSOR GÖTZ.

1171 women were delivered of 1196 children; of whom 648 were boys, and 548 girls. There were 1147 single deliveries, 23 cases of twins, and one of triplets. Twenty-four boys and twenty-three girls were born dead, and twenty-four children died during the first week: the latter were all born with symptoms of great weakness, or of apparent death. As to the position of the children, the first presentation of the occiput was observed 1054 times, the second 68, the third seven times, and the fourth twice. The forehead presented twice, the face ten times, the breech twenty-three times, and the feet ten times. Four times there was a transverse presentation, and four times the presentation was not registered. Twelve women were delivered in the street, while going to the hospital. Turning was performed four times; the forceps was applied thirteen times; the prolapsed funis was replaced three times; and three times the placenta was extracted on account of violent hæmorrhage, or adhesion and strangulation of the placenta itself.

In the thirteen cases where the forceps was applied, seven children were born alive, one was dead before the operation, four died during the operation, and one immediately afterwards.

In a rachitic woman, who died of puerperal fever, after having been delivered by the forceps five days previously, without any unfavourable symptom, the antero-posterior diameter of the pelvis was found to be only two inches and ten lines in length, the transverse one five inches and a half, and the oblique one four inches and five lines.—*Gazette Médicale*; and *Med. Jahrb. des Oesterr. Staates*.

OPHTHALMIC SURGERY.

To the Editor of the Medical Gazette.
SIR,

I HAVE read Mr. France's remarks on the results of the operations performed by me at the Royal Westminster Ophthalmic Hospital, and published by the Committee in their Annual Report. The operations for artificial pupil were successful, and no accident or evil whatever occurred in the 1474 operations for strabismus. When the operation is done after the manner I have directed, I do not believe they will ever occur. Of the 85 operations for cataract, 56 were performed by division through the sclerotica, or by puncture through the cornea. I do not believe there is anything peculiar in my practice, or that it is more successful than that of other surgeons who have sufficient opportunities of making themselves acquainted with ophthalmic diseases, and I am always happy to receive and give any explanation in my power to such members of the profession as might be disposed to favour me with their company on any Monday, Wednesday, and Friday, at one o'clock.

I am, sir,
Your obedient servant,
CHARLES GUTHRIE.

MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

By ROBERT LEE, M.D. F.R.S.

LECTURE XXXVI.

On Labours complicated with Convulsions.

THERE is a striking resemblance between the symptoms observed in a case of common epilepsy and in one of puerperal convulsions, or eclampsia as it is called by nosologists. In both these diseases insensibility takes place during the fits, and all the voluntary muscles of the face, trunk, and extremities, become convulsed. When a fit of puerperal convulsions comes on, the woman becomes perfectly unconscious of every thing around her, and the muscles of the eyes and face are usually first affected. Irregular spasmodic twitchings are observed about the mouth and eyelids, which produce great distortion of the countenance: the eyes are often turned upward and inward to the root of the nose, and roll rapidly about in different directions. The lower jaw is either firmly clenched against the upper, or it is drawn to one side; and the tongue, being protruded between the teeth, is often severely lacerated. Every muscle of the body soon becomes convulsed; the spasm is violent and universal; the respiration, which is at first hurried, afterwards becomes slow and stertorous, as the convulsions subside; and a quantity of frothy saliva, tinged with blood, is blown from the mouth with a peculiar noise, as in an ordinary epileptic fit. Sometimes the muscles on one side of the face and body only are at first affected; and after the

spasm has ceased in them, those on the opposite side become convulsed. The pupils of the eyes are usually dilated and insensible during a fit of puerperal convulsions; but in some women, both between and during the paroxysms, they are closely contracted. The pulse varies extremely, being either very hurried, or slower than natural. After the convulsion has endured for a longer or a shorter period, as in cases of epilepsy, it gradually ceases; and the patient, apparently greatly exhausted, is left in a state of deep stupor, with stertorous breathing. The consciousness generally does not return before another fit takes place; and this happens, in the greater number of instances, in a short period, when the same phenomena are observed. A great number of violent fits are often experienced by some women during many hours, at longer or shorter intervals, without any return of sensibility. The attacks may terminate in a state resembling apoplexy, as epilepsy sometimes does, which may soon prove fatal; or the fits may subside, and the recollection be gradually restored. If there have been no labour pains before the fits have come on, the os uteri most frequently begins to dilate; but the uterine contractions are usually feeble and irregular, and they seem to pass into convulsions, or to alternate with the fits. Sometimes the child is expelled by the pains; but more frequently they are inefficient, and the delivery cannot be completed without artificial assistance.

In some women the fits are preceded by certain symptoms indicating a plethoric state of the vessels of the brain, and great nervous irritability. There is usually headache, more or less intense; throbbing of the temporal arteries; sense of weight and constriction across the forehead; giddiness; drowsiness; the sight and hearing disturbed; flushing and tumefaction of the countenance; slight delirium, or confusion of thought, or loss of memory; and other signs of cerebral disturbance. Pain in the epigastric region,

and increased sensibility of the uterus, sometimes precede the fits: but there are cases of violent puerperal convulsions where no precursory or premonitory symptoms of any kind are perceived; there is nothing like the aura epileptica observed before attacks of puerperal convulsions. They may occur in the latter months of pregnancy, before the uterus has begun to contract, during the different stages of labour, and several days or weeks after delivery. I have never met with a case of true puerperal convulsions before the sixth month of pregnancy; the spasmodic affections which have occurred at an earlier period having been connected with hysteria, and unaccompanied with loss of consciousness.

It has been observed by all practitioners, that, in a very great proportion of cases, it is in the first pregnancy or labour that puerperal convulsions occur. "Women are far more liable," says Dr. Denman, "to convulsions in first than in subsequent labours; and then, it is said, more frequently when the child is dead than when it is living. But when women have convulsions the death of the child ought generally to be esteemed rather an effect than a cause, as they have often been delivered of living children when they were in convulsions, or of dead, and even putrid children, without any tendency to convulsions. Some women have also had convulsions in several successive labours; but having had them in one, they generally, by the precautions taken, or some natural change, escape them in future. Lastly, I was for many years persuaded that convulsions only happened when the head presented; but experience has proved that they sometimes occur in preternatural presentations of the child." Of 19 cases recorded by Dr. Joseph Clarke, 16 were first children. Of 48 related by Dr. Merri-man, there were 36 instances in which it was the patient's first labour. Of 30 cases which occurred to Dr. Collins, 29 were in women with their first children; and the other single case was a second pregnancy, but in a woman who had suffered a similar attack with her first pregnancy. 14 of the 32 children (two of the women having had twins) were born alive. In 18 of the 30 the convulsions subsided after delivery; in 10 the fits occurred both before and after; and in 2 the attack did not come on till after delivery. In 15 of the 30 the patients were delivered by the natural efforts; in 6 delivery was effected by the forceps; in 8 by the perforator and crotchet; and in one the feet presented. Two of the children were born putrid. Five of the women died. In 6 of the 48 cases related by Dr. Merriman the convulsions did not occur till after delivery. Five of these patients recovered; the other, after the epileptic attack, became maniacal,

but appeared to be gradually recovering, when, at the end of three weeks from the first seizure, she was attacked with another fit, and died. All the children were alive. In three cases the women were pregnant of twins. In two of these cases the attack of convulsions occurred in the interval between the births of the two children. All the women were delivered without artificial assistance; two of them recovered; and three of the children were born alive. In eleven cases the delivery was effected by the forceps. All these women recovered, and three of the children were born alive. In nine cases the perforator was employed. Seven of the women recovered. In four cases the operation of turning was resorted to; two of the women recovered; all the children were dead born. In one case the woman died undelivered. In 14 cases the children were born without extraordinary assistance. 10 of these women recovered, and 5 of the children were born alive. Thus 37 women recovered, and 11 died. 17 children were born alive (including the 6 born before the mothers were attacked with convulsions); 34 were born dead. Dr. Ramsbotham has related the histories of 26 cases; of which, 10 proved fatal. 13 occurred before delivery, 10 during labour, and 4 after. Dr. Ingleby relates 35 cases; of which, 11 were fatal. Mauriceau 42; 7 during pregnancy, 3 of which were fatal; 19 during labour, 11 of which ended fatally; and 16 after delivery, of which 5 were fatal.

Puerperal convulsions occur in all countries, and in all the different ranks of life. Those women are most predisposed to the disease who have had hysteria or epilepsy in early life, who have suffered from injuries of the head, or who have had violent attacks of fever with severe affections of the brain. Depressing passions of the mind appear to produce a predisposition to the disease. Unmarried women, who are excluded from society, and often addicted to the improper use of stimulants, are peculiarly liable to puerperal convulsions and mania. Terror, and other violent mental impressions, and sometimes the pains of labour alone, are sufficient to excite convulsions. The disease occurs not only in strong plethoric young women with their first children—in such as are of a coarse make, with short thick necks—but in weak, irritable, nervous females. There are some cases where irregularities of diet, especially the use of very indigestible food and stimulants, appear, without any other cause that can be discovered, to give rise to the disease. There are many cases in which the peculiar condition of the nervous system of the uterus appears to be the sole cause, and in all cases it is the principal predisposing cause, for the fits of convulsion occur in most women in the first

pregnancy and labour, and at no other time but during pregnancy and labour; and they often suddenly cease when the labour is completed, after every remedy has been employed without avail, except artificial delivery. The condition of the brain, on which the loss of consciousness and convulsions depend, is obviously produced by sympathy with the nervous system of the uterus; and the fits return, and increase in violence, till the uterus is emptied of its contents, as on them the irritation of the nerves of the uterus alone depends.

In some cases there has been observed an unusual degree of redness and softening of the cerebral substance in those who have died from puerperal convulsions; great congestion of the sinuses and smaller veins and arteries of the brain; effusion of blood or serum into the ventricles, and lymph covering the surface of the hemispheres. In others there has been no morbid appearance whatever found in the brain to account for the symptoms. At Edinburgh, in 1816, I examined, with Dr. J. Thomson and Dr. Gordon, the brain of a young woman who had died of puerperal convulsions; but, except a little turgescence of the blood-vessels, not more than is seen in many who have died of disease altogether unconnected with the brain, there was nothing to account for the symptoms. In other cases, however, organic disease of the brain has been discovered after death, as you will see by looking at the following table.

Dr. Ramsbotham made a post-mortem examination of the brain in four of the fatal cases which he observed. The first case was referrible to injury of the head. There was both convulsion and paralysis, and the woman died undelivered. "Blood was found extravasated between the dura and pia mater, and upon the orbital processes under the right lobe." In the second fatal case he states that there was no positive derangement detected in the brain, except turgescence of the vessels of the pia mater. The head of another patient was examined by an experienced anatomist, who reported that after a very minute examination of every portion of the brain no positive derangement could be detected, and that the only appearance in any way different from that usually met with was in the vessels of the pia mater, which were thought to be somewhat more loaded with blood than in the general cases of cerebral inspection. In case 4, after a most careful examination of the head, no positive breach of vessel could be detected. The blood-vessels of the pia mater were beautifully injected with blood, and a section of the substance of the brain showed more bloody points than usual. There was also a quantity of tinged serum in the ventricles. The vessels of the cerebellum were

likewise anormally distended with blood. From the dissections, and other circumstances, Dr. R. concludes that "the whole train of symptoms evinces considerable derangement in the functions of the brain and nervous system; yet, after death, correspondent marks of organic mischief within the head are seldom met with (vol. ii. p. 248). The different anatomical inquiries at which I have been present have not disclosed such regular appearances as to sanction the uniform deduction that the brain was the principal seat of the disease. I suspect that in many instances that important organ is no otherwise implicated than through the medium of sympathetic irritation." "Of the appearances after death," observes Dr. Merriman, "in those who have died of puerperal epilepsy, contrary statements have been given. Dr. Denman says, that in the examination of many women who have died from convulsions, he has never seen an instance of effusion of blood in the brain, though the vessels were extremely turgid; but has always remarked, that the heart was unusually flaccid, without a single drop in the auricles or ventricles: but he adds, that Mr. Hewson had informed him of a case of convulsions, where an effusion of blood in a small quantity had been found on the surface of the brain; and in his fifth edition, he mentions a case by Dr. Hooper, where a coagulum of blood, weighing nearly $\frac{3}{4}$ iv. was found between the dura and pia-mater. In one instance I have distinctly seen an effusion of blood in the posterior part of the cranium; but the quantity was not large, and Dr. Ley has lately met with a similar case." M. Cruveilhier examined a case in which not the slightest trace of congestion of the vessels of the brain could be detected. M. Bontilleux relates another, in which he could detect no manifest alteration within the skull. Dr. Collins says, "I conceive we are quite ignorant as yet of what the cause may be: nor could I ever find on dissection any appearances to enable me to even hazard an opinion on the subject."

Treatment of Puerperal Convulsions.

The best systematic writers on midwifery during the last two centuries have recommended copious blood-letting in puerperal convulsions, and artificial delivery where depletion failed to remove the fits. They have all considered the brain to be the seat of the disease.

Mauriceau thought prompt delivery to be the best remedy, and where the orifice of the uterus did not admit of this, he advised blood to be drawn from the arm and foot, and stimulating enemata to be employed, to diminish the quantity of blood in the brain. He states that he had seen emetics ad-

ministered without success, or with injurious effects. Where consciousness did not return between the fits, but the woman remained insensible, foaming at the mouth, with stertorous breathing, then both the mother and child he believed would die, if they were not promptly relieved by delivery. I have saved, he says, the lives of many women in this way, but others have not failed to die after having been delivered in the due time, and in the proper manner—"bien et dument accouchées."

He admits that some cases will prove fatal whatever is done. If the child is alive he recommends the operation of turning; if dead, craniotomy.

"There are some women," he says, "who are always attacked with convulsions either before or after delivery. To prevent such an accident he recommends bleeding from the arm twice or three times during pregnancy, and once after labour has commenced.

Puzos has also given an account of puerperal convulsions, and has recommended prompt and copious blood-letting, to relieve the brain from the excessive quantity of blood by which it is oppressed. After the bleeding, lavements, he says, must be employed, and it should be ascertained by an examination whether the uterus is dilating, and if the bleedings and other remedies do not calm the convulsions, then delivery is the best thing that can be done, which removes the pressure from the great blood-vessels of the abdomen, and allows it to circulate freely. The relief from delivery, he says, is not instantaneous, for the convulsions will often continue for a time, but at longer intervals, and patients sometimes remain for two days in a state of lethargy, and afterwards recover. But when the convulsions continue in spite of the blood-lettings and delivery, and the coma and stertorous breathing and foaming at the mouth, then the disorder will terminate fatally; but we have the consolation to know, that we merit no reproach, having employed all the means we possess to overcome so grievous an accident. It is to be presumed because we have not succeeded, that lesions (crevasses) have been made in the brain by the violence of the convulsions, and that delivery could not remedy these. Thus, he adds, in the acute convulsions which precede or accompany labour, we cannot be too prompt and vigorous in the application of the proper resources; and as these means are sometimes insufficient when the disease is once established, the accoucheur should be attentive to the first symptoms which announce convulsions; for it sometimes happens, that in a labour accompanied with the most favourable symptoms, a woman all at once complains of

dazzling of the eyes, of weight in the forehead or posterior part of the head, and of sudden loss of vision, symptoms which all announce that an attack of convulsion is at hand. I have seen women suddenly seized with frightful convulsions, he says, during labour, because attention had not been paid them when they complained of pain of the head. We perceive, then, that it is much more easy to prevent the evil, than to destroy it when it is once established; since the most powerful remedies do not prevent the death of the mother and the child, which these convulsions put in the greatest danger. Therefore I bleed copiously, and that on the first appearance of the symptoms which threaten convulsions; and I have often by this means relieved very speedily the headache, restored the vision, and completed the delivery happily in a short time.

Copious blood-letting in puerperal convulsions is the first remedy now employed by all practitioners in this country; but the extent to which depletion is to be carried must be regulated by the constitution of the patient, the violence of the symptoms, and the effects produced by the loss of blood. Profuse blood-letting will not invariably control the disease, as some have asserted; nay, I am persuaded that the sudden abstraction of fifty or more ounces of blood from the arm of some individuals, instead of arresting the disease, would destroy life. So feeble is the circulation of the blood in some women that it is impossible to remove this quantity from the arm. In young, robust, plethoric women, the best plan certainly is to take away as soon as possible after the attack twenty or twenty-five ounces of blood from the arm, to cut off the hair or shave the scalp, and apply over the head cold lotion or ice in a bladder; to put ten grains or a scruple of calomel upon the tongue, or two drops of croton oil, if the bowels require immediate relief; to throw up into the rectum a stimulating enema, and to apply warmth, mustard poultices, and rubefacients, to the inside of the legs and thighs; at the same time to adopt every precaution to prevent the patient from being bruised or injured by the violence of the convulsive movements into which the body is thrown. If the fits continue after these remedies have been employed, with undiminished violence, and if the pulse is full and strong, and signs of congestion of the brain are still present, you may open another vein in the arm, and remove fifteen or twenty ounces more. A third bleeding to this extent is undoubtedly necessary and proper in some cases, but I prefer greatly, after thirty or thirty-five ounces of blood have been drawn from the arm, to trust to local bleeding, and especially to the application of cupping-glasses to the temples and nape of the neck. When the constitution

has been previously exhausted by some chronic disease, or hæmorrhage; or without these, if it is peculiarly delicate, nervous, and irritable, and has been weakened by grief, and other depressing passions, and the pulse is very rapid and feeble, it is better to trust entirely to the local abstraction of blood, and to the remedies now described, and to abstain altogether from general bleeding. If you look at the following table, you will see that some women died who were bled profusely, and that others recovered where a small quantity was drawn from the arm, or where it was entirely drawn by cupping from the temples and nape of the neck. These observations are made with the view of preventing you from having recourse to extensive depletion in all cases of puerperal convulsions, without carefully considering the condition and previous history of the patient. Profuse and indiscriminate blood-letting cannot be practised with impunity in this disease.

This is the treatment which ought to be employed in cases of puerperal convulsions before labour comes on, and also after labour has commenced, and if the fits do not diminish in frequency and violence, and the parts are in a condition to admit of artificial delivery, it is very important that it should not be long delayed. In one case which occurred in the latter months these means were vigorously employed without effect, and when the patient appeared sinking, the operation of turning was performed, though the os uteri had not begun to dilate, and the fits ceased immediately after the delivery had been effected, and recovery took place. Should the head of the child not have descended sufficiently low for the forceps to be applied when delivery becomes absolutely necessary, recourse should be had to the perforator. Even when the os uteri is fully dilated, and the head of the child has passed so far into the pelvis that an ear can be felt, it is difficult to apply the forceps and extract the head without danger to the mother, and where the insensibility is complete, and the intervals between the fits short, and the patient cannot be retained in the proper position, the employment of the forceps is always attended with considerable hazard to the perineum and soft parts.

Opium has been almost universally condemned in puerperal convulsions, and I consider it always improper before blood-letting has been employed to a sufficient extent, and the delivery has been completed either spontaneously or artificially. In some of the most severe cases which I have seen after copious venesection and delivery, large doses of the liquor opti sedativus have appeared to produce very powerful effects in arresting the fits; in others no benefit whatever resulted from the employment of sedatives.

1816	—, æt. 21, first pregnancy, ninth month unmarried numerous violent fits of convulsion at short intervals during twelve hours, without a return of consciousness orifice of uterus soft and dilatable, but no sign of labour; pulse rapid and feeble the fits continuing with coma; the child was easily turned and delivered; death in six hours; V. S. ad. ʒi.; head shaved; cold lotions; calomel; enemata artificial delivery.			
*2, 1823	—, æt. 26, first pregnancy, ninth month; fifty hours in labour: head of child low in the pelvis; vagina and perineum rigid; pulse full and strong face flushed; occasional incoherence, and slight convulsive tremors of the face and extremities; venesection to ʒviii. followed by two severe fits of convulsion and insensibility; unsuccessful attempts to deliver with the long forceps; craniotomy; no fit after delivery; consciousness soon returned; uterine inflammation followed.			
1825	—, first pregnancy, ninth month numerous violent fits of convulsion; comatose during the short intervals; pupils widely dilated; no treatment allowed to be employed, and she died soon after undelivered. (At Biala Cerkow Ukraine.)			

ministered without success, or with injurious effects. Where consciousness did not return between the fits, but the woman remained insensible, foaming at the mouth, with stertorous breathing, then both the mother and child he believed would die, if they were not promptly relieved by delivery. I have saved, he says, the lives of many women in this way, but others have not failed to die after having been delivered in the due time, and in the proper manner—"bien et duement accouchées."

He admits that some cases will prove fatal whatever is done. If the child is alive he recommends the operation of turning; if dead, craniotomy.

"There are some women," he says, "who are always attacked with convulsions either before or after delivery. To prevent such an accident he recommends bleeding from the arm twice or three times during pregnancy, and once after labour has commenced.

Puzos has also given an account of puerperal convulsions, and has recommended prompt and copious blood-letting, to relieve the brain from the excessive quantity of blood by which it is oppressed. After the bleeding, lavements, he says, must be employed, and it should be ascertained by an examination whether the uterus is dilating, and if the bleedings and other remedies do not calm the convulsions, then delivery is the best thing that can be done, which removes the pressure from the great blood-vessels of the abdomen, and allows it to circulate freely. The relief from delivery, he says, is not instantaneous, for the convulsions will often continue for a time, but at longer intervals, and patients sometimes remain for two days in a state of lethargy, and afterwards recover. But when the convulsions continue in spite of the blood-lettings and delivery, and the coma and stertorous breathing and foaming at the mouth, then the disorder will terminate fatally; but we have the consolation to know, that we merit no reproach, having employed all the means we possess to overcome so grievous an accident. It is to be presumed because we have not succeeded, that lesions (crevasses) have been made in the brain by the violence of the convulsions, and that delivery could not remedy these. Thus, he adds, in the acute convulsions which precede or accompany labour, we cannot be too prompt and vigorous in the application of the proper resources; and as these means are sometimes insufficient when the disease is once established, the accoucheur should be attentive to the first symptoms which announce convulsions; for it sometimes happens, that in a labour accompanied with the most favourable symptoms, a woman all at once complains of

dazzling of the eyes, of weight in the forehead or posterior part of the head, and of sudden loss of vision, symptoms which all announce that an attack of convulsion is at hand. I have seen women suddenly seized with frightful convulsions, he says, during labour, because attention had not been paid them when they complained of pain of the head. We perceive, then, that it is much more easy to prevent the evil, than to destroy it when it is once established; since the most powerful remedies do not prevent the death of the mother and the child, which these convulsions put in the greatest danger. Therefore I bleed copiously, and that on the first appearance of the symptoms which threaten convulsions; and I have often by this means relieved very speedily the headache, restored the vision, and completed the delivery happily in a short time.

Copious blood-letting in puerperal convulsions is the first remedy now employed by all practitioners in this country; but the extent to which depletion is to be carried must be regulated by the constitution of the patient, the violence of the symptoms, and the effects produced by the loss of blood. Profuse blood-letting will not invariably control the disease, as some have asserted; nay, I am persuaded that the sudden abstraction of fifty or more ounces of blood from the arm of some individuals, instead of arresting the disease, would destroy life. So feeble is the circulation of the blood in some women that it is impossible to remove this quantity from the arm. In young, robust, plethoric women, the best plan certainly is to take away as soon as possible after the attack twenty or twenty-five ounces of blood from the arm, to cut off the hair or shave the scalp, and apply over the head cold lotion or ice in a bladder; to put ten grains or a scruple of calomel upon the tongue, or two drops of croton oil, if the bowels require immediate relief; to throw up into the rectum a stimulating enema, and to apply warmth, mustard poultices, and rubefacients, to the inside of the legs and thighs; at the same time to adopt every precaution to prevent the patient from being bruised or injured by the violence of the convulsive movements into which the body is thrown. If the fits continue after these remedies have been employed, with undiminished violence, and if the pulse is full and strong, and signs of congestion of the brain are still present, you may open another vein in the arm, and remove fifteen or twenty ounces more. A third bleeding to this extent is undoubtedly necessary and proper in some cases, but I prefer greatly, after thirty or thirty-five ounces of blood have been drawn from the arm, to trust to local bleeding, and especially to the application of cupping-glasses to the temples and nape of the neck. When the constitution

has been previously exhausted by some chronic disease, or hæmorrhage; or without these, if it is peculiarly delicate, nervous, and irritable, and has been weakened by grief, and other depressing passions, and the pulse is very rapid and feeble, it is better to trust entirely to the local abstraction of blood, and to the remedies now described, and to abstain altogether from general bleeding. If you look at the following table, you will see that some women died who were bled profusely, and that others recovered where a small quantity was drawn from the arm, or where it was entirely drawn by cupping from the temples and nape of the neck. These observations are made with the view of preventing you from having recourse to extensive depletion in all cases of puerperal convulsions, without carefully considering the condition and previous history of the patient. Profuse and indiscriminate blood-letting cannot be practised with impunity in this disease.

This is the treatment which ought to be employed in cases of puerperal convulsions before labour comes on, and also after labour has commenced, and if the fits do not diminish in frequency and violence, and the parts are in a condition to admit of artificial delivery, it is very important that it should not be long delayed. In one case which occurred in the latter months these means were vigorously employed without effect, and when the patient appeared sinking, the operation of turning was performed, though the os uteri had not begun to dilate, and the fits ceased immediately after the delivery had been effected, and recovery took place. Should the head of the child not have descended sufficiently low for the forceps to be applied when delivery becomes absolutely necessary, recourse should be had to the perforator. Even when the os uteri is fully dilated, and the head of the child has passed so far into the pelvis that an ear can be felt, it is difficult to apply the forceps and extract the head without danger to the mother, and where the insensibility is complete, and the intervals between the fits short, and the patient cannot be retained in the proper position, the employment of the forceps is always attended with considerable hazard to the perineum and soft parts.

Opium has been almost universally condemned in puerperal convulsions, and I consider it always improper before blood-letting has been employed to a sufficient extent, and the delivery has been completed either spontaneously or artificially. In some of the most severe cases which I have seen after copious venesection and delivery, large doses of the liquor opti sedativus have appeared to produce very powerful effects in arresting the fits; in others no benefit whatever resulted from the employment of sedatives of

A TABULAR VIEW OF FIFTY-TWO CASES OF PUERPERAL CONVULSIONS.

		Died; vessels of brain distended.	Recovered.	Died.
1	1816	—, æt. 21, first pregnancy, ninth month; unmarried, numerous violent fits of convulsion at short intervals during twelve hours, without a return of consciousness; orifice of uterus soft and dilatable, but no sign of labour; pulse rapid and feeble; the fits continuing with coma; the child was easily turned and delivered death in six hours; V. S. ad. xl.; head shaved; cold lotions; calomel enemata artificial delivery.		
2	July 12, 1823	—, æt. 26, first pregnancy, ninth month; fifty hours in labour: head of child low in the pelvis; vagina and perineum rigid; pulse full and strong face flushed; occasional incoherence, and slight convulsive tremors of the face and extremities; venesection to ℥viii. followed by two severe fits of convulsion and insensibility; unsuccessful attempts to deliver with the long forceps, craniotomy; no fit after delivery; consciousness soon returned; uterine inflammation followed.		
3	1825	—, first pregnancy, ninth month, numerous violent fits of convulsion; comatose during the short intervals; pupils widely dilated; no treatment allowed to be employed, and she died soon after undelivered. (At Biala Cerkow Ukraine.)		

4	Jan. 22, 1827	—, æt. 26, first pregnancy, 7th month; eight weeks before delivery suddenly seized with coma, from which she recovered after copious bleeding, &c.; headache, giddiness, and partial loss of speech, but consciousness and memory have remained; slight hemiplegia of the right side; pulse 90; went to the full period; labour natural; in a few hours, convulsions, coma, dilated pupil, retention of urine; died on the 29th; copious venesection and cupping; head shaved; cold lotions and blisters; cathartics.	Died; a thick layer of lymph on the surfaces of both hemispheres of brain, softening below; veins filled with firm coagula, and ventricles with serum.
5	1827	—, æt. 20, unmarried, first pregnancy, seven months and a half; had epilepsy in early life; headache, drowsiness, loss of memory; paralysis of right inferior extremity after a slight fit of convulsion and coma; labour natural; child alive; no fit after delivery; venesection, cupping, head shaved, cathartics, low diet.	Recovered.
6	Jan. 27, 1828	—, æt. 25, eighth month of second or third pregnancy; headache and general indisposition after violent excitement; soon seized with convulsions, which continued with short intervals of nine hours; complete insensibility; pulse slow, full, and strong; os uteri dilated; head of child low in the pelvis; expelled during the fits; venesection ad 3x. and 3xxiv.; head shaved and cupping to 3xii.	Recovered.
7	May 2, 1828	First pregnancy, unmarried, 9th month; severe fits in the first stage of labour; os uteri rigid and imperfectly dilated; venesection ad 3xxiv. repeated to 3xii.; fits continued; os uteri partially dilated; perforation; fits immediately ceased.	Recovered; soon after attacked with mania.
8	May 20, 1828	Delivered at 3 A.M.; convulsions came on soon after; venesection ad 3xxv.; at 1 P.M. the fits ceased and consciousness returned; weariness, headache, and oppression continued.	Recovered.
9	June 21, 1828	—, æt. 24, third or fourth pregnancy, 7½ months; epileptic in early life; after suffering for several days from an uneasy sensation of weight in the head and giddiness, was suddenly attacked with convulsions and insensibility; os uteri dilated; no symptoms of labour; no fit; stupor continues; pulse 80; copious alvine evacuations; went to full period, and was safely delivered of a living child; venesection ad 3xx.; head shaved, cold lotions, enemata, cathartics; venesection ad 3xii.	Recovered.
10	Sept. 16, 1828	—, æt. 24, first pregnancy, ninth month; constipation and headache for several days; several fits of convulsion; insensible in the intervals; pupils dilated; pulse 80, full and strong; face flushed; os uteri slightly dilated; feeble irregular uterine contractions; after venesection and free evacuation of the bowels, fits ceased; delivered next day, without assistance, of a living child; venesection ad 3xxv.; leeches; head shaved; calomel; enemata.	Recovered.

11	October 6, 1828	—, æt. 33, second pregnancy, first stage of labour; had convulsions during her former labour; headache, giddiness, and drowsiness, during the latter months; venesection recommended, but not employed; several severe fits, at short intervals, during the first stage of labour; muscles of left side most affected; face flushed; pupils dilated; pulse rapid, feeble, and irregular; os uteri widely dilated; head of child pressing through the brim of the pelvis; venesection ad 3xx. and cupping from the temple to 3xij.; child born alive next morning; fits soon ceased; but she died three months after in a fit of convulsion, after taking an emetic without advice.	Died; softening of the brain, with effusion of serum into the ventricles; tubercles in the lungs.
12	Jan. 24, 1829	—, æt. 18, first pregnancy, ninth month, delivered at 11 A.M., labour natural. The expulsion of the placenta was soon followed by a strong fit of convulsion; venesection was immediately employed. At 4 P.M. frequent severe fits without any intervals of consciousness; venesection repeated. At 8 P.M. fits and stupor continued, when forty drops of laudanum were given without my consent. January 25th—Fits continued; twenty drops of laudanum; sinapism to the legs. 26th—Severe fits during the night; has taken sixty drops of laudanum at three doses, which appeared to calm the violent agitation after the paroxysms. 27th, 10 A.M.—Severe and frequent fits during the night; breathing stertorous; pulse rapid and feeble; venesection ad 3xxv. repeated to 3xvi.; head shaved; enemata, calomel, ol. ricini, &c. Died on the 28th.	Died; turgescence of the blood-vessels of the pia mater; no other morbid appearance.
13	March 23, 1829	—, middle age, first pregnancy, and near full period. Convulsions during the first stage; headache complained of for some weeks previously; os uteri fully dilated, and half of the head in the cavity of the pelvis; pains ceased after the convulsions began, until the next morning, when they returned, and a dead child was expelled. The day after, the fits returned; and on the 27th she was attacked with uterine inflammation, and died in three days. Leeches, venesection, and cupping, were employed, together with calomel, blisters, &c.	Died; no post-mortem examination allowed.
14	April 15, 1829	—, æt. 30, ninth month. Headache, vertigo, and depression of spirits, during the seventh and eighth months; convulsions and hemiplegia of left side took place seventeen days before labour; she was bled to 16 oz. and cupped ad 3xvj. and afterwards venesection ad 3xij.; head shaved; blisters and cathartics. The labour was completed without assistance, but she died three days after, comatose.	Died; serum in the ventricles; a small scrofulous tumor adhered to the basilar artery; a portion of right lobe of cerebrum was soft, and of a yellow colour.
15	Dec. 1829	Convulsions and insensibility during labour; pulse rapid and feeble; delivery was completed by craniotomy; she was not bled; died comatose three days after delivery.	Died; a table-spoonful of serum was found at the base of the brain; great vascularity around the tuber annulare.

16	1829	—, æt. 30, ninth month of fourth or fifth pregnancy; violent convulsions at intervals during twenty-four hours, without sign of labour; convulsions continued in spite of copious venesection, calomel, &c.; turning was performed with difficulty before the os uteri had begun to dilate, and extraction completed with great difficulty, from the uterus contracting around the neck of the child; convulsions immediately ceased after delivery.	Recovered.
17	1829	—, æt. 20, hysterical, eighth month of first pregnancy; headache and giddiness for several days; twenty to thirty severe fits of convulsions during fourteen hours; insensible at intervals; labour came on twenty-four hours after the first fit, and child expelled; no fit after delivery; consciousness did not return for several days; uterine and crural phlebitis followed. Calomel, venesection, and enemata employed, and ice to scalp in a bladder.	Recovered.
18	Sept. 29, 1829	Ninth month of first pregnancy; violent convulsions during labour; $\frac{3}{4}$ iv. of blood had been drawn by her medical attendant; os uteri slightly open; no pain; fits continued five hours, when a dead child was expelled; no fits after delivery, but she continued comatose until she died.	Died.
19	1829	—, æt. 28; seized with convulsions eight days after a natural labour; ten severe fits in two hours; in the intervals she was completely insensible, with stertorous breathing, dilated pupils; the pulse 110, feeble; the fits went off in a few hours, but she remained several days in a drowsy confused state: the attack followed the use of very indigestible food: has since been twice confined, and had no convulsions; cupping $\frac{3}{4}$ xij.; calomel; cathartics; enema; head shaved; blistering.	Recovered.
20	April 8, 1830	—, æt. 25, first pregnancy, ninth month; hysteria at the age of 15; at the end of ninth month frequent fits of convulsion in the course of twelve hours; consciousness returned after venesection; severe headache, and occasional spasms of the face and extremities; labour natural; venesection $\frac{3}{4}$ xxx.; calomel, gr. x.; enemata; cathartics; cold to the shaved head.	Recovered.
21	Jan. 1, 1831	—, æt. 20, first pregnancy, ninth month; incoherence, followed by convulsions, towards the end of the first stage of a protracted labour; labour pains strong and regular, and the greater part of the head in the cavity of the pelvis; the fits were relieved, and she was delivered in a few hours of a dead child without help; venesection $\frac{3}{4}$ viiij.; venesection $\frac{3}{4}$ x.	Recovered.
22	Autumn 1831	—, æt. 30, first pregnancy; incoherence, stupor, and convulsions, at the end of the first stage of labour; symptoms relieved by venesection $\frac{3}{4}$ xxvj.; labour pains continued, and a living child was expelled without artificial assistance.	Recovered.

23	Dec. 1831	Severe fits of convulsion soon after the commencement of labour; no relief from copious venesection; os uteri partially dilated; head above brim of pelvis; pains ceased; perforation; one slight fit after delivery; consciousness gradually returned.	Recovered.
24	May 9, 1832	—, æt. 30, had epilepsy when a child; labour began at 8 A.M. 7th May; membranes ruptured in the night; os uteri dilated to the size of a crown on the morning of the 8th; pains feeble; complained of headache; pulse full and slow; venesection; enema; labour continued till the morning of the 9th, when severe convulsive fits supervened; venesection repeated; fits and unconsciousness continued for several hours, and the pains went entirely off: the head being still high up in the pelvis, and the os uteri rigid and undilated, craniotomy was performed: no fit after delivery; venesection 3xvj.; enema; cathartics; venesection 3xxv.; head shaved; cold lotions, &c.	Recovered.
25	Dec. 1832	Convulsion in the seventh month of first pregnancy, after drinking brandy; venesection ad 3xxxiij. and twelve leeches; fourteen days after delivered of a dead child without artificial assistance.	Recovered.
26	July 5, 1833	—, first pregnancy; delirium and slight convulsions came on suddenly after the labour had lasted upwards of twenty-four hours; vagina rigid, hot, and tender; os uteri not fully dilated; copious venesection produced no relief; the head being beyond the reach of the forceps, craniotomy was performed; the fits immediately ceased; consciousness was not perfectly restored for several days.	Recovered
27	October 1833	—, middle age; convulsions during first labour, without any precursory symptoms; venesection 3xxx.; a feeble child was born alive by the natural pains; convulsions ceased immediately after delivery.	Recovered.
28	Feb. 25, 1833	—, æt. 25, first pregnancy, ninth month; after eating roasted pork for dinner and supper, was seized with vomiting, convulsions, and insensibility, at 3 A.M.; after venesection and an enema, the fits became slighter, the pulse extremely rapid and feeble; the fits, however, returned occasionally till 10 A.M. when labour pains came on; at 1 A.M. a dead child was expelled; fits and insensibility continued four hours after. 26th—The fits had ceased, and consciousness had returned, though imperfectly; retention of urine; she died five days after with symptoms of uterine inflammation.	Died.
29	Dec. 30, 1833	—, æt. 20, first pregnancy, unmarried; violent convulsions sixteen hours after the commencement of labour; os uteri fully dilated; head squeezed into the brim of the pelvis; ear could not be felt; venesection 3xxx.; fits more violent and frequent after venesection; pulse rapid and feeble; labour pains ceased; perforation; head extracted with difficulty; no fits after delivery; sensibility returned the following day.	Recovered.

30	May 23, 1834	—, æt. 30, second pregnancy; convulsions appeared eight hours after labour had begun; head impacted; venesection employed; insensibility; pupils dilated; constant convulsive movements of the muscles of the face; pains very violent; rupture of the uterus threatened; craniotomy; fits ceased immediately after delivery. Puerperal convulsions at the end of eighth month; labour soon began; face presen-tation; pains very violent at short intervals; forceps tried, but craniotomy at last performed; venesection was performed before delivery; four fits took place after extraction of child; liq. opii sed. was given, after which the fits seemed much slighter, and they gradually went off.	Recovered.
31	March 3, 1835	First labour, full period; returned home from a dinner party, where she had partaken of a variety of diabes and wines, soon after which labour came on, accompanied with incoherence; violent convulsions then followed; venesection and enemata were employed; forceps was used, and the child was extracted alive; convulsions continued.	Recovered.
32	April 1835	Middle-aged woman, addicted to the use of stimulants, attacked with convulsions during the first stage of labour; V.S. ad 3xxv. without producing good effect. For-ceps applied, and a dead child extracted; fits increased in violence after delivery, and continued until she died.	Died five hours after delivery.
33	March 1, 1836	Convulsions occurring after a full dinner of currie and rice; pulsæ rapid and feeble; V.S. ad 3viiij.; os uteri slightly dilated; labour pains commencing; membranes were ruptured, and the liquor amnii evacuated; C. C. temporibus, ad 3vj; head of child descended into pelvis; the forceps were applied; the child was easily extracted, but dead; convulsions continued.	Died; vessels of the brain were un-usually distended with blood.
34	Aug. 16, 1836	Puerperal convulsions during labour; had 14 fits before she was seen; os uteri dilated; head low in pelvis; forceps applied, and the child extracted with ease; child dead; only 1 fit after delivery.	Died two hours after delivery.
35	Aug. 1836	Eighth month of third pregnancy; for two weeks had suffered from influenza and headache; attacked with convulsions at end of that period, having 17 fits in seven hours; 3xl. of blood were drawn; the fits during the day became more violent, and the muscles were violently affected; pupils dilated; membranes ruptured; os uteri slightly dilated; at midnight the fits came on again with tremendous violence; craniotomy was performed, and only one fit occurred after the extraction of child.	Recovered.
36	Feb. 8, 1837	Puerperal convulsions; no relief from copious venesection; fits ceased soon as deli-very was completed, which was effected by craniotomy.	Recovered.
37	August 15, 1837	First labour, very protracted, head jammed in brim of pelvis; an injudicious attempt was made to apply the forceps; convulsions threatened; craniotomy performed; labour completed; symptoms subsided.	Recovered.
38	1837		Recovered.

39	Jan. 4, 1838	In a patient, under the care of Mr. Brookes, convulsions took place immediately after the birth of the child; fourth labour; she had been bled copiously, by him and all other means vigorously employed; coma came on; cold extremities; rapid feeble pulse; she died the following day in spite of all treatment.	Died.
40	May 9, 1838	Convulsions occurring after the birth of the child; the patient had been excited at a concert, an hour after she had returned from which labour came on; she soon became insensible, with convulsive movements of the muscles of the eyelids and lips; venesection ad $\text{℥}xv.$ by cupping, and enemata exhibited; she remained unconscious two days, and on the evening of the third sensibility returned.	Recovered.
41	Nov. 28, 1838	Drowsiness and headache in the ninth month of the first pregnancy, which continued for two weeks, when she was attacked with convulsions; a severe fit of sickness preceded the convulsions; they continued during the day; pulse 84; labour pains commenced; os uteri high up and undilated; venesection ad $\text{℥}xv.$, and $\text{℥}xxx.$ were drawn by cupping from the temples. The next day the fits disappeared, and she was safely delivered; two days after, however, convulsions followed the birth of the child, but was again bled, and the fits were from that time controlled.	Died in convulsions.
42	Feb. 16, 1839	First labour, convulsions of a violent kind; venesection and other remedies employed; head within reach of the forceps, which was applied; convulsions became more severe; craniotomy was performed, but the convulsions continued, and she died soon after delivery.	Recovered.
43	March 13, 1841	Convulsions at the end of first stage of labour, without any premonitory symptoms; pupils dilated; insensibility; uterine action was suspended; $\text{℥}xxv.$ of blood were taken from the arm, and with the aid of sprinkling water on the face, applying ammonia to the nostrils, and dilating the external parts, the child was at last expelled by the natural efforts; fits ceased.	Recovered.
44	April 2, 1841	At seventh month of tenth pregnancy, convulsions came on without previous symptoms; muscles of extremities not convulsed; consciousness lost; recovered herself for five hours; venesection employed with cathartics and cold to the head; she gradually recovered, and went to the full period.	Recovered.
45	Nov. 13, 1841	Convulsions in the seventh month, from alarm at fancying that the house was on fire; insensibility; teeth clenched; pupils contracted; breathing slow and stertorous; fits renewed soon after with greater violence; pupils became dilated; head drawn to right side; pulse and respiration became quickened; venesection had been employed, together with the exhibition of calomel, croton oil, enemata, &c.; cupping from the temples; in three hours she was quite insensible, and appeared dying from exhaustion; forceps applied, and delivery accomplished; consciousness never returned.	Died fifteen hours after delivery.

46	April 16, 1842	Convulsions occurring one day after delivery; fits violent, and at short intervals; when the fits went off, the pupils were contracted, and widely dilated when they were about to return; venesection ad 3xxxv. and no return afterwards of the fits.	Recovered.
47		A lady, æt. 26; protracted labour, first child; convulsions suddenly appeared; venesection ad 3xxx.; fits continued with great violence, and the head was found to be pressing on the perinæum; the forceps was about to be applied, when the child was expelled naturally, and the convulsions ceased; she was in a state of stupor for ten hours.	Recovered.
48		A lady under the care of Dr. Sims had violent puerperal convulsions in the seventh month of first pregnancy; two pounds of blood were drawn from the arm; the fits went off, but she had insensibility and headache for a long period; V.S. was again had recourse to, but she continued to suffer until the full period, when she was delivered of a dead child.	Recovered.
49	Sept. 30, 1842	A lady under the care of Mr. Cathrow became perfectly insensible the instant after the birth of her ninth child; an hour after the uterus contracted, and the placenta was expelled; there were no convulsions, but all the muscles of the jaws, trunk, and extremities, were rigid; she remained twenty-eight hours in this state without speaking, the hands and feet being drawn inward, the jaws nearly clenched, and the eyeballs drawn upwards; pupils not dilated; pulse 80, and sharp; a few leeches were applied to the head, and cathartics and antispasmodics given, when the power of swallowing returned; the same occurrence had taken place, but in a much slighter degree, soon after the birth of every child; she never had hysteria or catalepsy in early life.	Recovered.
50	Nov. 23, 1840	A young married lady was attacked with mania on the eighth day after delivery; she soon became wildly delirious, and died six days after in convulsions; the pulse being very rapid and feeble, depletion was not carried to any great extent.	Died.
51	Nov. 22, 1842	A lady under the care of Mr. Johnson, Grosvenor Place, became maniacal on the fourteenth day after delivery; in the course of two days she was seized with convulsions, and had a number of severe fits; she recovered completely in a few days, after the repeated application of leeches to the head and region of the uterus, cathartics, &c.	Recovered.
52	Dec. 2, 1842	A lady, æt. 33, was seized with violent convulsions in her first labour, about twenty hours after the membranes were ruptured; venesection 3xxxv.; the labour pains continued, and the fits did not return for nearly ten hours; the uterus then having ceased to contract, and several severe fits being experienced, artificial delivery was had recourse to; the fits ceased the instant the child was extracted, and she appeared for several weeks to recover, but afterwards died with symptoms of effusion into the brain.	Died.

any kind. The application of leeches to the region of the uterus appeared, in a recent case of mania complicated with puerperal convulsions, to be attended with the most striking benefit after all other means had been tried without effect. Sedatives have been recommended to be applied to the cervix uteri, or thrown up into the rectum during labour, and after delivery, in cases of puerperal convulsion, but I have had no experience of their efficacy.

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 591.]

I SHALL now endeavour to apply these views derived from transcendental anatomy to the practical work of Naegele, and to his discovery of the pelvis oblique ovata. From time to time there occur, no doubt, in every dissecting room, specimens similar to the five or six now lying before me; they have been in my own museum nearly seventeen years, and have annually been exhibited to my class. I shall describe one of them with some minuteness, the rest more briefly.

1. A female pelvis, history unknown. The right os innominatum is not present; the left had been accidentally divided with the saw just before the acetabulum, and the fragment lost; the last lumbar vertebra is present; the sacrum also, and seemingly the first of the coccygeal vertebræ. To understand the preparation rightly, it requires to be seen, or to place Mr. Naegele's work before you. The left sacro-iliac articulation is obliterated or ankylosed; the iliac portion of the left innominatum small, and but partially developed. The sacrum is twisted away to one side; the area of the left half of the introitus could scarcely have equalled a third of the right: the specimen when entire must have presented exactly the form we find in M. Naegele's plate, and have been one of the very best specimens of the obliquely oval pelvis.

2. The preparation marked 980 is similar to the last in nearly all respects: the partial development has again happened on the left side; the anky-

losis of the joint is complete only on the surface, but the obliquely oval form would not have been so well marked as in the preceding specimen.

3. In the specimen now before me, which is an extremely instructive one, as shewing the early stage at which these deformations commence, the pelvis being evidently that of a young person, a female, the defective development had taken place on the right side: there is no appearance whatever of any ankylosis,—a change which seems to come on later, and at times to be altogether unconnected with the deformity. The first sacral vertebra strongly resembles the last lumbar; it has not yet united with the second, and the two lateral portions or wings are of extremely unequal depth; the one, the right, being scarcely half an inch; the other, the left, being fully an inch and $\frac{1}{2}$; neither does the body of this vertebra follow so exactly the direction of the second as is usual in the regular-formed sacrum, but slopes slightly backward; lastly, a line let fall perpendicularly from the symphysis pubis to the sacrum strikes that bone at the inner edge of the right foramina vertebralia, instead of the centre of the bone, as it ought to do. On looking at the specimen when held fairly before you, you may see nearly the whole of the right foramina vertebralia, which ought not to be the case had the right os innominatum been fairly developed; but instead of that semicircular line which the linea innominata ought to present, we find it nearly a constantly converging one from the articulation with the sacrum to the symphysis pubis. No one, I think, can now doubt what would have been the ultimate form of the pelvis had the person happily lived to mature years: it would have been a perfect specimen of the pelvis oblique ovata, the right side retaining the infantile and brute form, the left expanding into that of the well-formed woman.

I shall now very briefly notice three more specimens which I find on the same shelf with those just described, but evidently quite different in their nature; I notice these the more particularly, that their characteristic pathological condition may have originally led others as well as myself to overlook the essential differences betwixt them and the preceding specimens. They

are half sections of the pelvis taken at random from the Practical Rooms, exhibiting an ancyhlosis of the right sacro-iliac joint—no other deformity is present; the pelvis shewing no marks of deformation. One of the persons had probably suffered from rheumatism; at least other parts of the bones shew a strong disposition to exostotic deposits, which indeed abound. Thus anchylosis of this joint is in no shape necessarily connected with the pelvis oblique ovata, although it usually follows or accompanies it as a consequence of non-development.

The last specimen on the table reminds me of the vast variety of forms presented by the sacrum, and how difficult it is to give even the characteristic sexual distinctions. Here is one which would easily admit of its first bone being nicely removed with the saw, and yet leave a perfect sacrum, that is, a promontory and five bones. There appear to have been six sacral vertebræ in this specimen, but as neither the lumbar nor coccygeal bones are present, the matter remains doubtful. Another and a perfectly different view might be taken of this upper vertebra: it may be the last lumbar, but I feel disposed to say that, notwithstanding its anomalous appearance, it is the first sacral, and that the first coccygeal is here united to the last sacral.

As these observations have unexpectedly extended so much beyond the limits I anticipated, what I have further to say shall be very brief; it has a reference to two points: 1st, to some observations by Fischer and Autenrieth on the form of the pelvis of the quadruped mammal; 2d, as to the temporary relaxation of the pelvic ligaments in women preceding and during delivery.

1st, In addition to a vast number of very admirable and original observations, Autenrieth remarks, that the depth of the osseous symphysis of the pubis, and the comparative weakness of the sacral and caudal portions; the canal-like shape assumed by the pelvis in most of the lower animals; the rudimentary condition of the false or upper pelvis in some, and the like condition of the true pelvis in others; all these, he observes, are remarkable features in the pelvis of the quadruped. The influence of these changes is perceived in the condition of the muscles connected with these bones, in the com-

parative slenderness of the haunches of most quadrupeds, and the frequency of hernia in man as compared with them. The usual vertical position of the trunk in man has, no doubt, its share in giving rise to this circumstance. Autenrieth's mode of calculating certain dimensions of the pelvis is most ingenious, but to do justice to his ideas it would require that the work were translated and transferred to your pages entire: he divides the pelvis, for example, into what he calls a dorsal part and an abdominal, and he found that, whilst in the infant of two years the first was to the second in length as 10 to 11, and up to 14; in the adult it was as 10 to 16, up to 22.

It is sufficiently curious that, although in certain quadrumana, and in the elephant, the comparatively rounded form of the cranium in this respect somewhat, though rather remotely in the latter, resembling the human, might have been supposed adequate to produce a marked alteration in the form of the pelvis, it yet has not done so, at least not to any great extent. The pelvis of the highest of the quadrumana does not, in so far as I recollect, approach in form the female (human) pelvis; and in respect to the elephant, although it may be admitted to be more rounded in the *introitus*, or narrow, than most mammal pelves, its resemblance to the transversely oval human female pelvis is very distant.

2d, Do the articulations of the female pelvis relax during, and a little before, delivery? To what extent does the relaxation take place? Is it a rare or frequent occurrence? Is it a pathological or a healthy condition?

To answer these questions in as far as my own experience goes, I shall endeavour to relate, to the best of my recollection, some of the principal facts bearing on them in the order in which they presented themselves to me.

During the summer sessions of 1825, 1826, and 1827, I delivered, in Surgeons' Square, three courses of lectures on comparative anatomy. The desire to present as many fresh specimens of all the great classes, and principal genera, of animals, induced me to apply to the fishermen on our coasts, engaging them to send me any rare mollusca fishes, seals, dolphins, &c. which they might take by nets or otherwise. Now,

under those circumstances, a pregnant seal was brought me; the animal had been shot with a single ball, killing not only the mother but the foetus. From the size of the young seal and other circumstances, it was evident that in a very few days the foetus would have been born. I shall here abstain from mentioning any other circumstances respecting the anatomy of the seal and its foetus, saving what is directly connected with the history of the pelvis—I mean of the pelvis of this pregnant seal. The foetus, which lay in the uterus with all its natural connexions, appeared to me of extraordinary dimensions, and I was curious to know how such a foetus could pass the pelvis of the mother: the examination of this cavity displayed a singular and unexpected fact, and which was at the time quite new to me; the interpubic ligament, or ligamentous symphysis, was so elongated that the bones might be separated from each other to the extent of nearly two inches. When I now examined attentively the form of the osseous pelvis, I could see very evidently that in the quadrilateral-shaped pelvis, where the greatest diameter was the antero-posterior one, as in the quadruped mammal, and not the transverse one, as in woman, this temporary separation of the pubic bones of the pelvis admitted of a great enlargement of all the diameters of the pelvis; whilst in the transversely oval pelvis of woman, the artificial separation of the pubic bones merely, even to a considerable extent, say an inch, did but little increase any of the diameters of the brim and abdominal entrance to the true pelvis. As this was a matter which could be made the subject of comparative demonstration, several female pelves were divided at the pubes, as recommended by Sigault, when it became manifest to the class that unless the pubic bones were separated forcibly from each other for more than an inch and a quarter, nothing was gained on the diameters of the cavity; and that a more extended separation, so as to render the operation at all useful in respect to its object, was absolutely impracticable on the living woman, since, on its being attempted, the sacro-iliac joints were heard to give way. Having satisfied myself that the Sigaultian operation on the transversely oval pelvis of woman could lead to no

real benefit, being only applicable to that form of pelvis found in the quadruped, and but rarely in woman, my attention was next directed to ascertain whether or not, in woman, the ligamentous symphysis of the pubis became relaxed during parturition? Whether or not this was frequent or rare? Whether or not it was accompanied by a corresponding relaxation of the sacro-iliac joints, without which the relaxation of the ligamentous symphysis would be of little avail? And, lastly, whether such relaxations were to be viewed as pathological or natural? An opportunity soon occurred, after the dissection of the seal described above, to put some of these questions to the test of direct observation.

A middle-aged woman, who had died of flooding following delivery, was brought into the Practical Rooms: the pelvis was of full dimensions. On examining its articulations, they were found to be all relaxed; the bones could be made to slide over each other. The dissection was shewn to the class, and compared with that of the seal, whose skeleton was in the museum; the opinions, likewise, of several distinguished accoucheurs in town were asked: they all declared the relaxation to be the effect of one of two causes: it was either, said they, the result of putrefaction after death, or of a diseased or pathological condition of the pelvis. On consulting the published works of a most distinguished surgeon and accoucheur (Mr. Burns, of Glasgow), I found that he also maintained the doctrine, that when relaxation of the articulations of the pelvis did take place during delivery, it was a pathological and not a healthy process.

Since 1825 and 1826, I have now had an opportunity of examining carefully the pelves of five women of different ages who have died soon after delivery, and having found in all of these a relaxation of the articulations of the pelvis to a greater or less extent, but always remarkable, I feel disposed to think the process a regular or healthy one, and not pathological.

In conclusion, I trust it has been made apparent that the great laws of transcendental anatomy and physiology, even admitting them to be not yet very fully established, are yet extensively and happily applicable to human anatomy and physiology: certain devi-

ations of the pelvis, for example, from its normal and specific form, have been shewn to be *merely a persistence of its foetal shape*; and this shape again, being the *type of shape in every mammal*, the deformation gives to the adult pelvis thus constituted the shape at once of the human foetal and quadruped pelvis. Or, to express the generalization as a law, perhaps we may say, "the laws regulating the growth of *specific forms* are the antithesis of the laws presiding over *transcendental forms*; the one bestows individuality on the species, the other struggles to reduce all to one type; as the one prevails, the specific form is preserved; with the predominance of the other, a destruction of all *speciality* exists: we call these laws of type deforming laws, because they are opposed to our ideas of species, and to the obvious endeavours of nature to maintain this struggle and to perpetuate species.

[To be continued.]

OBSERVATIONS AND EXPERIMENTS CONCERNING

DIABETES MELLITUS,

&c. &c.

By JOHN PERCY, M.D. (Edin.)

Physician to the Queen's Hospital, and Lecturer on Organic Chemistry at the Royal School of Medicine and Surgery, Birmingham.

[Continued from p. 595.]

(For the London Medical Gazette.)

WE now proceed to examine the subject of *the formation of grape-sugar in diabetes mellitus*. Several distinct questions are here naturally suggested.

1st. In what situations is the grape-sugar found in this disease?

2nd. In what part of the system is it formed?

3rd. What are the particular conditions attending its formation?

1. It is present in the *blood*. This fact is now firmly established; although, for a considerable time, chemists failed in their attempts to discover the existence of sugar in the blood of diabetic patients. M'Gregor, Dr. Rees, Dr. Maitland, M. Bouchardat, and Ambrosiani, have substantiated the fact by direct experiment.

The elegant analysis of diabetic blood by Dr. Rees, detailed in Guy's Hospital Reports, Vol. 3, p. 398, is extremely satisfactory, for the sugar was obtained in a crystallized form. I believe I have also met with similar success. Feb. 17, 1842, I received the blood, taken by cupping in the loins, from a young lady suffering under confirmed diabetes mellitus. I examined her urine several times, and obtained from it beautifully crystallized sugar; its sp. gr. was 1045. The patient died recently. I dried over the steam-bath 549.5 grains crassamentum and serum. I treated the dry residuum with successive portions of boiling alcohol, of sp. gr. 860°, to the amount of f3v. The alcoholic solution was evaporated to dryness. The residuum was treated with distilled water, and the aqueous solution was evaporated to the consistence of syrup, and then left exposed to the air for several days. After the lapse of this time I distinctly observed small globular masses of a light fawn colour, and of the characteristic appearance of diabetic sugar; they were interspersed with crystals, apparently of chloride of sodium. The separation of sugar from the blood is often attended with considerable difficulty, and I have even failed to detect it in the blood of a dog, after the injection of sugar into the jugular vein. In the early stage of one case of diabetes, Dr. Christison could not detect any sugar in the blood; while in another, where the disease was far advanced, fermentation indicated its presence only in the small proportion of one grain in eight ounces. (Library of Medicine, Vol. 4, p. 252.) The existence of sugar in the blood of diabetic patients only in minute proportion, will not appear surprising, when we consider the extreme rapidity with which sugar, after its introduction into a vein, is eliminated by the kidneys, and when we also further consider that, in the disease in question, the quantity of water which passes through the blood in a given time is so much greater than in the condition of health. We receive it, then, as an established fact, that sugar exists in the blood in diabetes mellitus, and is circulated throughout the system.

I may here direct attention to the fact, that sugar, whether grape or cane, does not appear to produce any sen-

sible effect upon the nervous system; and, in proof of this, I need only refer to the experiments previously recorded. Cane sugar may be even injected into the carotid artery without effecting any decided cerebral disturbance. I have injected 1000 grains of cane sugar, dissolved in ℥ij. of warm water, into this vessel, without observing any other effects than those which I have seen result from the injection of pure water into the same artery.

Sugar is also reported to have been occasionally detected in the *saliva* and *perspiration* of diabetic patients, and we cannot be surprised at this statement when we consider that the circulating liquid is itself impregnated with sugar.

We now arrive at a fact of the highest interest in connection with the pathology of diabetes, viz. the existence of saccharine matter in the *stomach* of diabetic patients, after all saccharine matter has been excluded from their food. This part of the subject necessarily includes the question next in order, viz.:

2dly. In what part of the system is the sugar formed?

It will be borne in mind, that my intention in this communication is not to examine the various hypotheses which have been proposed to explain diabetes mellitus, but simply to confine myself to an examination of what appears to be positively known upon the subject. More facts are yet required; and it would be advantageous to science if pathologists, who may have opportunities of practically studying the disease, would apply themselves to the investigation of particular points, which demand further elucidation.

To Dr. M'Gregor we are indebted for experimental evidence of the existence of sugar in the stomach in diabetes. Several questions arise in connection with this fact. *Is sugar found in the stomach only when the food has contained vegetable matter?* M'Gregor has answered this question in the negative, for he "found saccharine matter in the stomachs of persons in whom vomiting had been produced, and who had been kept for several days on a very strict animal diet," (Bell on Diabetes, Transl. p. 50.) This statement is one of extreme interest, and requires confirmation by other pathologists. The generation of grape-sugar

in the stomach from azotized tissue, as fibrin or albumen, would not admit of easy explanation. Experiments in relation to this subject must be performed with the greatest care, for those who have watched diabetic patients well understand the difficulty of ensuring the necessary condition of restricting a patient to an exclusively animal diet for several days. And in this case even milk and bread should be entirely excluded. I would express my earnest hope that some pathologist may be induced to direct his especial attention to the investigation of the statement under consideration.

Is the statement of M. Bouchardat correct, that the proportion of sugar in the urine is in the direct ratio of the quantity of fecula or saccharine matter contained in the food? (Bell, op. cit. p. 47.) It is difficult to understand how this statement should be perfectly compatible with that of M'Gregor, which we have just considered, for it would lead to the conclusion that the sugar is generated exclusively from amylaceous or similar vegetable matter. And if this conclusion were correct, a strictly animal diet in diabetes mellitus should be immediately followed by a return of the urine to a perfectly healthy condition, in so far as relates to the absence of sugar; which, however, I am not aware has hitherto been found to be the case. That the proportion of amylaceous matter of the food determines to a certain extent the proportion of sugar evacuated with the urine, we are not prepared to deny. It is only the constant and definite relation of Bouchardat, which requires confirmation by further experiments. Here, again, we must lament the deficiency of experimental data. We need well-established facts in the present day, and not mystical and indefinite opinions. If some pathologist would restrict himself to an investigation of the chyme of a diabetic patient—an investigation, it is true, attended with difficulties, but not insurmountable—valuable facts might be obtained.

M'Gregor discovered sugar, not only in the contents of the stomach, but also in the *feces* of diabetic patients, and, what is deserving of attention, the sugar was capable of crystallization.

Another question is, *whether sugar, in diabetes, can, in any degree, be produced from previously assimilated mat-*

ter? Now, one of the most striking and invariable symptoms of the disease is emaciation. The loss of weight in some cases is remarkable; and of this we have an illustration in the history of Merchant. Absorption, therefore, of previously assimilated matter, must occur to a great extent; and the question arises, whether any of this matter is converted into sugar and evacuated with the urine, or whether it is entirely consumed in the process of respiration. The food, it is well known, serves two important ends, viz. the supply of matter for pulmonary oxidation, and for the reparation of waste. If these ends be not satisfactorily accomplished, whether from a deficient supply of nutriment, or from some defect in the process of assimilation, emaciation and exhaustion are the inevitable consequences. Now, the condition of a patient suffering under progressing diabetes is exactly the condition of a man exposed to one or other of the preceding circumstances. The food which he takes, although abundant, and suitable in quality, is converted, in great measure, into matter which is useless to the system, and which is expelled by the urinary organs. The condition, then, of a diabetic patient perfectly resembles that of starvation from a deficient supply of nutriment; and hence the consequent emaciation. Material must be continually introduced into the blood for the purpose of respiration; but in diabetes that material is in great measure virtually withheld, for grape-sugar, it would appear, is incapable of satisfactorily answering that purpose. Absorption, therefore, of previously assimilated matter, which is adapted to supply the demand of respiration, takes place with rapidity, and fat especially soon disappears. In the case of Merchant it will be remembered that almost every trace of fat had been removed; and that even the muscular tissue itself appeared to have suffered in some places extensive degeneration. In fact, every thing suitable for pulmonary oxidation had been removed. That fat is really adapted to this purpose, we learn from the following considerations, which have been lucidly expounded by Liebig.

1. When an animal is deprived of nutriment, the fat first disappears.

2. Fat animals, *cæteris paribus*, can exist longer without food than lean animals.

3. Hybernating animals which before the commencement of their period of torpor are well provided with fat, are afterwards reduced to leanness.

4. Rest, with the consequent diminution in the quantity of carbonic acid evolved in respiration, is favourable to the development of fat; whilst the converse is true in a state of activity.

Now, there is an obvious relation between the quality of food and the formation of fat; a relation of great practical importance to the farmer. Amylaceous matters, especially, tend to the production and deposition of fat. Accordingly, starch, in one form or other, is frequently employed in the fattening of poultry and pigs. Liebig has well insisted upon the relation of ultimate composition between fat and fecula, and explains the formation of the former from the latter by the simple abstraction of oxygen. (Vid. *Animal Chemistry*, edited by Dr. Gregory, page 83, et seq.) Whether the oily matter which I extracted from the chyme by alcohol in the experiments detailed in the present communication, might, in part, be derived from the starch, in the manner supposed by Liebig, is a question worthy of further investigation. Dr. Prout maintains that the conversion of fecula into oily matter in the stomach occurs in healthy digestion. However this may be, it is nevertheless certain that fat is in some way or other generated in the system from amylaceous matter. Now it is probable that in progressing diabetes mellitus, this conversion is, in great measure, if not altogether, arrested; for in the case of Merchant, although a liberal allowance of bread was prescribed, yet scarcely a trace of fat was discovered in any part of the body in the *post-mortem* examination. If the explanation of Liebig be admitted, that starch is changed into fat by the abstraction of oxygen, the question may arise, *whether in diabetes the fat may be converted in any degree into sugar by the absorption of oxygen?* A few months ago, I saw a tall, corpulent man, suffering under confirmed diabetes mellitus. His age was between 50 and 60. His weight in health must have been from 16 to 18 stones. He lost in less than a month more than two stones, and during this time his appetite was considerably impaired. The sp. gr. of the urine was 1045°, and furnished well crystallized sugar.

He died a week after I saw him. Now, this case might possibly favour an affirmative answer. The quantity of food taken was much less than in health, whilst the urine was highly saccharine, and 28lbs of matter, consisting, doubtless, in great measure, of fat, rapidly disappeared. Another curious and similar case I shall adduce in the sequel. I leave the question to be decided by further observation.

We now arrive at the third question.

3. *What are the particular conditions attending the formation of grape-sugar?* This question, it is evident, involves the *proximate cause* of the disease. Let us first interrogate morbid anatomy.

1. Mr. Bowman, whose reputation as a microscopic observer is so well established, examined the mucous membrane of Merchant's stomach, and was unable, by the aid of the microscope, to discover any morbid appearance. The mesenteric glands are generally enlarged, but this enlargement often exists in other diseases essentially different from diabetes. A tuberculated condition of the lungs, sooner or later, is almost constantly present, and the disease frequently terminates in phthisis pulmonalis. The kidneys and ureters are sometimes considerably enlarged, yet frequently without any alteration of structure. And we should reasonably expect that, in proportion as the natural function of an organ is increased, in the same proportion, within certain limits, will the volume of that organ be augmented. It must not be omitted, that in some cases of diabetes the urinary apparatus has been found to be altered in structure, but such alteration is clearly incidental, and is certainly in no way essentially connected with the formation of sugar, for, if the contrary were true, then, of necessity, similar structural change should exist in every case of diabetes, which, we know, is not the fact. Besides, it would be matter of surprise if the urinary apparatus were not in diabetes occasionally diseased beyond mere hypertrophy, for the liability of one organ to disease is, *ceteris paribus*, increased in proportion as the function of that organ is preternaturally excited. I may here introduce the result of the microscopic examination of one of Merchant's kidneys, kindly undertaken by Mr. Bowman, at my request.

"There were superficial abscesses, and destruction of certain parts of the renal vein by fibrine, adherent to the inner wall, and softened in its interior. In the principal part of the organ the Malpighian bodies and the tubes appeared to me to be healthy in structure." I need not refer to the morbid appearances which have been occasionally observed in diabetes. From a careful examination of numerous published cases, we arrive at the negative conclusion, that the *disease may exist independently of any appreciable alteration of structure whatever.*

2dly. Of the condition of the blood and secretions. Upon this subject our knowledge at present is extremely imperfect. I have previously alluded to the elegant analysis of diabetic blood by Dr. Rees, but it teaches us nothing concerning the formation of grape-sugar. The salivary secretion is generally, if not almost uniformly, acid, and is also frequently much diminished. In some cases, however, it is increased, even to salivation. (Vide Cases by Dr. Watts, in a recent number of the *Lancet*). The patient suffering from diabetes often complains of the disagreeable sensation of dryness of the mouth and fauces. If the saliva really perform so important a part in the process of digestion as my friend Dr. Wright and some other physiologists maintain, then the fact of the salivary secretion being generally decreased in diabetes acquires considerable importance. At one time I stimulated Merchant's salivary glands by means of capsicum gargle, which increased the secretion to such an extent as not only to enable him, but to require him, to spit freely. I did not, however, during this period, observe any marked alteration either in the symptoms or the quality of the urine. With respect to the condition of the skin, some observations are required. One of the most frequent exciting causes of diabetes is certainly habitual exposure to sudden and great alteration of temperature. The functions of digestion, respiration, and cutaneous exhalation, appear to be intimately connected with each other; so that a disturbance of one is often attended with a corresponding disturbance of the others. With the precise nature of the function of the skin, it must be admitted, that, at present, we are but

imperfectly acquainted; but that it is of great importance we are assured from a variety of considerations, which it would be superfluous to enumerate. How carefully is the state of the skin watched by the judicious practitioner! How often has the restoration to healthy action of the suspended function of the skin in febrile diseases satisfactorily indicated a return of convalescence! And, again, how often has a peculiar atmospheric condition, by modifying or arresting the function of the skin, induced disease! Future investigation, it is hoped, will shed more light on this interesting part of pathology. All that we can do now is to insist upon the general fact of the suppression, in a greater or less degree, of the cutaneous function in diabetes. In the case of Merchant I did not witness that peculiar degree of harshness which I have frequently remarked in other cases. Occasionally, as we learn from the register, he perspired freely. I may here appropriately introduce some remarks of Dr. Graves in respect to the state of the skin in diabetes. "I may observe," writes that eminent physician, "that it is by no means so dry, acrid, and harsh, as we frequently find in diabetic patients; indeed, it feels nearly natural, and is partially covered with moisture at various times of the day. Some persons, looking almost exclusively to the condition of the skin, have taken a very limited view of this disease. They consider it as arising from perspiration being repressed, and turned inwards in the kidneys. This, however, is by no means satisfactory. Some of the worst cases I have ever seen were attended by colliquative sweats." Dr. Graves also cites the case of a gentleman affected with diabetes, who used to perspire copiously every day at the time that his urine was 1049°. The fact, however, is nevertheless *general*, though not *universal*, that in diabetes the function of the skin is, in a greater or less degree, suppressed. There is also one fact, which should not be omitted in this part of the subject, namely, that according to the experience of Dr. Prout, which we are assured must have been very extensive, "diabetes usually *follows* cutaneous affections." (Op. cit. p. 35.)

In respect to the condition of the urine, several points are deserving of

especial attention. By the results of direct experiment we are enabled satisfactorily to explain the presence of sugar in the urine; for we have seen that, when sugar is introduced into the blood, it is in great measure rapidly eliminated by the kidneys, in the precise chemical state in which it is injected. Cane sugar, for example, passes through the circulation without in the smallest degree being converted into grape sugar, or appearing to suffer any other change. And the same is true of sugar of milk, or lactine; in proof of which I may relate the following experiment:—Into the right jugular vein of a middle-sized dog, I injected 300 grains of pure lactine, dissolved in ℥iv. of distilled water. An hour afterwards the animal was destroyed by prussic acid, and during the convulsive action ℥v. of pale straw-coloured urine were evacuated and collected. The sp. gr. was 1038°, and the odour was similar to that of ordinary diabetic urine. The syrup, obtained by evaporation, became a solid mass of crystallized lactine. The mass consisted of small circular clusters of minute prisms radiating from the centre. No trace of sugar was detected by fermentation in the usual manner. *The kidneys, then, in diabetes, appear to act simply the mechanical part of filters.* In further proof of this conclusion may be adduced the fact that, in the case of Merchant, obstinate diarrhoea occurred, during which the urine was sometimes remarkably diminished, although it was not changed in *quality*. Now there is no reason to believe that a diminution in the quantity of sugar generated in the system corresponded to this diarrhoea, which therefore may be conceived to have been, to a certain extent, a *vicarious* action. The theory, however, of Dr. Prout supposes that the kidneys complete the development of the *low sugar*, by communicating to it the *crystalline* form. "The portion (of the *low sugar*) that is assimilated is applied to the purposes of the economy; the portions modified and unassimilated pass together through the system to the kidneys, by which glands the portion modified is disorganized, and finally appears in the urine as crystallizable sugar, along with the portion originally remaining unassimilated in the stomach." (Op. cit. p. 37.) And in corroboration of this view, Dr.

Prout adduces the fact, that "when the disorganizing function of the kidneys is suspended, or when these glands are partially diseased, the urine, besides albuminous matters, and more or less of crystallizable sugar, often contains the saccharine principle in imperfectly developed forms." But the fact of sugar having been obtained from the blood of diabetic patients, in a distinct crystallized form, would certainly not seem favourable to the theory of Dr. Prout concerning the supposed function of the kidneys.

It might here be remarked, that the thirst, which is so invariable, and frequently so urgent, a symptom of diabetes, may possibly be an expedient of nature, by which to insure the introduction of a sufficient quantity of water into the system, for the purpose of diluting the blood, and so facilitating and expediting the elimination of the sugar by the kidneys, and thereby preventing its accumulation in the system to an injurious extent. And this notion would appear to receive support from the fact, that the thirst increases in diabetes in proportion as the quantity of amylaceous matter in the food is augmented.

To Dr. Prout we are indebted for the knowledge of two important facts in relation to saccharine urine. The first is, that "a saccharine condition of the urine exists in dyspeptic and gouty individuals much oftener than is supposed; and hundreds pass many years of their lives with this symptom more or less constantly present, who are quite unaware of it till the quantity of urine becomes increased." (p. 33.) The second is, that "diabetes very frequently (and, so far as Dr. Prout's experience goes, *always*) accompanies carbuncles." (p. 36.)

Another singular point in respect to diabetic urine is the disappearance of sugar from the urine previously to dissolution. Of this we have an excellent illustration in the case of Merchant. His death appeared to be entirely the effect of exhaustion of nervous power; for the autopsy revealed no disorganization of structure apparently commensurate with the fatal termination. In some cases of diabetes, it is reported that the saccharine condition of the urine ceases when pulmonary phthisis supervenes. In the case of Merchant, it is true, tuber-

cular matter was scattered here and there through the lungs, yet not to a sufficient extent materially to interfere with the function of respiration.

There is still another point in connection with diabetic urine worthy of notice, viz. the *general fact* of the absence of uric acid, or urate sediments. Dr. Prout asserts that he has sometimes been enabled to trace the disease nearly to its origin by ascertaining when the urine was last observed to furnish a red-coloured deposit. Occasionally, however, uric acid is found deposited in diabetic urine of high specific gravity. A short time ago I obtained a beautiful specimen of crystallized uric acid spontaneously deposited from saccharine urine of so high a specific gravity as 1.045°. In the case of Merchant, for some days before his death his urine was loaded with deposits of urate of ammonia and uric acid; but this condition only occurred when the sugar had almost entirely disappeared.

Concerning the state of the other secretions in diabetes, we know nothing of a satisfactory nature.

Before concluding this part of the subject, it is proper to mention that the appetite is by no means so generally inordinate in diabetes as some authors have asserted; occasionally it is even much diminished; and of this I have already adduced one example. The thirst, however, is, so far as published reports inform us, and, so far as I have had an opportunity of observing, a *constant symptom*.

It may now be expedient to present, as succinctly as possible, a series of inferences and observations in connection with the preceding remarks.

1. Although the liquid of the stomach is capable of inducing the conversion of starch into sugar by digestion at a suitable temperature, yet we do not derive satisfactory and demonstrative evidence that this conversion takes place in a sensible degree in the stomach in the condition of health, and under ordinary circumstances.

2. As the formation of dextrine is the first step in the conversion of starch into sugar, it is required to ascertain whether dextrine may not be the ordinary product of the digestion of amylaceous matter, in the condition of health, and whether it may not be directly absorbed.

3. In diabetes mellitus sugar is found

in the stomach, the intestines, the blood, and some other secretions.

4. In this disease, also, sugar is reported to be found in the stomach, even after the exclusion of all vegetable matter from the food. On this point further observations are desirable.

5. It is asserted that the quantity of sugar in the urine, *ceteris paribus*, varies directly with the quantity of amy-laceous matters in the food. On this point, also, future observations may throw much light.

6. Sugar is certainly formed in the stomach in diabetes.

7. It is not clearly ascertained whether previously assimilated matter may not be absorbed, and be capable of conversion, in a partial degree at least, into saccharine matter.

8. The disease may exist independently of any appreciable disorganization of structure whatever.

9. Enlarged mesenteric glands, and the deposition of tubercular matter in the lungs, are, perhaps, the most frequent structural changes in diabetes. Enlargement, and a flaccid condition of the kidneys, cannot be regarded as indicating alteration of structure.

10. The kidneys appear simply to eliminate the sugar from the blood.

11. Our knowledge of the state of the blood and the secretions in diabetes is yet very imperfect, and has hitherto shed no light upon the pathology of the disease.

12. Disturbance or suppression of the function of the skin almost constantly exists.

13. The salivary secretion is generally much diminished, and has an acid reaction; the reaction of saliva in health being feebly alkaline.

14. A saccharine state of the urine may exist without the actual symptoms of diabetes.

15. Sugar, according to Dr. Prout, is not unfrequently present in the urine of gouty and dyspeptic persons; and, so far as the experience of that distinguished physician has hitherto extended, invariably exists in the urine when the system is affected with carbuncle or malignant boils.

16. Thirst constantly occurs in connection with confirmed diabetes.

17. The appetite is sometimes inordinate, at other times capricious and much diminished.

I venture not to support or propose

any specific theory of the disease, but await the evolution of additional facts; being assured that at present our data are insufficient to enable us to arrive at decided conclusions. If I have contributed in the smallest degree to our general store of knowledge, I shall consider myself amply rewarded for the time and attention which I have with pleasure bestowed upon the subject.

TREATMENT

OF

GONORRHOEA BY SUPERFICIAL CAUTERIZATION OF THE URETHRA.

To the Editor of the Medical Gazette.

SIR,

I HAVE for some time past been pursuing experiments on the treatment of gonorrhœal urethritis, and as the results of these experiments have realised more than I could have anticipated, I think the time has now arrived when I ought, in justice to the profession, to lay this treatment before them.

I am aware that there are numbers of the profession who are exceedingly timid in pursuing what may be considered bold measures in the treatment of disease, and in sooth, the recollection of some unfortunate case, in which these measures were carried out, makes them shudder at the bare expression, and shun a "bold practitioner" as they would a stalking pestilence; but boldness, combined with judgment and discretion, will, I contend, be far more successful in the treatment of disease, than timidity and indecision.

Unfortunately, however, instances of the former combination are comparatively rare, and we find that boldness is too frequently the offspring of ignorance.

In medicine there is no such thing as abstract principle. The whole science of healing is built upon fortuitous and chance discoveries. Like the alchemists of old we have discovered a thousand valuable things where we never thought of looking for them, and whilst uselessly seeking for talismanic gold, have lighted on a pearl of great price. Every thing in fact is presented to us as the result of experiment, and in the treatment of

disease the most valuable remedy, can boast of no higher origin than its more humble neighbour.

It is a great pity, therefore, that men, possessing all the requisite essentials for an honourable and lucrative career in their profession, should allow their prejudices to tamper with those talents nature has bestowed upon them.

How bold must that man have been who, heedless of the destructive influence of arsenic, dared to prescribe it as a remedy, and to define the limits to which we might safely administer it; or that individual who, without precedent, rashly cut into the human bladder, and from its hidden recess exposed to the wondering gaze of mankind a human calculus. Such men, in these enlightened ages, would be called "bold practitioners," and would become a mark at which a thousand shafts of ridicule would be pointed.

It is true, the direct application of a stick of lunar caustic to an inflamed and irritable urethra may savour of rashness; but it is deprived of half its terrors when we know that a membrane equally as delicate as that lining the urethral passage is frequently subjected to the same treatment, viz., the conjunctiva; and still further, that as far back as the time of Wiseman, strictures of the urethra were treated in a similar way.

In our own time, MM. Lallemand and Ricord have both employed superficial cauterization of the urethra as a means of relief for morbid sensibilities of that passage, and the latter gentleman in protracted discharges, which had resisted all other modes of treatment.

If I may presume, therefore, to take to myself any credit for the employment of caustic as a remedy in gonorrhœa, my reason for so presuming rests upon the period at which I recommend its adoption, viz., at the commencement of the disease, when pain and inflammation are present, attended with discharge. I am not aware that this mode of treatment has been adopted by any other practitioner than myself; if otherwise, I am quite ready and open to receive conviction.

Immediately a patient applies to me, I introduce an instrument, a modification of Lallemand's caustic-holder, smeared with oil, carrying it as far back the passage as from the symptoms may

be deemed expedient. The caustic being exposed by pressing the stilet forward, the button at its extremity must be rapidly rotated between the thumb and fore-finger of the right hand, in order that no part of the mucous lining may be left intact, whilst the instrument is at the same time gradually withdrawn from the passage.

In a few hours a considerable degree of inflammation ensues, and in some instances slight bleedings, but these symptoms are but temporary, and subsiding, leave the membrane almost free from discharge.

In most cases of gonorrhœa the inflammation does not extend beyond three or four inches from the orifice of the urethra; this was called by Mr. Hunter its specific extent; further back than this, therefore, the instrument need not generally be passed.

One application of the caustic I have sometimes found to destroy the virulence of the disease; but when, after the irritation attending the first application has subsided, any discharge remains, we should again resort to its employment. Whilst pursuing this treatment internal revulsives are to be administered in the form of copaiba and cubeb combined, and the penis is to be enveloped in a cold saturnine lotion.

With such means as these we shall rarely fail to check the disease in a few days; an assertion I could easily corroborate by the recital of cases, did I feel it might be requisite so to do.

An objection probably will be urged to this treatment from a dread of stricture or epididymitis ensuing; but I contend, and it is fully borne out by experience, that the chances of these affections are considerably less the earlier we destroy the specific inflammation attending gonorrhœa.

The first and most important indication in the treatment of gonorrheal urethritis is to make such an impression on the inflamed vessels as shall change the original character of the disease, and substitute, in its stead, simple common inflammation of a sufficient extent to overcome the diseased action; and I feel assured nothing can so effectually induce this as superficial cauterization.

I have the honour to remain, sir,

Your obedient servant,

G. B. CHILDS.

34, Fore Street, City,
July 13, 1843.

CASE OF
PRESENTATION OF THE
BELLY.

—
To the Editor of the Medical Gazette.

SIR,

As the following case is one of unquestionably rare occurrence, and as it has been doubted whether it can occur, I am induced to send you an account of it, with the view chiefly of establishing its possibility, and of corroborating the testimony of some eminent writers concerning it. Dr. Rigby, in his excellent system of Midwifery, has unhesitatingly denied that such a presentation can occur unless when the labour is premature, or the child some time dead and softened by disorganization, and has censured Baudelocque for admitting it, though that eminent author distinctly asserted its existence (in a table contained in his *Art des Accouchemens*), while its rarity was admitted by the statement that out of 12,605 labours only *three* presented the belly. The experience of Dr. Ramsbotham has, however, furnished proofs that the presentation may occur; but, as in regard to a disputed point, it may be useful to increase the weight of evidence, you may not think the following account inappropriate to your pages.—I am, sir,

Your obedient servant,

A. F. HOLMES, M.D. ED.

Professor of the Theory and Practice of
Medicine, McGill College, Montreal.

Montreal, Canada,
June 26, 1843.

May 23, 1843.—Between 9 and 10 o'clock in the evening, I was requested to visit Mrs. Rolls, who had been in labour since the preceding night under the charge of a midwife.

The account I received was, that the pains had commenced in the evening, but not strong: that about 3 A.M. the liquor amnii was discharged, and that the pains then became stronger, and during the afternoon had been strong and frequent. A dose of castor oil had operated freely. The midwife was quite at a loss to name the part presenting, but supposed it might be the breech.

On examination, the labia were found much swollen, but they had been so before labour. Introducing the finger it was met by a soft resisting body, too soft for the nates, and which exhibited

no sulcus or parts of generation. It had much the feel of a hydrocephalic bag, and passing the finger towards the anterior part of the pelvis, loose bony points were felt, not unlike the angles sometimes felt at the fontanelles when ossification is incomplete. As, however, parallel separations between the bony parts were perceived, I could not decide on the presentation till, carrying the finger towards the left side, I came upon what I at once recognised as the abdominal insertion of the umbilical cord: this was pulseless. Enlightened now as to the nature of the case, I found I could follow with my finger the whole contour of the false ribs on both sides, and as the presenting part had been forced down considerably into the pelvis, it was evident that the body must be doubled on itself.

The woman being at her full time, there was no reason to expect expulsion *viribus naturalibus*, and therefore I resolved to turn. The child being dead, my attention was of course exclusively directed to the mother. The membranes having broken 18 or 19 hours before, the waters had entirely drained off; the pains had been, and continued, frequent and forcing; the doubled body was considerably forced down into the pelvis, and therefore I anticipated great difficulty in bringing down the feet. The first step was to quiet the uterus, which I attempted by administering one dram of laudanum, the pulse not being strong. I left her for an hour, and on my return found the pains had been entirely stopped, but were again beginning. I then attempted to introduce my hand, but having entered the vagina, found the uterus so hard, that I desisted, and resolved to try the effect of venesection in relieving its rigidity, being fearful of trying turning in such a condition. I first administered $\frac{1}{4}$ of a grain of hydrochlorate of morphia, and then bled her to over thirty oz., when she complained of faintness. I then immediately proceeded to the operation, and supposing from the apparent position of the child that I should find the left hand most convenient (the patient being on her left side), I introduced it with considerable difficulty, and frequently cramped by the action of the uterus, along the presenting part towards the left side, but instead of its passing along the front of the

thighs, it was found to pass on to the buttocks and back of the child, and in endeavouring to bring it to the front of the thigh, it came in contact, not with the knee, but the elbow. The position then was different from what I had supposed, and instead of the body being simply doubled, it was also twisted, so that while the right side of the abdomen was opposite the vulva, the pubic region was turned in a contrary direction, and the elbow of the left side forced against it.

Finding I could not reach the feet or front of the thighs with my left hand, I withdrew it, and introduced the right, and having with much pain and difficulty reached the elbow, I found behind and below it the knee, and having insinuated a finger into the ham, held on during a pain, and endeavoured in the interval to draw it down. I finally succeeded, and when it had once begun to move I was able with no great difficulty to bring it down into the vagina, and finally the foot through the os externum. By gentle traction during the pains, the body was gradually extricated, the other leg and thigh remaining of course doubled up, till the nates were expelled; the arms were brought down, but some delay occurred in the expulsion of the head, it being large, while the outlet of the pelvis was rather small from the approach to each other of the rami ischii, and a strong unyielding coccyx. Even with the finger in the mouth, considerable force was required to bring it out.

On examining the body, the presenting part was well marked by its purple colour, and was found to be the right side of the abdomen.

It is well to remark that there was no prolapsus of the cord, only about two or three inches of its umbilical extremity being felt.

The case unfortunately terminated unfavourably. Next morning when seen, she expressed herself quite comfortable; no pain of abdomen, or untoward symptom. In the evening pulse quickened, still without pain, except some soreness in the left ilium on motion; ol. ricini ordered. At 11 P.M. violent intermitting pains came on, with tenderness of hypogastrium; she was bled to 8 oz. but pulse sank; fomentations, lavements, calomel, morphia, &c. ordered in vain: she died at 11 A.M. 36 hours after delivery. Inspection of the body was refused.

MESMERISM.

To the Editor of the Medical Gazette.

SIR,

As the communications of your correspondent, Mr. Southam (pp. 352 and 459), have evidently a tendency to discourage practitioners from the employment and investigation of Mesmerism, and hence to throw an agent, which he acknowledges to be a most potent one, still more completely than even at present into the hands of charlatans, I beg to offer a few remarks in reply.

"The Mesmeric power," he tells us, "is but a combination of exciting causes of disease" (354)—precisely the nature of all our most valuable remedial agents. Do any of these produce health, or healthy action, directly? Do they not rather remove one diseased action by setting up another?—either antagonist to that already existing, as is the case with counter-irritants, transferring the morbid action to another part of less importance, or, as with sedatives, directly diminishing vascular action in inflammatory affections; or, on the other hand, setting up an action analogous to, but more powerful than, the primary derangement, which subsides with the subsidence of that artificially produced, on the removal of the artificial exciting cause.

It seems extraordinary that a gentleman who really entertains such just views as to the true nature of the agency at work, should not have seen that its power might be made highly useful as well as deeply dangerous. If it possesses the power to produce "mischievous consequences," and of "exciting dangerous diseases of the nervous system," it must be capable of being employed as a therapeutic agent, either in one way or other. Because opium has been used for aiding the purposes of the followers of Burke, does it only claim our study on account of its mischievous power? Because a patient may be murdered by calomel, and may, after taking many doses, be rendered so susceptible of its influence, that a single added dose may induce violent and hazardous ptialism, are we to abjure the remedy altogether? A negative answer must be given. Yet, according to Mr. Southam's argument, "if they have any claim on our notice, it is not on account of any remedial power they may possess, but from the

mischievous consequences they produce."

I am not one of those transcendental mesmerists who entertain the wild hypotheses which have occasioned the *facts* themselves to be disputed, but, like Mr. Southam, I have endeavoured to trace the metaphysical and physiological action of the means employed, and during the last twelve months have employed most of my leisure moments in working out a theory based on these grounds, which I hope ere long to lay before the profession. In the meantime I cannot but express my regret that the whole of the matter should have been so summarily dismissed by medical men generally without fair investigation, merely because the facts *appeared* at variance with our preconceived opinions. Many, after denying the truth of the facts, have taken pains to shew how the phenomena might have arisen; others, admitting that such phenomena were really presented, have asserted that they were contrary to nature, and have absurdly attributed them even to Satanic agency; whilst most have assumed them to be mere collusion and trickery. That there has been much of this no one who has studied the subject attentively can deny; but the existence of counterfeit coin certainly presupposes the existence of genuine.

As my theory is not yet sufficiently perfect to be offered to the public, I shall content myself with presenting a few cases in opposition to those of Mr. Southam, shewing the "*beneficial* effects of mesmerism," and which, I think, will render it probable that he might, had he so chosen, have influenced his patient for good rather than for the contrary, as he evidently confesses was the case. During the last year I have produced the mesmeric sleep on upwards of twenty different individuals, and have *never* discovered the slightest "injurious effect." After witnessing Lafontaine's experiments, I was as much disposed to be sceptical as any of the most virulent anti-mesmerists—not that I could gainsay what I saw, but because I felt the hypothesis advanced to be untenable. However, shortly afterwards a case of violent hysteria came under my care, and on leaving from one of my visits I was recalled, as a fit was evidently coming on. The friends around prepared to

restrain the struggles of the patient by main force, but at my request relinquished their purpose. After diverting the patient's attention, by telling her she should not have a fit, I took her hands as in Lafontaine's method, and commenced the manipulations. In a quarter of an hour she was asleep. I inquired most specially respecting the case, and have every reason to believe that she knew nothing of mesmerism previously. I acted on her repeatedly afterwards, and could at any time produce perfect rigidity of the whole body, or of any part separately, at will, assuring her at the same time that she would not have another fit. The self-confidence established realized my prediction; and more than twelve months have now elapsed without any return. In this case perfect rigidity, and apparent loss of feeling and vision, were produced. Hearing alone seemed to remain in full activity; and she recollected what was audible, but nothing more. I could not detect any source of fallacy; and though at first startled at the result, I determined to investigate further. The limbs acted on being placed in any position, even the most painful, remained in the same form for half an hour at a time without wavering; and the same has occurred to me in several other cases.

My next case was also one of hysteria, with violent pain in the occiput; but here no rigidity was producible. On the contrary, there seemed to be an entire loss of muscular tonicity, so that the whole body appeared like plastic clay, and might be flexed in any way without resistance, whilst no sensation or power of any kind was apparent. Here, too, a cure was effected, as I believe by the self-confidence inspired.

In each of these cases the effect was produced about twenty times. I pass over several other cases of interest, in order to come within the legitimate limits of a communication; but I cannot deny myself the opportunity of recording two cases at present under treatment, and which have surprised me more than any I have witnessed.

The first is that of a young man suffering from hysteriform palpitation. Almost all the usual antispasmodic remedies, and many others, had been tried long and in vain; and beginning to tire of treatment which seemed use-

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

THE LAST NEWS FROM GRÄFENBERG.

THE physician, says Sir Charles Scudamore, must be a student for ever, and not disdain to learn till the last moment of his existence. He therefore went to Gräfenberg last April, to gaze with his own eyes on the doings of Priessnitz, and judge of the merits of hydropathy in the place where it is exercised with the greatest vigour. He returned much gratified with what he had seen, and has recently added another pamphlet to the multitude

"Quæ scribuntur aquæ potoribus."

With Priessnitz himself every one is pleased; were it otherwise, could a rustic practitioner boast a daily list of patients varying from two to five hundred? "His countenance," says Sir Charles, "is full of self-possession; rather agreeable; mild, but firm in expression; with an eye of sense, and a pleasing smile." And, best of all, "*He inspires his patients with the most entire confidence, and he exacts implicit obedience.*" This is half the battle. Half! it is nine-tenths of the victory over chronic disease, to have obedient patients. A physician who should take a large house at Richmond or Shooter's Hill, and fill it with dutiful and submissive patients, behaving like the good boys of a story-book, and observing in the minutest particulars the hygienic code of their physical pastor, might boast almost as many cures as the sage of Gräfenberg without the aid of hydropathy. However, we have no objection to add water and

less, I resolved to try mesmerism. In fifteen minutes from the commencement of the manipulations he was in a perfectly rigid state; and on one occasion I hung a chair on each of his extended arms, which still retained the position unwaveringly for twenty minutes, beyond which I did not think it right to protract the experiment. He always expresses himself relieved after each manipulation, and the benefit lasts just in exact proportion to the time the mesmeric state is kept up.

The other case is one of hysteria, in which somnambulism was induced at the second trial; and so strange and unexpected was the result, that I strongly suspected deception. This case, however, fully bears out Mr. Southam's views as to phreno-magnetism; and that there was no deception I had afterwards an opportunity of proving to my satisfaction, if not to that of others. Having been asked to give a lecture on the subject to a literary institution at West Bromwich, I took this patient with me to exhibit the effect. It happened that she suffered most severely that day from toothache; but I declined extracting the tooth in the morning, thinking it would be a fair means of proving that she was not deceiving me, by having it removed in the mesmeric state. In the evening, therefore, I mesmerised her, and her tooth was extracted by Mr. Charles Mole, M.R.C.S., in the presence of Dr. Dickinson, Mr. Silvester, and Mr. W. Jackson, all medical practitioners at West Bromwich, beside the usual audience of such institutions; and no one was able to detect the slightest muscular movement of any kind, or of any part, nor the least change of colour or respiration. Her hysterical fits also have never returned.

In all these cases I have never told my patients what effect I intended to produce; nor, so far as I know, had they ever seen any thing of the kind before. With these facts before me, I cannot help thinking that "a power so energetic in exciting disease," (p. 463) is also endowed with remedial virtues.

I am, sir,

Your obedient servant,
 GEORGE BEDDOW, M.R.C.S.

5, Jenner's Row, Birmingham,
 July 17, 1843.

mountain air to the healing agents, and have read with interest Sir C. Scudamore's account of the details of the system.

The first item on the list is the *Leintuch*, or wet sheet to lie on. The patient is wrapped up in a wet sheet, and then covered with a blanket, feather-bed, and quilt, in which he generally lies for three-quarters of an hour. This does not produce perspiration; but if in any case—catarrhal fever, for example—sweating is desired, the time is extended to an hour or more.

The next variety is the *Abreibung*, or rubbing down with a wet sheet which is thrown over the patient. This is continued from two to five minutes, when the skin becomes reddened.

In the variety termed the sweating blanket (*Das Schwitzen in der Kotze*), the patient is packed up in blanket, feather bed, and wadded counterpane, till perspiration breaks out, which sometimes requires four hours. The sweating is then continued for a prescribed time, and at its termination the patient takes a tepid shallow bath, or a cold plunge bath, or both. "It is only the practised patient who goes at once into the cold bath; but, with either, it is a rule first to dash some water over the face, head, and chest." The safety of this practice depends on the heated state of the body; for the system merely parts with its superfluity of caloric.

Sir Charles found that the thermometer, placed under the tongue of a certain patient before entering the blanket, stood at 98°; just before and after the breaking out of the perspiration it was at 100°; after much perspiration it sank to 99°; and after the plunging bath to 97°. This method is obviously not the same thing as a vapour bath, with which some persons have confounded it. Priessnitz does

not use the sweating blanket so much as formerly, but still relies upon it to remove any old virus, or to extract latent mercury from the frame. None undergo it more than gouty invalids. The word "tepid" applied to a bath has diverse thermometrical significations in different places; we should intend by it from 80° to 92° of Fahrenheit; at Gräfenberg it means from 58° to 68°; and the temperature most commonly employed for the shallow tepid bath is 62°. It is called at Gräfenberg *Das abgeschreckte Halbbad*. "The newly-enlisted patient, after quitting the *Leintuch*, enters this bath, and is diligently rubbed before and behind; taking himself a part, if able; if not, having more assistance, and for a longer or shorter time, as circumstances may direct; but, in the beginning, about two minutes."

This is clearly a very safe variety. The plunging bath (*Wannenbad*) at a temperature of 44° is more terrific, but is soon arrived at by most patients. It is commonly taken early in the morning, but is often enjoyed a second time in the afternoon.

The hip-bath (*Sitzbad*) varies in temperature from 44° to 64°; the time of immersion from a quarter of an hour to an hour. The patient, while sitting in it, uses friction to his back and abdomen; and, on emerging, restores the warmth of surface by due rubbing and drying. The hip-bath, employed in this decisive manner, is highly useful in many maladies of the pelvic viscera, and aids in correcting a disordered state of the mucous membrane of the intestinal canal.

The head-bath (*Das Kopfbad*) consists in lying on the ground with the back of the head in a basin of water.

The foot-bath (*Das Fussbad*) does not imply the deep tibio-fibular immersion of this part of the world; for the depth of water in the vessel is only from one to three inches. The soles

of the feet are to be rubbed with the water; but the friction is extended to the whole of the feet, ankles, and even legs, if they are weak and apt to swell, until a glow is felt.

The wet bandages (*Umschläge*) are of two kinds. When intended to stimulate, the wet portion of the bandage is covered with that which is left dry; when designed to cool, the whole compress is wetted, and left to evaporate uncovered. "For example, I saw the case of a large painful boil on the hand, in progress of suppuration. On this, the wetted part of the bandage, covered by the dry, was constantly kept, to serve as a water poultice; but above, on the wrist and fore-arm, a wet cloth only, never allowed to be dry, or even warm; on a just surgical principle of producing a sedative action on the vessels and nerves contiguous to the seat of disease."

The *Umschlag* often produces a great belt of rash round the body, or sundry boils, which are always hailed with satisfaction at Gräfenberg.

Next comes the douche, which, if vigorously used, is the most active of all the processes in the water cure. The temperature of the douches for gentlemen, in the wood at Gräfenberg, was as follows:—"Concordia, the strongest, about twenty feet fall, and of the size of a man's wrist, 54°; the stone douche, 48°; and the Ferdinand, 44°."

Strong patients sometimes use the douche in the coldest weather, when the attendant has first to break away the ice; but weaklings must beware of imitating their hardihood. The douche is a powerful rubefacient, and produces eruptions resembling measles, scarlatina, &c.

As for drinking, the quantity of water taken at the beginning of the course is from eight to twelve glasses daily, each glass holding from ten to eleven ounces. None is to be drunk when the body is very cold; nor much

without exercise. Water and milk are the only beverages at Gräfenberg.

On his return home, Sir Charles Scudamore had a conversation with Liebig on the water-cure. This eminent chemist believes the purity of the water drunk to be of the utmost consequence for its quick absorption. If it contains two per cent. of saline matter, it will pass to the bowels; but if it is of sufficient purity, eight-tenths will be eliminated by the kidneys in the shortest possible time. In answer to a question of Sir C. Scudamore's, Liebig thought that no injury would arise from the water carrying off the salts of the blood, as the quantity of salt in the foods might be a little increased, to allow for this waste. Pure water is absorbed so instantaneously, that Liebig, like Sir Everard Home, is inclined to believe in a short cut between the stomach and kidneys.

Sir Charles objects to the drinking a large quantity of water in cases of hæmorrhage that require restraining; even in piles, if the blood is arterial, the flow must not be rashly encouraged or permitted.

Sir C. Scudamore went to Gräfenberg partly to be treated himself, having been a sufferer for many years from rheumatic and nervous headache, with noises and deafness in the left ear; and being constantly dependent on medicine for the action of the bowels.

His treatment began on the 18th of April, a few days after his arrival, and continued till the 20th of May. Once during this period he took blue pill and colocynth at night, and Cheltenham salts in the morning, being bilious from the change of diet, and the free use of milk.

The details of his course are very interesting, and replete with instruction. The result has been most satisfactory, his health having improved in all the points where it was deficient.

He narrates forty cases where the water-cure was employed, and generally with complete success.

In one instance, a patient of five-and-twenty, having been attacked with violent pain between the lower ribs while walking, was subjected to pretty active treatment by Priessnitz, and recovered perfectly. Sir Charles thinks that there was an error in diagnosis on the part of Priessnitz, who supposed it to be a case of internal inflammation; Sir Charles knew it to be a muscular pain connected with indigestion and intestinal flatulence. During his stay at Gräfenberg, he often heard of the stains of mercury and iodine, of a blue or reddish colour, on the sheets. Liebig offered this explanation to Sir Charles: that mercury may remain combined with animal matter for an indefinite time, and may be separated through the quick change of matter which belongs to the water-system.

After seeing Liebig, Sir Charles visited the establishment of Marienberg, close to Boppard, on the Rhine. This is perhaps the handsomest hydropathic establishment in Europe, but the treatment is less vigorous than at Gräfenberg. It is under the direction of Dr. Schmitz; and patients have the advantage of consulting a distinguished English physiologist, whose name is known to all our readers, and who has himself benefited by the treatment there.

Sir Charles very properly speaks of the water-cure as a valuable addition to the resources of the medical art, rather than its rival or foe. What the proper limits of the system may be, remains to be ascertained. The hydropathists seem still to be in the honeymoon of their experience; they have not yet trodden the thorny paths of ordinary practice, when enthusiasm has fallen asleep, and patients are no longer docile.

CASE OF SUDDEN DEATH SIMULATING POISON BY OPIUM;

SHOWING THE NECESSITY OF MEDICAL
CORONERS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you think the following case worthy of notice, you will oblige me by inserting it in your valuable periodical.—I am, sir,

Your obedient servant,

J. BERNCASTLE, M.R.C.S. &c.

Croydon, July 16, 1843.

I was sent for, on Tuesday, the 25th April, 1843, at 6 A.M. to attend, on the part of the Croydon Union, the illegitimate infant, six weeks old, of a pauper named Aldridge. The child was said to be in a fit. On my arrival at the house I found the child dead. I had scarcely asked the mother and grandmother a few questions, when the latter begged of me to examine the body, and see that there had been no "misconduct" on their part. I thought that remark rather unusual, and examined the body more minutely, but could discover no marks of violence, or anything to lead me to suppose that the child had not died from natural causes. The face and body were quite pallid, and the mouth and eyes closed, without any unusual appearance.

A few hours afterwards, Mr. Smith, the registrar of deaths, sent to know whether an inquest would be required, as he had heard it reported by the neighbours that the child had died by unfair means. The inquest was consequently ordered, and thinking that I might elicit from the parties a few more points concerning the case, I called again in the afternoon, seven hours after death had taken place, and found the body laid out. I requested that the clothes should be taken off, and, to my great surprise, I observed the head, trunk, and extremities, to be covered with livid patches of ecchymosis, of a large size, pretty general all over the body. Knowing this cadaveric appearance so soon after death to be one of the common results from poisoning by opium, and having seen it in several cases that had terminated fatally, my attention was immediately directed to that channel, and I asked the friends whether they had given the child any syrup of poppies, Godfrey's cordial, or laudanum, but they stoutly denied having given anything at all.

After cross-examining them pretty closely, I learnt that the child, otherwise remarkably healthy, had been for the last few days un-

commonly fretful, and particularly so on the Sunday; that on Monday he became very drowsy, and slept all day and night without intermission, until early on the Tuesday morning, when it was suddenly seized with the convulsive fits that carried it off, and to relieve which I had been called in.

The history of the case, coupled with the appearances of the body after death, being, as every medical man knows, exactly those of poisoning by opium, the impression on my mind at the time was, that the child might have died from the effects of that drug, or some of its compounds, either given intentionally, or in an over-dose through ignorance. The child being illegitimate might have also tended to strengthen the first suspicion. In fact, had the child been known to have died from opium, the appearance above named would be all that one would expect to find without an autopsy.

Well, what did Mr. Carter, the coroner for Surrey, do? Instead of being guided by the medical evidence, and using it as the means to come at the truth, he at once turns round upon me, and wishes to persuade the jury that there are no grounds whatever for presuming that the child had died from any other than natural causes; that he had frequently seen the livid appearance of the skin, which always arose from persons lying after death; that infants frequently died from apoplexy, and the like trash; that, besides, it was absurd to suspect that any thing had been given when the mother and two other respectable witnesses swore to the contrary; that they being respectable people (all three, paupers and interested parties), he was bound to believe them on oath; and that he did not think a *post-mortem* necessary, as there was not the slightest tittle of evidence to prove that any thing in the shape of narcotics had been administered! Now the chain of symptoms and circumstantial evidence throughout this case were so clearly those of death by opium, and so unlike death from any other infantile disease, that nothing but the grossest ignorance on medical subjects can excuse Mr. Carter for having so totally overlooked them, and disregarded the suggestions of the medical witness. On the contrary, he so far forgot his duty, that he actually, in summing up the case to the jury, endeavoured to throw a slur upon the medical witness, by inferring that he had acted wrongly by at all exciting suspicions in a case where nothing whatever could warrant any person in supposing that the child had died from any other than natural causes.

But had a *post-mortem* taken place, and, in spite of the oaths of these three very respectable witnesses, poison had been found in the child's stomach, annulling all doubt upon the subject—and such cases are not uncom-

mon—would he have thought them so lightly of medical evidence?

The case was now dismissed summarily, and all parties entirely exculpated from any blame, the verdict being—"Died from natural causes."

Now would not a medical coroner at once have fallen in with the views of the medical witness, and would not his attention have been seriously arrested upon the probability of poison in a case where all the circumstances were so well linked together as to arise rather more than a suspicion of guilt? Is it not generally by some vague unconnected facts that cases of poisoning are at first brought into notice? Before detecting the poison, are there not premonitory and concomitant signs and circumstances, that put one on the *qui vive*, and lead one to seek for it by further anatomical investigations? How, then, can any person not well acquainted, practically as well as theoretically, with this intricate branch of the profession, presume to offer his opinion on subjects of such importance that they may involve the life of a fellow-creature? It is an anomaly that cannot exist any longer in a country that boasts of ranking first in civilization. The time must come, and come shortly it will, when none but medical coroners will be allowed to fill that high office. Until then we must not be surprised to see doubtful cases smothered in a similar way to the one here cited, by Mr. Carter, or any other of his sapient non-medical colleagues.

DISEASES OF THE EYE.

To the Editor of the Medical Gazette.

SIR,

IN reviewing my recent work "on Diseases of the Eye, and on Miscellaneous Subjects Medical and Surgical," the following statement is made in the last (July) number of "The British and Foreign Medical Review:" "On points of history Dr. Hall is generally wrong; as, for instance, where he ascribes the notion, that in purulent ophthalmia the cornea dies from the pressure caused by the chemosed conjunctiva, to Mr. Middlemore (p. 56), the first demonstration of the advantage of mercury in iritis to Dr. Farre (p. 101), &c. &c." I should feel much obliged if the reviewer, or any of your correspondents, would inform me to whom the priority in question properly belongs.

I remain, sir,

Your faithful servant,

J. C. HALL.

Grove Street, East Retford,
July 19th, 1843.

THE QUEEN'S COLLEGE, BIRMINGHAM.

HER MAJESTY has been graciously pleased to grant a Royal Charter of Incorporation to the School of Medicine and Surgery at Birmingham, with the privileges, immunities, rank, and title of "The Queen's College at Birmingham." Her Majesty has been graciously pleased to nominate Samuel Wilson Warneford, Clerk, of Bourton on the Hill, Gloucestershire, the first visitor.

Edward Johnstone, Doctor of Physic, of Edgbaston Hall, in the County of Norfolk, First Principal of the said Society.

James Thomas Law, Clerk, Chancellor of the Diocese of Lichfield, the first Vice-Principal.

John Edwards Piercy, Esq. Justice of the Peace of the County of Stafford, Treasurer.

William Sands Cox, Fellow of the Royal Society, London, Senior Surgeon of the Queen's Hospital, Dean of the Faculty; who, together with—

William Penn Curzon Howe, Earl Howe, George William Lyttelton, Lord Lyttelton,

John Kay Booth, Doctor of Physic, Licentiate of the Royal College of Physicians, Honorary Physician of the Queen's Hospital,

Edward Townsend Cox, Senior Surgeon of the Town Infirmary,

Egerton Bagot, Clerk, Vaughan Thomas, Clerk of Corpus-Christi College, Oxford,

James Taylor, Esq. Justice of the Peace for the County of Worcester,

Joseph Webster, Esq. Justice of the Peace for the County of Warwick,

Richard Wood, Senior Surgeon of the General Hospital, Birmingham,

Thomas Uppill, Merchant,

James Johnstone, Doctor of Physic, Fellow of the Royal College of Physicians, London, Senior Physician of the General Hospital, Birmingham, Professor of Materia Medica,

John Best Davies, Doctor of Physic, Extra Licentiate of the Royal College of Physicians, London, Senior Physician of the Queen's Hospital, Birmingham, Professor of Forensic Medicine,—as the First Council.

COLLEGE OF PHYSICIANS.

THE following is the correct list, in the order of their admission, of the Physicians elected Fellows of the Royal College of Physicians, London, on the 25th of last month :—

Dr. Thomas Thompson, Tunbridge Wells.—Dr. Augustin Sayer, Upper Seymour Street, Portman Square.—Dr. John Webster, Lower Grosvenor Street.—Dr. Thomas Dowler, Richmond.—Dr. Sigismund Stolterforth, Dover.—Dr. Edward Rigby, Spring Gardens.—Dr. Peyton Blakiston, Birmingham.—Dr. Arthur Farre, Curzon Street.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, July 21, 1843.

T. Cattell.—J. C. Harper.—G. M. Henning.—H. F. Williams.—P. P. Ransom.—T. L. Philippa.—A. Markwick.—R. D. Walker.—J. L. Milton.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXXVII.

*On Labours complicated with Inversion and
Rupture of the Uterus and Vagina, and
Extravasation of Blood into the Labia.*

IN the autumn of 1825, I was consulted by a lady at Odessa, in the ninth month of pregnancy, who was suffering much more than she had ever done before during gestation from pain increased by pressure in the region of the uterus, and febrile symptoms. I recommended her to lose blood from the arm, or to have leeches and fomentations applied to the abdomen; but no antiphlogistic remedies of any kind were employed, and she continued to suffer till the pains of labour commenced. The child was soon expelled, but the midwife in extracting the placenta inverted the uterus, and when I saw the patient about half an hour after, the whole uterus, the entire fundus and body, was hanging out between the thighs like the head of a child; the uterus had in fact been drawn like a stocking or glove completely inside out. The bed and floor were covered with a great quantity of blood, and the lady was expiring in convulsions. On applying my hand over the hypogastrium, the fundus of the uterus could not be felt there in the usual manner; and although the placenta had been entirely detached and removed, there could be no doubt, from the globular shape of the tumor, its peculiar softness and compressibility, its sudden appearance along with the placenta after the birth of the

child, the red colour of its investing membrane, from which the blood still continued to ooze, that it was the inverted uterus. By grasping the uterus with the hand, and compressing the upper part firmly with the points of the fingers, there was no difficulty in reducing or reinverting it: a sufficient length of time had not elapsed to allow of the cervix and os uteri contracting, to prevent its reduction. The midwife informed me that the placenta was retained, and that little force was employed by her in removing it. This is the only case of complete inversion of the uterus which I have ever seen, and there was no difficulty in the diagnosis, and no doubt about the necessity of immediately replacing the uterus, for if the patient had lived, the reduction of the uterus would have been impossible in a few hours, from the strangulation of the body produced above by the cervix, and inflammation and swelling of the parts. Inversion of the uterus is frequently, if not invariably, the consequence of pulling at the umbilical cord, to extract the placenta immediately after the birth of the child, before the uterus has had time to contract, and while the placenta is still adherent. It is also stated to have happened when the child has been allowed to be rapidly expelled, when the umbilical cord has surrounded the foetus, or been unusually short. "From the same cause," says Dr. Burns, "or sometimes, perhaps, from sudden pressure of part of the intestines on the fundus uteri, occasioned by a strong contraction of the abdominal muscles, a part of the fundus becomes depressed like a cup, and encroaches on the uterine cavity. This generally rectifies itself, if let alone, but if the cord be pulled, or if there be any tendency in the uterine action to go toward the fundus, as happens when that part is lacerated, and may in like manner occur in the present case, the depression is speedily converted into perfect inversion, which may thus take place spontaneously, and without any fault of the attendant." "It has been

very thick root. It exactly resembled in size and structure this specimen [exhibiting it] of large fibrous tumor growing from the neck of the uterus by a peduncle as thick as the wrist. From this case, and the following related by Dr. Gooch, you will perceive that the diagnosis of completely inverted uterus is not always so simple and easy as some authors would lead us to suppose, or, indeed, can be drawn without a previous knowledge of the history of the patient, and that it is possible the uterus has not been extirpated in all the cases in which the operation has been supposed to have been successfully performed.

Mr. Borrett, surgeon, at Yarmouth, was called to a lady in labour with her sixth child. On his first examination he found a large fleshy tumor within the vagina. The anterior segment in the os uteri was easily felt, but the posterior was occupied and covered by the attachment of the tumor. After the orifice had dilated, and the membranes had burst, the head of the child not descending, Mr. Borrett introduced his hand, brought down the feet, and extracted the child. The placenta was expelled spontaneously. The patient now being delivered and easy, he left her at 7 in the morning. At 3 in the afternoon he found her in strong pains, as if there was another child, but as the abdomen was flat, and the contracted uterus could be felt in the abdomen, he was satisfied there was not, and gave her an opiate. At 8 o'clock at night he found that the pains continued violent, with a sensation as of a substance coming away, and he discovered a soft round tumor pressing against the outer orifice. What could it be? He would have thought that it was the uterus inverted, but it was the same tumor which he had felt in the morning before the child was born; there was no hæmorrhage; the placenta had been expelled spontaneously, and the uterus was distinct in the hypogastric region. He consulted his medical friends in the town, and sent off to Norwich for Mr. Rigby. The pains continued with violent expulsive efforts all night, and the next morning they found her with a languid pulse and pallid countenance: a large fleshy livid tumor had been forced out of the vagina, and every pain brought it more and more in sight: she continued to suffer and to sink through the rest of the day: in the morning Mr. Rigby arrived, but she had expired about half an hour before.

As soon as he arrived he examined her, and was convinced that it was an inverted uterus. On opening the body in the morning, the uterus was found contracted, but its orifice was dragged down as an external orifice by a tumor which he felt it by a thick stalk; it was at the posterior part of the orifices,

and some way up the neck, was of a livid colour, and weighed three pounds fifteen ounces.

"When the uterus," says Dr. Merriman, "with the placenta attached to it, is drawn in an inverted state without the vagina, no doubt can exist as to the nature of the accident, but if it should happen after the exclusion of the placenta, more difficulty in forming an opinion would arise. The following rules, however, would lead to a correct judgment:—If a globular tumor is found soon after delivery in the vagina, or protruded through the os externum, it must be supposed to be either a polypous excrescence, a prolapsed uterus, or an inverted uterus. If it were a polypus, it would be known by its insensibility, its mobility, and its pedicle, which a careful examination could hardly fail to discover; the edges of the os uteri surrounding the tumor would likewise be perceptible. A prolapsed uterus may always be known by the os uteri being situated at the most depending part of the tumor. The inverted uterus is sensible to the touch, is less moveable than the polypus, has no pedicle, nor a dependent mouth; in a recent state it is entirely covered with a grumous discharge proceeding from numberless blood-vessels upon its whole surface."

All the systematic works on midwifery contain the histories of cases of complete inversion of the uterus. I have selected the following from many others to illustrate the effects produced by this dangerous accident, and to impress upon you the necessity of immediately detaching the placenta if it adhered, and reducing the uterus. Should you meet with a case in your own practice, it would be a lasting disgrace to you to invert the uterus, whatever the result might be.

In 1684 Mauriceau saw a woman whose uterus had been inverted eight months before by an ignorant midwife, and who was much exhausted by hæmorrhage. He found it impossible to reduce the uterus. He relates another case which occurred in 1693, two days before he saw the patient: the uterus was irreducible, and she ultimately died from the pain and discharge.

Giffard's 176th case is entitled "A delivery where the uterus was inverted and drawn out beyond the labia pudendi, and the placenta adhering to the uterus." "January the 29th, 1730-31, I was, about 8 o'clock in the evening," he says, "sent for to the wife of a brother surgeon in Surrey Street. The child was born about an hour before I came, and the midwife, in attempting to bring away the placenta, had inverted the uterus, for, upon examination, I found the whole body of the uterus, with the placenta, adhering to the fundus, hanging out beyond the labia; there was a great profusion of blood, and the woman was dead before I came. I rebuked

the midwife for not sending sooner, and told her that she, through her ignorance, was the immediate cause of the poor woman's death, for, by pulling the string too forcibly, she had drawn out and inverted the womb. Before I examined, the midwife told me the placenta was partly brought out, being ignorant that she had also pulled out the womb; but I showed her her error, that the placenta was all brought out, and only adhered to the fundus uteri, which, as the whole womb was inverted, hung out beyond the labia pudendi. This case should be a caution to all practitioners how they attempt to bring away the placenta, and not to pull the string too rudely, lest they invert and draw out the uterus, by which the woman dies a martyr to their temerity and ignorance, as was too plainly the case in the precedent observation." Chapman's 28th case is similar:—"I was, in the greatest haste, sent for to a woman six miles distant from me, to whom I went with all possible speed, but found on my arrival that she had been dead nearly half an hour. I conjectured she had died from flooding, but upon asking the question was answered in the negative. The midwife told me that the after-birth stuck so fast in one part that she was not able, with all her strength, to take it from her, though she had gained most of it. Upon this I desired the favour of seeing the corpse, which being granted, I found, to my great surprise, that the uterus was inverted, and entirely out of the body, hanging down between the thighs, with the placenta adhering to its fundus, which I separated before the midwife and several matrons there present, and convinced them all of the dismal accident. This woman, it seems, had a very good and easy delivery of the child; but, that born, the midwife pulled hard at the string, and so brought down the uterus, which as soon as she could take hold of, she did, and then pulling with fresh violence, and not being deterred by the loudest cries, the poor miserable woman in a few minutes fell into strong convulsions and deliquiums, and so expired. Thus was a young healthy mother cut off in the bloom of life, and cast into the cold arms of death just as she was about to clasp her first-born in her own."

Smellie was called to a woman who died before his arrival. He found the uterus inverted, pulled quite without the external parts, and the placenta adhering firmly to the fundus. This misfortune was occasioned by the midwife pulling at the placenta with too great force. Mr. Lucas, of Pontefract, sent the following account of a case of inverted uterus to Smellie, which occurred in 1753:—

"In April last I was called to a woman just delivered of a live healthy child, and to my surprise found the uterus totally inverted, lying between her thighs, of the size of a

large foot-ball. The woman's pulse was weak and unequal, and there was a continued pouring forth of blood from the vessels of the uterus. I apprised the friends of the great danger of so deplorable a case. Nevertheless, with the approbation of a judicious physician, her neighbour, I undertook and succeeded in the reduction, and after gave her gentle anodyne and cordial medicines, and left her, in appearance, better and tolerably easy. In about half an hour I was again called, and found her speechless, the pulse imperceptible, clammy sweats, respiration deep and slow, and in a few minutes death closed the scene. All the parts were so lax that the uterus had not the power of contraction, for it was lying like a loose piece of tripe, and taken for an excrescence, till I examined it more strictly, and after separating the placenta reduced it into the abdomen.

"On Thursday, the 21st of September, 1820," says Dr. Ramsbotham, "I was desired to be present at the opening of the body of a woman who had died in child-bed, and whose death had raised much clamour in the neighbourhood. I was informed by her accoucheur that she was, to all appearance, safely delivered of her second child on the Sunday evening, after a natural and quick labour; that he waited for the after-birth the greater part of an hour, before he made any attempt to remove it; and that he then began to pull at the funis, without being able to bring it down. Finding, after some further time, that it did not descend, he attempted to introduce his hand into the uterus; but in this attempt he was foiled. Waiting a little longer, a strong after-pain came on, when he made another trial by the funis; and finding an advance, as he thought, continued to extract, when, to his surprise and alarm, the uterus came out of the parts as large as a child's head, with the placenta adherent to it. Previous to this unfortunate occurrence there had not been much discharge of blood, but now the woman began to flood violently, and soon became faint. He now endeavoured to separate the placenta with his hand, but the violence of the flooding deterred him, and he desisted. Frightened beyond measure at the dilemma into which he had brought himself, and not knowing how to proceed, he sent for a medical friend, at the distance of about a mile, and waited his arrival; the poor woman all the time becoming worse and worse. His friend peeled off the placenta while the uterus was inverted, and during the operation there was an increase of loss. The woman was now in *articulo mortis*, and the uterus was passed into the vagina, but not reverted. I first passed my finger into the vagina, and found it completely filled up by the inverted uterus, which had now become flaccid; during life it had been firm and re-

sistant." Nothing farther was ascertained respecting the relative state of parts in this case. Dr. Ramsbotham has "never seen a case immediately after inversion; but I was desired," he says, "some months ago, to visit a poor woman in Shoreditch parish, three weeks after delivery, to whom the accident had happened at the time of labour, but it had not been detected. The inverted uterus was then about the size of a goose's egg, and regularly contracting. The woman had suffered much from flooding and its consequences, but was recovering."

But inversion of the uterus may be partial or incomplete, so that the fundus and body are retained within the vagina, or protrude very slightly through the os uteri. On the 17th February, 1843, I saw, in consultation, a case of partial inversion of the uterus, fourteen hours after the accident had occurred; and this is the only case of inverted uterus I have seen in London. The patient had been delivered of her first child after an easy labour; but the umbilical cord was not only twisted firmly round the neck, but was remarkably short. The placenta was not expelled for half an hour, and then Mr. — found it protruding through the external parts with the uterus, to which it still adhered. The placenta was detached from the uterus and removed, and an unsuccessful effort made to reduce the uterus. The discharge of blood which took place was not very profuse; and an opiate having been administered, the patient, though considerably exhausted, suffered little pain during the interval between the delivery and the time I was called to see her. On passing my hand into the vagina, I found its upper part completely occupied with the fundus, and a portion of the body of the uterus, like a soft cricket-ball. So firmly was the neck of the uterus contracted above, that all my efforts, which were long continued, to reduce or push up the inverted uterus, were unavailing, and the uterus remains now, I believe, in the same condition, and the patient suffers continually from pain, profuse menorrhagia, and leucorrhœa, and will continue to suffer from these symptoms from the inverted uterus during the remainder of her life. There is the greatest probability that if the same efforts to reduce the uterus had been made within a few hours after the displacement occurred, they would have been perfectly successful. If you should meet, therefore, with such a case, the symptoms of which would be the absence of the fundus uteri in the hypogastrium, hæmorrhage, pain, and the tumor in the vagina, pass the hand at once within the vagina, grasp the inverted portion of the uterus, and firmly compress its upper part with the fingers like a hernial sac, and force it back, and carry the hand forward into the cavity to be sure that the

reduction is complete. Remember, that if the attempt fails, the evil speedily becomes irremediable. If the placenta still adheres, some recommend that it should not be removed till we have reduced the uterus; but it is difficult to conceive what benefit can result from pushing back the mass of the placenta into the uterus, and afterwards extracting it. Partial inversion of the uterus, though sometimes immediately fatal by hæmorrhage, does not always produce death. In a patient whose case has been related by Dr. Cleghorn, menstruation was performed by the inverted uterus, and she enjoyed tolerable health for twenty years after the accident. When the inverted uterus is irreducible, we ought to palliate the symptoms, of which pain, hæmorrhage, and leucorrhœa are the most distressing, by appropriate remedies. If the life of the patient is greatly endangered by the irritation and discharge, it is justifiable to attempt her relief by removing the inverted uterus with a ligature. Numerous cases have been recorded since the days of Ambrose Paré, in which this operation was successfully performed, and there are many others in which attempts to extirpate the inverted uterus have been followed by fatal consequences. It should not be had recourse to if the patient's life can be preserved by any other means. It is unnecessary to detain you by reading any of these cases, fortunate or unfortunate; and the operation, which is nearly the same as tying a polypus of the uterus, will be described hereafter.

On Rupture of the Uterus.

This may take place in any part of the walls of the uterus, but it is most frequently observed in the cervix and towards the sides, or behind in the part corresponding with the promontory of the sacrum. The rent may have a longitudinal direction, or it may take a transverse, or oblique, or curved course. When the cervix uteri is torn, the vagina is most frequently involved in the mischief. The edges of the laceration are usually thin and ragged, and of a red livid colour, as if gangrenous. Where the rupture is extensive, and is situated in the lower part of the uterus, the foetus, with the placenta and membranes, are sometimes forced out of the cavity of the uterus, through the rent, into the sac of the peritoneum; and if the hand be applied to the abdomen, the different parts of the child can be distinctly felt through the parietes.

In all cases of difficult and protracted labour, where an obstacle is presented to the progress of the child, which the uterus has not power to overcome, the occurrence of fatal rupture of its coats is the accident we have most to dread. It is of no importance whether the disproportion between the child

and pelvis depends upon an unfavourable position of the child itself, as in arm and shoulder presentations, hydrocephalus or ascites, distortion of the bones of the pelvis, or tumors of the ovaria and uterus, malignant disease of the os uteri, or cicatrices of the vagina. The effect produced is the same, whatever the cause of the disproportion may be; and the upper part of the uterus often goes on contracting, until it forces the head of the child, or the whole body and placenta, through its walls into the abdominal cavity among the intestines. The reason why the lower part of the uterus is most frequently lacerated is obvious. In labour it is the fundus and body only which contract; the os and cervix uteri are relaxed. The lower part is in a state of relaxation; and when the head of the child here meets with a resistance from the distorted pelvis, which cannot be overcome, it is forced laterally or posteriorly, by the pressure above, through the walls of the uterus; the coats burst over the head as a small soft glove does when drawn hastily upon the hand, or the hand is roughly pushed into it.

"There is one fact," observes Dr. Collins, "which clearly shews disproportion to be a frequent cause, namely, its being oftener met with in the expulsion of male children; thus of thirty-four cases which I am about to state, twenty-three of the children were males; and of about twenty mentioned by Dr. M'Keever, fifteen were males. This is satisfactorily accounted for by the greater size of the male head, as proved by accurate measurements made by Dr. Joseph Clarke, which may be seen in his second letter to Dr. Price. Of sixty male and sixty female children born at the full time, Dr. Clarke found that the average circumference in the males was fourteen inches, and in the females thirteen inches and five-eighths; the arch from ear to ear over the crown was seven and a quarter inches in the males, and only seven one-fifth inches in the females. Of the one hundred and twenty examined, there were only six where the circumference of the head exceeded fourteen and a half inches, all of which were males. This difference may appear trifling, but in a practical point of view it is of vast importance, especially where any diminution in the size of the pelvis exists."

"The part that most usually gives way is at the junction of the cervix uteri with the vagina, either anteriorly or posteriorly; and, according to my experience, equally in both situations. Of thirty-four cases that occurred in the hospital, in thirteen the injury was in the posterior part; in twelve, anteriorly or posteriorly; in two, laterally; in one the mouth of the womb was torn; and in six *the particular seat of the laceration was not described.* In nine of the thirty-four cases

the peritoneal coat of the uterus was uninjured, although the muscular substance of the cervix was extensively ruptured. One singular case occurred in the hospital, precisely similar to that recorded by Dr. John Clarke, in the Transactions of a Society for the Improvement of Medical and Surgical Knowledge, vol. iii. where the patient died with all the symptoms of ruptured uterus. On examination, however, no rupture could be discovered; but on throwing forward the fundus uteri numerous lacerations were observed in the peritoneal covering of its posterior surface; the injury being confined to this membrane. I have never seen an instance where the fundus was ruptured; nor did Dr. Clarke, during his residence in the hospital, meet with such an occurrence."

Soon after the occurrence of this dangerous accident the labour-pains diminish greatly in strength, or entirely cease, the presenting part of the child recedes, hæmorrhage to a greater or less extent takes place from the vagina, and it is evident from the collapse of the features that a serious internal injury has been inflicted on some vital organ; the respiration becomes hurried and laborious, the pulse rapid and feeble, the extremities and the whole surface cold, and vomiting of dark-coloured fluid matters, like coffee-grounds, takes place.

These are the symptoms by which you will recognize laceration of the uterus during labour, and which sometimes takes place without any precursory signs. The pains are not so violent as to lead to any suspicion of what is about to occur; the uterus may be torn extensively before the patient has been twenty-four hours in labour, and where there has been nothing peculiar observed in the character of the pains, and nothing like irregular violent spasmodic contractions of the uterus around the body of the child; the accident may happen without the patient feeling any peculiar pain or sensation of tearing of the parts within, and where no sound is heard either by herself or by those around her. But if rupture of the uterus has taken place in some cases without any premonitory symptoms, there is reason to believe that it has happened in many where it might have been foreseen and prevented. What can be expected to occur but rupture of the uterus where the hand is rudely forced up into the cavity of the uterus to turn the child, when the organ is firmly contracted around its body, and the liquor amnii has been long discharged? What else can be looked for but laceration of the uterus and vagina where the blades of the forceps are pushed up between the head and a deformed pelvis, before the os uteri is more than half dilated? In cases of distorted pelvis, where the head of the child has been allowed to remain many hours jammed in the brim,

where the promontory of the sacrum projects in the form of a sharp angle, and the sacro-pubic diameter is much reduced, fatal laceration of the posterior part of the uterus is what we have just reason to apprehend, if we do not, in proper time, relieve the patient by the operation of craniotomy. In a deformed pelvis, where the head has long remained in the same position, and the abdomen is tense, and the different parts of the child can be felt remarkably distinct, and the labour pains occur at short intervals and with unusual intensity, and produce more suffering than labour pains usually do, making the patient exclaim that she is about to burst, rupture of the uterus will probably take place, if the labour is allowed to proceed and no treatment is employed. It was supposed by La Motte, Levret, and Cranz, that the violent movements of the child could rupture the uterus; but the child is entirely passive when this occurs.

Softening of the uterus, by chronic inflammation or some other morbid process, appears occasionally to take place in the latter months of pregnancy, which renders it liable to spontaneous rupture when labour commences. A rent has sometimes occurred, with fatal internal hæmorrhage probably from the same cause, as early as the period of quickening, before the uterus had begun to contract. This preparation [exhibiting it] now upon the table was taken from the body of a woman who died from spontaneous rupture of the uterus, who had been delivered with the forceps in a former labour. The presentation was natural; there was no distortion of the pelvis; but towards the end of the first stage of labour the pains ceased, the presenting part receded beyond the reach of the finger, considerable hæmorrhage followed, and dark-coloured vomiting took place, and she died undelivered. This was the history of the case which I received from the midwife. I examined the body, and found the whole contents of the uterus in the peritoneal sac, with very little blood. There was an immense rent in the lower part of the uterus and vagina on the left side, the edge of which was of a dark red colour, and as soft as jelly. This softening had affected a considerable part of the uterus, and was not the result of decomposition. Dr. Merriman has related a similar case; and the uterus which I saw in the recent state had undergone a process of softening in the muscular coat at the part where the laceration existed.

The uterus has been torn by various kinds of external violence applied to the abdomen, and it is reported to have occurred from a violent fit of passion. "A woman," says M. Desormeaux, "has the abdomen strongly pressed between the wall and a carriage, another is thrown down by a horse upon an

angular stone or body which is directed against the umbilicus, a third falls with violence upon the abdomen; in all these cases the uterus is ruptured, and the foetus passes partially or completely into the peritoneal sac. The contusion, in these cases, has sometimes not led to immediate laceration; this has taken place afterwards, on making an effort or raising a weight. In a case of contraction of the cervix uteri, with retention of the placenta, the hand of the practitioner was forced through the coats of the uterus, and the woman soon died."

Treatment of rupture of the uterus.—Where the head of the child presents, and rupture of the uterus takes place, the best plan is without delay to deliver with the perforator and crotchet; and to prevent the child, during the operation, from passing through the rent into the peritoneal sac, pressure should be made over the fundus uteri, and the opening made in the head in the most gentle manner. I have seen no case of ruptured uterus in which it was possible to deliver with the forceps; and I am not aware that any case of ruptured uterus has been recorded in which a living child was delivered with the forceps. "Efforts have frequently been made to deliver with the forceps in such cases," says Dr. Collins, "but this instrument is seldom applicable, as the introduction of the blades generally forces the head out of our reach; besides, but little would be thus gained, for the child dies shortly after rupture takes place; the dimensions, too, of the pelvis are in such cases for the most part defective; all which circumstances would seem strongly opposed to this mode of delivery. In three of the thirty-four cases above alluded to attempts were carefully made to deliver with the forceps, but without success." Dr. Burns is of a different opinion. He says the child may live for hours, after rupture of the uterus, if the placenta be not detached, or the hæmorrhage great. If the head have entered the pelvis, and be within reach of the forceps, we must cautiously introduce the blades, taking great care not to press up the head or make it recede. From this hazard, and from observing that in such cases the child is generally dead, it has been advised, by good authorities, to perforate the head; but if we have no other inducement to use the perforator, I should consider that, unless the head be high, the forceps would be as safe in this respect.

If the child has passed entirely from the cavity of the uterus into the peritoneal sac, an attempt should be made without delay to extract it, by introducing the hand into the cavity and through the rent in the uterus, grasping the feet and drawing the child back into the uterus, and delivering as in the

common operation of turning. In the following case, related by Dr. Blundell, recovery took place under these circumstances. "A woman in this neighbourhood," he says, "had a contraction of the pelvis. It was a case that occurred to one of yourselves, but no blame attached to its management. I was called in, in consequence of collapse of the strength; and when I examined I found the child lying in the peritoneal sac, distinct from the uterus, the aperture of which was contracted, and I found further a large transverse rent opposite to the bladder. Well, in this case, agreeably to the rule, I determined to turn, and for this purpose introducing my hand into the peritoneal sac, I perceived the intestines, felt the beat of the large abdominal arteries, touched the edge of the liver, and ultimately reaching the feet of the child, I withdrew it by the operation of turning, subsequently abstracting the placenta and membranes, the woman recovering in a few weeks afterwards. About five years after the recovery I saw her, not so vigorous as before the accident, but nevertheless tolerably well. On very careful examination at this time the os uteri was found to present the natural characters, and not a vestige of a cicatrix was discoverable in the vagina any where above or below. The rupture, therefore, had been above, in the uterus itself. When, in this case, my hand was introduced to turn the foetus, the womb, large as a child's head, was felt lying upon the promontory of the sacrum, above and behind the rent."

If a considerable period has elapsed after the accident, and the uterus has contracted so closely that the hand cannot be passed through the orifice and the rent, the best practice would be to leave the case to nature. Some have recommended gastrotomy under these circumstances; but the child is already dead, and the mother could hardly be expected to survive after such an operation. But I had nearly forgotten to mention that the Cæsarean section was actually proposed by Cranz where, from the size of the head and dimensions of the pelvis, there were symptoms merely threatening rupture of the uterus, and before rupture had positively taken place; and that he considered it a great honour to have been the first to make this barbarous proposal. "J'aurais encore ici la gloire," he says, "d'avoir proposé le premier l'usage d'un moyen dont personne avant moi n'avoit eu l'idée pour le cas dont il s'agit."

If the foetus has escaped into the peritoneal cavity, and is allowed to remain there, the patient may recover without gastrotomy, and the foetus be afterwards discharged through an ulcerated opening in the parietes of the abdomen. It is probable that the

greater number of cases recorded by authors, in which this event took place, were cases of extra-uterine gestation, and that the foetus had never been within the cavity of the uterus. But in Dr. Cheston's case the foetus had undoubtedly been within the cavity of the uterus, for he states that, after acute labour pains, symptoms of ruptured uterus took place, and that the presenting part receded. The foetus remained many years in the abdomen, and became covered with a layer of calcareous matter.

In 1814, Dr. M'Keever published an interesting case of recovery after lacerated uterus, which shews the power which nature possesses in some individuals to repair the most dreadful injuries. A stout young woman had the uterus ruptured during labour which continued nearly thirty hours, and nearly four feet of intestine protruded into the vagina, and sloughed off on the 16th day after the accident. For about two years the patient voided all the fæces through the breech in the uterus. At the conclusion of that period the fæces took their natural course. Eighteen months afterwards the woman conceived, and has since at the full time been safely delivered of a small feeble child. I have already related to you the history of a case of rupture of the uterus from hydrocephalus in the foetus, similar in some respects to the preceding case, which fell under my observation on the 22d of June, 1842. If the patient is delivered after rupture of the uterus, and survives the immediate shock of the accident, it should be remembered that she is liable to perish from an attack of peritoneal inflammation and suppuration in the neighbourhood of the uterus.

Extravasation of Blood into the Labia.

One of the labia pudendi sometimes becomes suddenly and excessively distended with blood during labour, or soon after the birth of the child, from rupture of varicose veins or other vessels. The labium becomes of a dark livid colour, and as large as the head of a child in a very short time, and a great quantity of blood is sometimes lost, from the inner surface of the labium becoming lacerated. Its situation on one side, and its dark colour, will prevent you from supposing that it is the foetal membranes protruding, or a hernial tumor. Dr. Dewees states, that if the bursting of the inner surface of the labium does not take place in the first instance, the tumor is sure to yield in a short time from gangrene. When the part sloughs, he says, it exposes a large surface of coagulated blood, which quickly becomes decomposed and foetid. If the parts do not give way the pain is agonising: fever of an active kind is excited, delirium takes place, and the patient's life is greatly endangered. Her

sufferings are augmented by the retention of urine, and nothing gives relief but a free incision into the tumor to give vent to the extravasated blood. This should be done, he thinks, before the process of ulceration has commenced, or the chance of bursting. The urine should then be drawn off by pressing the enlarged labium to one side, and introducing the catheter, and warm fomentations to the hands and feet; but the progress of the symptoms is sometimes so rapid as scarcely to allow time for the administration of remedies. In the *Archives Générales de Médecine*, August 1834, several cases are related. A woman, aged 41, pregnant with her fifth child, was seized with labour pains, which gradually abated after the liquor amnii was discharged. In a short time, however, a violent pain was experienced, and the left labium became enormously swollen and discoloured. The tumor soon burst, and a great quantity of dark-coloured blood was discharged. She became exhausted, and soon died in convulsions. There was a laceration on the inner surface of the labium an inch and a half in length, through which the finger could be passed into a large cavity containing coagulated blood. On the right labium and inner surface of both thighs there were varicose veins. In another case the labour had lasted upwards of twenty hours, when the right labium was found greatly distended and discoloured, and blood was dropping from its inner surface. The patient died in a quarter of an hour. A rent two inches in length was found on the inner surface of the right labium, which led into a cavity nearly four inches in circumference, and which extended under the os pubis, and on the outer side of the ascending ramus: at the bottom of this sac was seen the ruptured orifice of the varix. There was distortion of the pelvis. Dr. Elbert was summoned to the assistance of another woman in labour, but she had just expired on reaching the house. She was 34 years of age, and the mother of seven children. The labour had begun favourably, and the pains had been at first regular and steady. On a sudden the woman felt that a quantity of fluid was running away from her, but she thought it was the waters; the nurse, however, found that it was blood. In half an hour the patient expired. On the right labium, which was swollen and livid, were seen three ragged wounds; through each of these the finger could be passed into a large cavity, which still contained a quantity of black coagulated blood. On the left labium and both thighs were numerous distended veins.

In all these cases death took place before delivery, and the children were dead when extracted. In the fourth case the delivery had taken place before the rupture of the

varicose swelling. Immediately after the expulsion of the child, the external parts became enormously swollen, and at length the integuments gave way at one point, and an alarming hæmorrhage took place. Professor Rieche immediately applied rags dipped in cold water, which arrested the flow of blood, and the exhausted strength of the patient was then supported by sinapisms to both legs, and by a cordial medicine exhibited frequently. Another woman, æt. 46, mother of eight children, suddenly expired in labour. Dr. Carus found the head of the child detained in the outlet of the pelvis: he delivered it with the forceps, but not without considerable difficulty; for the pelvis was confined. On introducing the hand afterwards to extract the placenta, he found near the cervix of the uterus a ruptured varicose tumor; the rent was about $1\frac{1}{2}$ inch long, and the extent of the cavity about two inches all round.

On the 13th of January, 1840, a patient of the Saint Marylebone Infirmary, with slight distortion of the pelvis, was in labour, and the face presented and became jammed in the brim. Violent uterine action was allowed to continue many hours, the head being too high for the forceps, when the right labium became enormously distended with blood, and burst on the inner surface, and a great hæmorrhage took place. When I first saw the patient the hæmorrhage was supposed to proceed from the uterus, but on making an examination I felt the labium immensely enlarged, and my wrist was covered with blood. It was evident that the patient would soon have died had the hæmorrhage not been arrested. The discharge of blood was checked by strong pressure with a sponge over the rent, while I opened and extracted the head. Cold applications were afterwards made to the part, and when the hæmorrhage had ceased emollient poultices, and she recovered rapidly. On the 2d November, 1841, I saw in consultation Mrs. —, who was far advanced in pregnancy, and had suffered much during the latter months from a varicose state of the veins of the right foot, leg, thigh, and labium. For six weeks the right labium had been much enlarged, and a painful circumscribed swelling had formed in it like an abscess, with throbbing, which led Mr. — to open it with a lancet: when this was done a small quantity of venous blood escaped, but no pus; and soon after the labium began to enlarge and assume a dark livid colour. It had attained nearly the size of a child's head when I saw the patient, and was as black as one's hat, and was so tense that it threatened to burst. It was evident the hæmorrhage was still going on. To arrest the discharge the labium was covered with pieces of ice with the best

effect, for the effusion soon ceased, and on the following morning the labour came on, and was completed by the natural efforts without a renewal of the hæmorrhage. Rapid absorption of the extravasated blood took place, and the patient speedily recovered.

In the next lecture I shall proceed to consider the Diseases of Puerperal Women.

EARLY MARRIAGES SO COMMON IN ORIENTAL COUNTRIES NO PROOF OF EARLY PUBERTY.

By JOHN ROBERTON, Esq.

[Concluded from p. 615.]

It has been already observed that the marriage of a ward was often put up to sale by the guardian. "In the Pipe Rolls of 28, 29, and 30, Henry II. Robert de Were, called son of Robert, son of Harding, accounted for fifty marks, and a golden cup of the value of forty marks, for having the daughter of Robert de Gant in ward."*

In some cases the sale brought a large, in others a moderate sum: William, Bishop of Ely, gave 220 marks that he might have the custody of Stephen de Beauchamp, and might marry him to whom he pleased. John, Earl of Lincoln, gave Henry III. 3000 marks to have the marriage of Richard de Clare for the benefit of Matilda, his eldest daughter; and Simon de Montford gave the same king 10,000 marks (equal to £100,000 at present), to have the custody of the lands and heir of Gilbert de Unfraville, with the heir's marriage; and Hugh de Flammerville proffered £10 for the custody of his sister with her land. In Maddox's History and Antiquities of the Exchequer, the reader who is curious will find a lengthy list of sales, such as the above, in Chapter X. "of the Crown Revenue."†

The most curious thing connected with the treatment of this species of property is the extremely cool manner in which wards are bequeathed along with ordinary goods and chattels: thus Sir John Cornwallis, Knight, in his will of date April 16, 1554, after a very

devout and pious exordium, and a specification of certain bequests, proceeds—"I bequeath to my daughter my wife's gown of black velvet; to my son Henry my own gown of tawny taffita; to my son Richard my ward, Margaret Lowthe, which I bought of my Lord of Norfolk, to marry her himself if they both will be so contented; but if not, I will that he shall have the wardship and marriage of her, with all the advantages and profits."*

Sir Reginald Bray, Knight of the Garter, August 4, 1503, bequeaths, among other items of property, two wards, in these terms: "Whereas I have in my keeping Elizabeth and Agnes, daughters and heirs of Henry Lovell, Esq. I will that Elizabeth be married to one of my nephews, son to my brother John Bray, and that the said Agnes to another son of my said brother."†

John Colet, the Dean of St. Paul's, August 22, 1519, wills, "all those my lands and tenements, rents, services, wards, marriages, reliefs, &c. &c. in the towns, fields, and morasses of Chip-pesby, &c. in the county of Norfolk."‡

Sir Thomas Wyndham, Knight, October 12th, 13 Henry VIII. 1522, bequeaths to certain parties "all my wards and marriages now bought by me, with all advowsons by any means belonging to me, &c. in the counties of Norfolk and Yorkshire."§

It would seem that the dread of wardship and marriage sometimes operated with parents in marrying their child at a tender age, with a view to evade this oppressive law. Thus Maurice, fourth Lord Berkeley, was knighted at 7,|| and was married at 8 years old to Elizabeth, daughter of Hugh, Lord Spencer, then but 8 years old, the reason being that early marriage prevented wardship, the payment of a large fine to the king, and assisted the party's own affairs with interest and powerful connections. This instance happened in the reign of Edward III. From a

subsequent entry it is uncertain whether or not the juvenile couple were permitted to cohabit till the age of 16; since at the age of 14 the young husband, it appears, was sent to travel two years in Spain.*

In my paper in this journal for July 1842 (*MED. GAZ.* vol. xxx. p. 677), on the period of puberty in the negro, I have given a number of instances (in a note) of early marriage, chiefly in the families of our kings, up to the date of the marriage of Henry VIII. with Catharine of Arragon. To these I now add some instances which I have gleaned when looking into family memoirs: although not very numerous, they will yet be found sufficient to establish the fact, that the gentry in general, and particularly the eldest sons, married about the age of puberty as late as till the middle of the seventeenth century. The libraries of a provincial town afford little scope comparatively for research in this particular line; but inquirers may possibly be incited by what they find in these pages to pursue the path now opened up, in circumstances more favourable to the elucidation of this trait of old English manners.

1247. John, [eleventh] Earl of Warren and Surrey, was married A.D. 1247, when 12 years of age, to Alice, daughter of Hugh de Brun, Earl of the Marches of Aquitaine.†

1303. Robert de Tatershal of Abkettleby, Leicestershire, married while under age Eva, daughter of Robert de Tiptoft, 13 years old.‡

1351. The Earl of Holland married Maud, daughter of the Duke of Lancaster: the lady, although a widow, was only 19.§

1456. Margaret, wife of Edmund Tudor, was left a widow and a mother at the age of 14.||

12 Edward IV. We learn from Cotton's Records that it was accorded that, at the age of 13 years, Cicill, only daughter of Katharine (some time the wife of Bonsile, Lord Harrington), should marry Thomas, the eldest son of the Queen, "between whom, if there was no mutual society, that the said

Cicill should marry with Richard, the brother of the said Thomas."*

17 Edward IV. The king creates Richard, his second son, Duke of York and Norfolk, &c., and appoints his said son to marry with Anne, the daughter and heir of John, late Duke of Norfolk, "the said Anne being then of the age of 6 years."†

1536. Henry Fitzroy, Duke of Richmond, in Somerset, married to Mary, daughter of the Duke of Norfolk, died, aged 17, July 24, 1536, without issue.‡

1532. Elizabeth Leak of Hasland, in Derbyshire, was married, at 14 years of age, to Robert Barley, of Barley, Esq. same county, "who was also very young."§

The mother of Catharine Parr (the last of Henry VIII.'s wives), Matilda Green by name, married Sir Thomas Parr when she was 13. Catharine, the daughter, was herself by a family arrangement to have married Lord Scroop when he came to the age of 13, and she to 12. This fell through, but she did marry Lord Borough, a widower, when she could not have been much above 12, since she is found by and by to be a widow in her fifteenth year. Again, while as yet under 20, she took for her second husband Lord Latimer.

By a solemn matrimonial treaty, signed at Windsor, the Emperor Charles V. engaged to marry his cousin, the Princess Mary, as soon as she arrived at her 12th year. This treaty fell through; but Cardinal Wolsey endeavoured to effect a marriage between Francis I. and the same Princess Mary, she being then only 11,—neither did this take effect. The fair Geraldine (of the poet Surrey), a lady of the court of Queen Mary, is married to Sir Anthony Brown when she is 16.||

1551. In certain instructions to the ambassadors in France, of this date, they are directed to inform the French king that, on the 12th October of the next year, Edward VI. would be 14 years old, and to request that the marriage with the lady Elizabeth (daughter of the French king) may take place three months after she shall have attained the age of 12 years.¶

1603. James, first Duke of Hamilton, born 1603, married the daughter of the Earl of Denbigh, he 14, and the bride 7.* Burnet says, "after the years for consummating the intended marriage were over, he was forced to it not without great aversion, occasioned, partly, by the disproportion of their ages, and partly by some other secret consideration."

1629. Lord Thurles married his cousin, Elizabeth Preston, (a king's ward,) only child of Richard Earl of Desmond, aged 14.†

A. D. 1667. Lady Diana Russell was married to Sir Grevil Verney when she was aged 15 years.‡

1680. Elizabeth, sole heiress of Joseline Percy, Duke of Northumberland, was married to Henry Cavendish, Earl of Ogle, who, however, died before he was of age to cohabit with her.§

1663. Elizabeth, Countess of Bridgewater, died this year in the 37th year of her age, having been married at the age of 13.||

These scattered instances of early marriage, gleaned at random from a variety of sources, are not without interest; but a clearer and more precise idea as to the prevalence of this custom in families of rank is obtained when the records of marriage in a particular family in successive generations are before us, as in the case of the Berkeleys; from which we shall see that the Lords of Berkeley, some ages ago, differed in this trait of manners little or nothing from the nobles of Russia, in the time of the Empress Catharine, or of her predecessor Peter.

Thomas, fourth Lord Berkeley, was contracted to Margaret, daughter of Gerard Warren, Lord Lisle [41 Edward III.] Amongst other items in the contract is this: "The same Margaret, by reason of her tender age (then about 7,) shall for *four* years remain with her father, and this Thomas de Berkeley with his father."¶ Elizabeth, only daughter and heir of the aforesaid Lord Thomas Berkeley, was contracted for marriage when she was under 7 years of age; the husband Richard the Earl of Warwick. It may be presumed

that the consummation of the marriage would take place about the age of puberty.* Thomas, son of William Marquis Berkeley, [Edward VI.] when 5 years old, was contracted by his father to Mary, daughter of Anne, Countess of Pembroke.† Maurice, fourth Lord Berkeley (whose case has been already mentioned), married at 8, his wife being of the same age. Maurice, sixth Lord Berkeley, 8 Henry VIII., "bought of the King the wardship of the body and lands of John, son and heir of Sir Richard Berkeley of Stoke; and, by his will, directed that he should be married at 16 years of age to Isabele Dennys, his sister's daughter; and if she should refuse, to Helen her sister, and so to Margaret her sister."‡ Lady Catharine, a daughter of the Earl of Surry, was married at 16 years of age to one of the Berkeleys, "by the bedside of her grandfather, the Duke of Norvolk, as he lay in his bed, then grown weak with age and sickness."§ George, Lord Berkeley, [12 James I.,] was married to Elizabeth, second daughter and co-heir of Sir Nicholas Stanhope, in the church of Great St. Bartholomew, London, and, in the presence of both their parents, he being 13 years old, and she 9. It appears that the bridegroom was sent to Christ Church, Oxford, to study for a time, his wife remaining with her father.|| What remains, though out of place as to date, is the most curious piece of information of any. Maurice, third Lord Berkeley, [Edward I.] was married at 8 years old, and a father before he was 14. The historian adds, "more than a dozen instances of paternity occur before that age."¶¶

More than a dozen instances of paternity occur, such are the words of the author of the *Lives of the Berkeleys*, before the age of 14. What an insight does such a sentence afford into the condition of families in the fifteenth, sixteenth, and seventeenth centuries, when this detestable precocity was unblushingly encouraged; assimilating the people of a Christian country, in this revolting feature, to the Pagan inhabitants of the South Sea Islands:

regarding whom, the Rev. Mr. Ellis informs me, that the union of the sexes is *never*, he believes, delayed so late as the period of puberty. It must have been a full acquaintance with, and strong perception of the evils of this nature, resulting from wardship and marriage, which could have drawn from Grafton, a faithful chronicler in the reign of Elizabeth, the following extremely curious display of humane and patriotic feeling.

"It is much lamented that wards are bought and sold as commonly as are beasts; and marriages are made with them that are many times very ungodly; for divers of them being of young and tender years, are forced to judge by another man's affection, to see with another man's eye, and say yea with another man's tongue, and finally consent with another man's heart. For none of these senses be perfected to the parties in that minority, and so the election being unfree and the years unripe, each of them, almost of necessity, must hate the other, whom yet they have had no judgement to love. And certainly the common bargaining and selling of them is to be abhorred, besides the shameful polling that many use, which, if they consent not to such as are their sellers, they shall be handled, as the common saying is, *like wards*, and stripped almost out of all they have, when the same should do them most good. God grant the magistrates may take some good order therein, for surely it is needful, for many do use them as the same is not sufferable in a Christian realm. For who seeth not daily what innumerable inconveniences, divorces, yea and some murders, have of such marriages (or rather no marriages) proceeded, the present time sheweth too many examples, which minister sufficient cause for us to bewail the same; but the greatest injury is to God, who hath made that free, namely, matrimony, which the law of this realm maketh bond; the redress whereof belongeth only to the Prince, in whom, like as the same God hath caused more virtues to meet than in any other creature of her calling, so we doubt not, but that his Godhead will, when his good pleasure shall be vouchsafed, not only to preserve her Highness, with the increase of virtue and wisdom, but also to move her heart to the godly

redress of these, and many other enormities and abuses, to the great comfort of all her Grace's loving and obedient subjects."*

Ireland, placed on the western verge of Europe, and never included within the bounds of the Roman Empire, from its remote position, was comparatively little exposed to those early migrations of energetic races from the north-east, by which nearly every other European country was at different periods visited, and by which the inhabitants were either extirpated, or renovated and improved. In this respect Ireland has undergone little change when compared with the island of Great Britain, and hence, (for reasons which will be obvious to the student of history, but which it is foreign to my present object to dilate upon,) it wears the traces of a somewhat recent civilization; the population in some of the remoter districts having, even at the present day, a resemblance in the depressed cranium, and strongly marked development of the bones of the face, to the rudest varieties of our species.

Amongst those evidences of a low state of moral advancement which might be mentioned, *that* supplied by the early age at which the sexes unite in marriage is not wanting, as we learn from various writers on the social condition of Ireland. To Dr Griffin, of Limerick, in the first place, we are indebted for an interesting table, exhibiting the ages at which 735 women of that city married. Of this number there were, at 13 years of age, four; at 14 years, seven; at 15 years, twenty; at 16, fifty; at 17, forty-eight; at 18, sixty-eight; at 19, seventy-two; at 20, eighty-three, being at the rate of about 50 per cent. married under age; whereas in England the highest per centage of women marrying under age is 25.19 per cent: this is in the county of Bedford. In North Wales it is only 7.89 per cent.†

"The extremely early age at which many of these marriages took place," says Dr Griffin, "will no doubt surprise people very much. I have reason to think they are not very incorrect; and those which occurred at the very

* Grafton's Chronicle, vol. ii. pp. 249-50. Lond.

† Fourth Annual Report of the Registrar-General of Births, Deaths, and Marriages in England, for 1842; containing very interesting tables concerning the ages of 40,874 persons married in three years. June 1841, folio, p. 8.

early ages stated were always strictly inquired into. Of the four females stated to have been married at 13, two are well-authenticated instances which occurred in the county; one of these had her first child at 14. The other two took place in the city, and were actually not quite 13 at the time of marriage. In one of these instances, when I said to the mother, 'this girl must have been exceedingly anxious to get married, to marry so very young,' she replied, 'Oh ! no sir, she knew nothing about marriage, or what belonged to it, but the priest sent her away three times, he thought her so young.' In general, I believe these early unions are brought about entirely by the parents."*

Mr. Edward Wakefield, in his *Statistical and Political Account of Ireland*, published in the year 1812, has furnished a good deal of curious information concerning social life in that country, and animadverts with severity on the early improvident marriages of both the lower and upper classes. He says, that "celibacy being unfashionable, domestic servants are generally married;" that the Roman Catholic peasant marries "in the greenness of youth, when reason seldom interrupts his career, and asks him whether he may not bring into the world a progeny for whom he cannot find the means of support. Thus a voluntary submission to the lowest state of life, and a disrelish for superior comforts, having become habitual, the system of premature marriage is perpetuated, while the increase of numbers is an unchecked increase of misery."

He represents the condition of women of the lower ranks as degraded in the extreme; that the man considers his wife as his slave; and that females are treated more like beasts of burden than rational beings; owing to which the traces of youth rapidly fade away. "In consequence of this harsh treatment, and continual exposure to the weather, added to the smoke of their cabins, and scanty fare, they exhibit a miserable spectacle, and acquire, at a very early period, every mark of old age. I have seen women who, from their appearance, might be supposed to be past the time of child-bearing, followed by very young children,

whom I did not consider as their own; but on inquiry, I found I was mistaken, and that their mothers were not above 30 years of age."

Mr. Wakefield asserts that young ladies in the higher classes "generally enter into the married state between the ages of 16 and 19;" that match-making in this rank of life is universal; that eighteen out of twenty marry the moment their mothers inform them that suitable offers have been made; and that, as might be expected, there is much deficiency in such youthful wives, both with respect to mental cultivation, and a competent knowledge of house-keeping.*

Perhaps the facts which have now been presented may be thought to warrant the following conclusions.

1st, That in England, Germany, and Protestant Europe in general, early marriage—that is, marriage about the age of puberty, would seem to be comparatively rare.

2d, That early marriage prevails amongst the uncivilized tribes which wander within the Arctic Circle; as it likewise does in all cold countries, without any exception, the inhabitants of which are in a state of ignorance and moral degradation.

3d, That throughout European Russia, which is confessedly low in civilization, extremely premature marriage was the universal custom at no distant date.

4th, That, at the present day, in the most southerly countries of Europe, where the people are immersed in

* An Account of Ireland, Statistical and Political, 4to. vol. ii. pp. 578, 579, 801, 802, 797, 799. From Mr. Crofton Croker we learn, that courtships are generally commenced among the peasantry of the south of Ireland "soon after the parties attain their teens." See his work on the South of Ireland, 4to. pp. 234—236. See also Letters from the Highlands of Connemara, 1825, by a Family Party, p. 96. Whilst I am writing this paper, I observe in the London Times of February 1st, 1843, a notice issued by an Irish landlord to his tenants, warning them against the practice of early marriage. "Is it possible for parents to shut their eyes, says this gentleman, to the consequences of it, which they must daily witness, in producing poverty and wretchedness around them? Yet, they permit their young married children to take their abode under the same roof with themselves, and thus give encouragement to hasty and improvident marriages, thereby impoverishing the entire family." The landlord proceeds to threaten such tenants as turn a deaf ear to this word of advice, with expulsion from his estate. The above notice is copied into the Times from Freeman's Journal, but the name of the philosophical landlord is prudently withheld.

* *Journal of the Statistical Society of London*, vol. iii. p. 322—3.

superstition and ignorance, marriage is early.

5th, That in Ireland, which, as to its moral condition, somewhat resembles the last mentioned countries, the marriage union takes place among the Roman Catholic population at an age probably almost as early.

6th, That in England about two centuries ago, when debasing political and social circumstances combined to favour the practice, early marriages were general, at all events in the upper ranks.

7th, That in all the countries to which reference has been made, juvenile marriage is invariably seen as an attendant on ignorance and moral debasement, and this without reference to *climate*.

8th, That consequently it is perhaps allowable to infer that early marriage in oriental countries (which has generally, in the absence of all proof whatever, been ascribed to precocious puberty,) does solely depend on the same moral and political causes as elsewhere produce it; more especially as those very causes are well known to exist, at present, in an aggravated degree in all oriental and intertropical countries.

9th, That, instead of ascribing early marriage, so prevalent in our Asiatic dominions, to precocious puberty, (in the absence of all evidence whatever of the fact,) it would be desirable to try moral and legislative remedies, with a view to the removal of a practice so injurious; a practice which seems to be incompatible with social improvement.

ON
SUMMER ASTHMA,
CATARRHUS ÆSTIVUS, OR HAY-
FEVER,

ITS CAUSES AND TREATMENT.

BY T. WILKINSON KING.

Dr. Bostock's cases.—Various symptoms—rationale—summer eruptions—the fever, variable—dyspnœa—mixed cases—treatment.

HAVING suffered from what is called hay-fever, more or less, for some fourteen summers, I have thought it worth while to set down my own conclusions on the subject, together with an addi-

tional fact or two; but I should scarcely have been led to do this at the present time were it not that I wish, in this way, to point to, and confirm, more general views of disease.

Dr. Bostock*, who has investigated the affections here referred to, speaks of twenty-eight cases, of which he had gathered various particulars. He says—

“They all agree in the complaint making its appearance at the same season of the year; in its seat being the membrane lining the nose, the fauces, and the vesicles of the lungs; and, for the most part, in the paroxysms being excited, and the symptoms aggravated, by the same causes. The twenty-eight cases referred to above all agree in the complaint commencing about the end of May or the beginning of June, and continuing from four to eight weeks. Most of them are attended with fulness of the head, stoppage of the nose, sneezing, watering of the eyes, and discharge from the nostrils. In about half of the whole number the respiration is considerably affected, and in three or four instances it is almost the only symptom. Some of the cases are attended with distinct cough, most of them with irritation of the fauces, and some with a degree of sore throat. Actual inflammation of the eyes is not a very common occurrence; and in some of the cases there is not even the discharge of tears, or the irritation of the eyes. The degree of general indisposition varies very much in the different cases; in some, the patient, during the whole period, is unable to use any exertion, or to continue his ordinary occupations; while, in other instances, he feels no inconvenience, except what arises from the fits of sneezing and the copious discharge from the nose.”

With regard to the local symptoms, Dr. B. observes—

“The immediate cause of the symptoms seems to be sufficiently obvious; it consists in an increased action of the vessels of the membrane which lines the eye-lids, the nose, the fauces, and the pulmonary vesicles, by which it becomes acutely sensible to external impressions, has its natural secretions

* This gentleman, who is justly distinguished in physiological and chemical science, was the subject of the affection in question, and has given the only original and satisfactory account of it that I am acquainted with. See the fourteenth and tenth vols. of the *Med.-Chir. Transactions*.

augmented, and probably its bulk increased; to this last cause I think we may ascribe the very distressing sense of dyspnoea which exists in some of the cases. Although this membrane is continued without interruption over the different organs that are the seat of the affection, yet it is observed that the different parts are affected in different degrees. Hence we may divide the disease into four varieties, according as the eyes, the nose, the fauces, or the lungs, is the part more immediately affected. It is in the last variety only that I have observed the constitutional symptoms of fever and the subsequent debility to exist in any considerable degree."

I conceive that Dr. Bostock could not intend, as above, to consider the injection as the cause, rather than the consequence, of impressions from without. And I do not suppose that the extreme languor that summer may produce is altogether set out of the question. He notes lightly the attendant fever which may be severe, and even continued, or exceed all other symptoms.

The various causes of the local irritations hinted at in books are more curious than instructive. One patient suspects his asthma to depend on a sewer; another seems to find relief from coal-smoke diffused in his chamber. Different sufferers appear to find peculiar ease only in situations which are peculiarly obnoxious to the sensations and respiration of others. One can sleep no where so well as in a close carriage; another found a cure in the very preparation for a journey. Some accuse this, and others that state of atmosphere. Here an asthmatic discovers that a feather pillow is his peculiar bane; and another is cured by cold ablutions of the chest. A full dinner aggravating the disorder, is foolishly thought to be a cause of it. Opium, stramonium, tobacco, or brandy, may work a sudden cure; but most of all, as in summer catarrh, the affection disappears (fails to reappear) as it were by chance. The preceding and countless vagaries are to be accounted for by reference to simple principles*. We have to calculate that, according to circumstances, a certain number of hours having elapsed after exposure (specific or general), eating,

or lying down, capillary excitement or distension is to be evinced by uneasiness, obstruction, and various forms and quantities of secretion. Beyond this, we believe, very few of the phenomena of hay-fever or asthma will remain unresolved. The time at which the affections prevail is that of diminishing our clothing.

It seems to me, in the first place, not unreasonable to compare these affections with summer eruptions, in which we must discover both a cause of local disturbance, which we treat locally, and more or less of general internal disturbance, for which we administer medicines. A delicate female passes a few hours in the open air, wearing, perhaps, only a light bonnet, and suffers from blistering of the face. Now, whether the external cause be heat or air, we see that defective nutrition is the first internal local condition. On the other hand, another, in more robust health, after exposure, or a feast, suffers almost imperceptibly from feverishness, and herpetic vesicles break out over the lip.

There are a good variety of disorders which, if we consider the seat or the elimination (as to quantity or quality), seem to indicate but inconsiderable deteriorations (say of the blood), with rather more of decline of vital or nutrient powers—deficiency rather than perversion. External agency here becomes proportionably efficient to disturb. Our present subject may illustrate this opinion.

In the case of hay-fever, the febrile symptoms are, I think, to be referred to a perfectly distinct causation, beginning mostly with the effects of cold to the surface, but I by no means exclude the probability of increased susceptibility, and even some general decline and atrophy, the more gradual effects of heat. The variability and relapses of the languor and fever, as well as of the local symptoms, demand a reference to fresh disturbing causes, and no doubt diet, exercise, and even posture, have their particular, yet changeable effects.

I make some exception to the conclusion of Dr. Bostock, that the air-cells of the lungs are especially affected; and I prefer to set down the dyspnoea as the result of turgescence in the lining of the air-tubes. It seems natural that the more superficial dis-

* *Vide a series of papers on Angina, MEDICAL GAZETTE, 1841.*

orders should be most controlled by direct atmospheric influence, and certainly that the deeper should rather be dependent on less direct and more general causes. Sputa of branching mucus declare their own origin.

I think I have at different times experienced most of the symptoms described by Dr. Bostock, but not only in summer.

I am subject to slight attacks of dyspnoea especially on lying down, attended by a very slight ropy and clear secretion in the trachea. It seems to depend on a local injection and diminution of the laryngeal passage. On rising or walking it quickly disappears, and my feet betray the accumulation of blood (only) which gravity has removed from the neighbourhood of the pharynx, which at times also readily becomes tumid.

An attentive unprofessional man of very similar diathesis, who is subject to this kind of derangement, sits up in his bed and finds relief in a dish of hot coffee, which accelerates the general, and liberates the local circulation.

Dr. Bostock observes that he has met with nothing of these affections among the lower classes of society, but I think I have known of its occurrence in masked and aggravated forms, which I attribute to difficulties and exposures of a severer kind to which the poor are subject. I make very little doubt also that these same catarrhal disturbances of summer are of more frequent occurrence under a less distinct form; namely, that of aggravation of affections which in some degree the sufferer considers as habitual and almost natural to him. One cannot travel without incurring ophthalmia, another asthma. Many suffer in particular localities, or seem to require very peculiar circumstances to ensure tolerable ease. The above considerations, and my own experience, make me conclude that none of the affections are positively and necessarily confined to any season, or such a specific cause as hay, or the powder of ipecacuanha.

Dr. Bostock observes, "as far as regards medical treatment, an anxious desire to obtain relief from an annual indisposition of several weeks' continuance, and sometimes of considerable severity, has induced me to try, with the greatest perseverance, every remedy which held out the least prospect of advantage. I

think myself warranted in asserting, that on the whole the depleting system is injurious, and that some benefit is gained by a moderate use of tonics. This is the only point in which the various accounts that I have received from others, and my own experience, appear to agree; and in general it would seem that the symptoms proceed nearly in the same way under very opposite plans of treatment, and are very little influenced by medicines of any description."

It ought to be remembered that if a paroxysm be about to set in, a tonic regimen is premature, and may aggravate the distress to the highest degree, as in the case of incipient catarrh of any other kind. The time for support is that of the departure or decline of the disorder, provided no fresh or recent causes of disturbance require to be allowed for.

Dr. Bostock continues—"the experience of many years has taught me not to expect a cure for the complaint, so that I now only aim at relieving any peculiarly urgent or distressing symptom. Bathing the eyes in tepid water, and fomenting the face generally, occasionally applying small blisters to the chest, mild purgatives, small doses of ipecacuanha, Dover's powder, squills, and digitalis, bathing the feet in warm water, a moderate but not spare diet, perfect rest, and carefully avoiding all extremes of heat, comprise the whole of the means that I have found useful to myself. In order to prevent others from making useless experiments, I may remark that among those things which I have tried without success are bark, iron, opium, mercury, large blisters, topical bleeding, the waters of Harrowgate and Leamington, the baths of Bath and Buxton, sea-bathing, the shower-bath, abstinence from wine, and animal food, and a more free use of them; each of these having been made, as it may be said, the subject of distinct experiment, and persevered in until some circumstance rendered it necessary to discontinue them, or until they produced a decidedly injurious effect*."

It may be already apparent that the superficial disturbance is to be in part controlled by attention to local circum-

* Dr. Elliotson held hay effluvium for the cause, and seemed to cure a case with vapour from the chlorides. The Doctor seems to resemble Lord Bacon not a little in crediting curious assertions.—*Vide MED. GAZ.* vol. viii. p. 411.

stances. It may be that the eye cannot be protected but by closing the lid. The affection of the nares and trachea I have found relieved by inhaling steam; and there is no remedy after warm clothing on which I rely so much as on a sea-trip; yet I have known a most marked relapse caused by taking cold under such circumstances. I conceive that merely sitting in a cool room, or being coolly covered, as quite enough to account for a subsequent paroxysm, disturbing the whole balance of the capillary functions, which are already defective.

Cool air is well calculated to give immediate relief to the inflamed parts, but it would seem also to keep up the local susceptibility to reaction under easier circumstances, or when warmth or repletion is renewed. Now, if reaction be essential to the due nutrition and invigoration of the capillaries, the cold air, which gives temporary relief, is only a cause of relapse and troublesome delay.

It is not very much a subject of wonder that the delicate and exposed tissues near the summit of the capillary system should fail of its nutrition, and become in a degree too sensible under external influences, when the whole body is more or less so.

The objects of treatment are to diminish the existing disturbance, obviate the causes, and set the frame, by free nutrition, above the influences which pervert it; both as to the face and surface generally. That a slight wasting of the body with the advancing warmth of summer should be connected with the capillary states to which we advert, does not seem unreasonable; but still the specific affections may require a specific cause in the atmosphere to which the delicate membranes concerned are peculiarly and exclusively subjected. For my own part, the end of summer has seemed most liable to introduce disturbance. Dr. Bostock advises to avoid the extremes of heat; and his commendation of an airy room for the sufferer to sit in seems to me to account in a good measure for his want of success in the management of the disorder. Doubtless the more a feebly-nourished body is motionless or feverish the more it has need of warmth. Of course all exposure of the susceptible parts should be delayed. The more the symptoms are oppressive the more I should infer extreme sus-

ceptibility, as well as the neglect and need of what may be best understood as comfort for an enfeebled febrile body.

From what I have felt and witnessed of the disorders in question, I feel assured that the following reflection on common catarrh is justly applicable to them, though in widely different degrees. Throughout the disorder, the patient is peculiarly susceptible of the impressions of cold, even although the skin be warmer than natural. It may need much watchfulness both of cause and consequences to discover this. He is also (says Dr. Copland) "inordinately" disposed to experience an accession of, or to contract a fresh, cold upon the slightest exposure to its causes, or even to the least depression of temperature; indeed, nothing but personal experience, or the most careful and sedulous investigation, is likely to convince those who are strong, of the results of merely a cool bed. The specific local effects of season are increased by all exposure, and even by exertion. The slightest motion of the air about the body augments the effect of coolness and quiescence.

A good measure of clothing, a warm room, the absence of draught, gentle exercise, fair support, and even tonics, are the happiest means of obviating relapse and invigorating the frame. These, employed in the order here named, with opium if needed, and all that these suggest being maintained, will be found, I trust, so much the more satisfactory, as they are not empirical but rational. The disease is *general and local susceptibility for lack of comfort and nutrition*, which are the specific preventives of relapse.

It is perfectly in vain for the robust to judge of the requisite clothing and warm rooms for the susceptible, without the most careful experimental observations of the effects which cold, under different circumstances, produces within three or four, or eight or nine hours subsequently.

In conclusion, I have to propose, for the test of my views—a sufficiently warm room, or clothing to obviate the slightest coolness of the surface of the body, particularly when at rest. This is the first essential of the constitutional treatment, as relapses, if carefully watched, will soon testify. A certain degree of moisture in the air is the chief local palliative. After these,

remedies on common principles may be expected to act curatively. Fever unaggravated may take days to subside. Depletion may be required, and narcotics have often acted like magic, causing some sense of general action, and proportionate local relief.

36, Bedford Square.

SYMPTOMS ATTENDING THE ILLNESS OF THE LATE SIR CHARLES NIGHTINGALE;

WITH THE POST-MORTEM EXAMINATION.

To the Editor of the Medical Gazette.

SIR,

I BEG to send you, for publication in the MEDICAL GAZETTE, a correct narrative of the symptoms attending the illness of the late Sir Charles Nightingale, Bart., from the time of my attending him up to the period of his dissolution, together with the inferences drawn from the anatomical exploration.

I am, sir,

Your obedient servant,

EDMUND LAMBERT.

Park Street, Bath,
July 26, 1843.

On Tuesday the 4th of July I was for the first time requested professionally to visit the late Baronet. He was then labouring under the following symptoms:—Ejecting from the stomach a tough viscid mucus, apparently discoloured by blood from ruptured capillaries, or, what I think more probable, by the introduction of some extraneous substance into the stomach, great distension in the epigastrium, with slight tenderness on pressure, frequent pulse, hot skin, panting, extreme restlessness, and anxiety; but no emaciation or diminution of strength. I then prescribed for him the following medicines, with the view of acting upon the bowels, which had not been opened during that or the preceding day, and at the same time allaying the irritability of stomach.

R. Calomelanos, gr. x.; Confect. Opii, q. s. ut ft. pil. ij. h. s. s.

R. Acidi Hydroc. dil. (Ph. L.) ℥xvj.; Mist. Amygdalæ, ʒvlij. M. sumat cochl. ij. ampla 4tis horis.

Palv. Rhei, ʒj. mane si opus sit.

I did not see him again till Thursday evening, when I was informed that Dr. Henry Johnson had been sent for in the intervening period, who also

prescribed the hydrocyanic acid to be taken in an effervescing draught, and the following ointment to be rubbed into the region of the liver:—

R. Ung. Hydr. fort. ʒxij.; Camph. ʒij; Iodinii, ʒss.

As Dr. Johnson had supplied my place in consultation, it was not my intention to have called again. On Friday morning, however, the 7th, Dr. Greville, the usual medical attendant, called at my house, and requested that I would accompany him to see Sir C. Nightingale, at the same time observing, he did not think there was much use in my going, as in all probability we should not find him alive. When I arrived I found him still throwing up the dark-coloured viscid mucous secretion; the epigastrium hard and distended; pulse scarcely perceptible; icy coldness of the hands, the lower extremities retaining a due degree of animal heat; panting very severe, with greater anxiety and restlessness than heretofore manifested; voice stridulous, but no obscuration of the intellectual powers. For this train of formidable symptoms, which I considered the forerunner of death, I simply recommended the frequent administration of stimulants and nourishment, and an opiate to tranquillize. I saw him again the same evening, when no alteration for the better or worse had taken place. Dr. Greville visited him between one and two o'clock on Saturday morning. During the night I was informed by one of his attendants that he was seized with a frightful convulsion. On Saturday I saw him at 3 p.m. for the last time, as death closed the melancholy scene at half-past 5 on Sunday morning the 9th. It was decided by the coroner that neither myself or Dr. Greville should be present at the post-mortem examination; but as Dr. Greville was the executor to whom the deceased bequeathed the whole of what he possessed, the coroner could not exclude him from the house, where he remained till the surgeon had completed his operation. The following are the morbid appearances recorded by Mr. Field:—

“The external appearances of the body presented a quantity of coffee-ground fluid about the mouth, nose, and chin; discoloured appearance of the skin about the neck and upper part of the chest; and a little above

the left groin the appearance of a wound made by a scalpel or some surgical instrument. The body generally exhibited the signs of great decomposition, more rapid than is generally the case, even allowing for the time of year and the period which had elapsed since death. The internal appearances presented on being opened—*in the cavity of the chest an effusion of fluid in both pleural cavities, congested state of the lungs at their posterior parts*, and some emphysema in the anterior or inferior portions. The heart was flabby, and its left ventricle dilated. I now proceeded to the examination of the abdominal cavity, and found the marks of slight peritonitis over the intestines. On proceeding to separate the stomach from its connections, I found very considerable adhesion between its smaller curvature and under surface of the liver. On breaking through those adhesions, I found a cavity containing grumous blood and portions of fibrine. The cavity extended a considerable way behind the stomach. On removing the stomach and slitting it open, I found about six ounces of coffee-ground fluid in its cavity. There was not the slightest appearance of inflammation or ulceration in the mucous membrane, which was unusually pale. The liver was a little enlarged, congested, and very much disorganized in its lower surface and inferior border. The gall-bladder was literally crammed with biliary calculi, large and small together about 200. The kidneys were extensively diseased, presenting an advanced stage of the malady designated 'Bright's disease.' There are no other morbid appearances. From the morbid appearances discovered, I conclude that the cause of death in the deceased was hæmatemesis and the inflammation of the peritoneum, the result of diseased state of the viscera. The entire absence of inflammation or ulceration in the lining membrane of the stomach, precludes the idea of any deleterious ingredient, mineral or vegetable, having been taken by the deceased. I did not analyse the contents of the deceased's stomach, for I considered it a work of supererogation."

Mr. Field states in his evidence that there was not the slightest appearance in the mucous membrane of inflammation or ulceration, which was more

than usually pale; but what would have been the appearances in the stomach if the vessels had not emptied themselves by secretion during the last stages of life? Would not the retention of coffee-ground fluid within the vessels have presented all the signs of congestion, and conveyed to the mind of the toxicological pathologist unequivocal indications of an irritant poison acting either directly upon the mucous surface, or, what is more probable, indirectly through the medium of the nervous and circulating systems? Did not the icy coldness of the hands indicate that one portion of the spinal marrow had ceased to generate heat, although it still continued to animate the circulation in a feeble manner, for the pulse was scarcely perceptible? and was not this depression of the circulating powers extremely favorable to the processes of secretion, exhalation, and congestion, so strikingly exhibited in the post-mortem examination? Is the icy coldness of the hands a common symptom of disease, or the panting a usual symptom in diseases of the respiratory organs? I put these questions, for I confess I have not witnessed them myself. Can coffee-ground or black vomit be called hæmatemesis, when the essential characteristics of the latter disease are entirely absent, viz. coagula?

Notwithstanding the gall-bladder was stuffed with calculi, I never heard the deceased complain of suffering any inconvenience from them.

As to the wound made by the scalpel, through which the intestine was partially protruding, I shall leave it to the profession to decide for what purpose that was made. A servant swore that he saw a gallon of fluid drawn off; but the surgeon who is said to have tapped the body ought to have been examined upon that point. There was no collapse of the abdominal parietes.

It is not my intention to enter into any controversial discussion; suffice it to say, that I vouch for the accuracy with which all the pathological phenomena have been detailed.

P.S.—I entirely differ with Mr. Field as to the analysis of the contents of the stomach being a work of supererogation. When the slightest suspicion of poison exists, and such a large quantity of fluid is found in the stomach after death, it should undoubtedly be

submitted to chemical analysis. But the proceedings at this inquest were not conducted in a very satisfactory manner.

OBSERVATIONS
UPON THE
NEW PROCESS PROPOSED FOR THE
DETECTION OF CORROSIVE
SUBLIMATE
BY MEANS OF
METALLIC SILVER.

BY FORENSIS.

(*For the London Medical Gazette.*)

DR. FRAMPTON has proposed to use silver as a test for corrosive sublimate, upon the grounds that the affinity of silver for chlorine, and the great tendency of silver to amalgamate with mercury, offer, or at least promise, facilities for detection superior to other methods. Dr. Frampton, at the same time, very liberally and very properly submits his processes to investigation, and courts inquiry. Upon these terms I beg to offer the following for his especial consideration, as well as that of toxicologists in general. Dr. Frampton's first proposition is, that silver triturated with bichloride of mercury effects the reduction of the salt and the liberation of the mercury, which then forms an amalgam with the remaining silver. This is inferred from the change of colour. Upon this it may be observed, that two substances, exerting no chemical action whatever upon each other, by mere mechanical admixture, frequently modify, and sometimes even generate perfectly new and distinct colours. Again, it is a rule of chemical action that bodies do not act upon each other unless one at least be in solution, or contain water of crystallization. Although there are exceptions to this, yet I determined to place this matter beyond all doubt. For this purpose, bichloride of mercury having been rubbed on a plate of metallic silver till it was darkened, the plate was digested in a solution of ammonia. The fluid was now filtered, and the filtered portion boiled in a tube, when it became turbid. On the addition of nitric acid, a white curdy-looking precipitate fell down, insoluble in nitric acid, and which became dark

on exposure to bright light. Ammonia again redissolved it, and, when reprecipitated by hydrochloric acid, a button of pure silver was obtained by reduction and cupellation. Therefore there can be no doubt that silver reduces bichloride of mercury by mere contact, and that a transfer of the chlorine to the silver takes place on mere triture.

Dr. Frampton's next experiment consisted in boiling a solution of bichloride of mercury with very finely and minutely divided silver, when the reduction of the mercurial salt, and the liberation of the metal, were equally the ultimate results. But the third case is the most important, in which bichloride of mercury is complicated with organic matter. Organic matter may be considered in the two-fold relations of animal and vegetable. As regards animal organic matter,—albumen for instance,—bichloride of mercury is rendered insoluble in water by it; that is, the albumen and bichloride of mercury enter into some sort of combination, which is insoluble. Upon this metallic silver exerts no action, nor would any action be exerted even at a boiling temperature. But, although insoluble in water, the compound is easily decomposed by various salines and other agents. Thus, hydrochlorate of ammonia and the alkaline chlorides redissolve the mercury in the form of bichloride. The same may be said of diluted hydrochloric acid, and of an excess of bichloride of mercury, or of albumen. In Dr. Frampton's experiment hydrochloric acid was added to the animal organic complication, by which the bichloride was brought into solution, and the silver thus enabled to act on the mercurial salt.

But although the process by silver, as detailed by Dr. Frampton, may answer for animal mixtures, I fear it will be found quite unsuited to vegetable mixtures. The reason probably is because bichloride of mercury is *reduced* by vegetable organic principles, so that hydrochloric acid will not act upon it, nor redissolve the mercury. Thus: "The solid compounds," says Christison, "formed by corrosive sublimate with animal principles, are either soluble in the hydrochloric acid, or part with all their mercury to it. The matter left does not yield a particle by reduction. But this is not the case with the compounds formed with vegetable

principles. Diluted hydrochloric acid, boiled gently for two hours on the compound formed in tea, dissolves little of it, and leaves much undissolved powder, which yields, by destructive distillation, a large quantity of mercury*."

Hence it must be evident that Dr. Frampton's process could not by any means suit such a complication. Whatever bichloride may have combined with animal principles—those of the milk, for instance—after digestion in diluted hydrochloric acid, might yield a trace, perhaps, of mercury, but more frequently no indication whatever of the presence of mercury is afforded. It now remains to consider whether silver offers any advantages in researches upon mercury.

I triturated some tin-filings of extreme tenuity with one-eighth, and in a second operation with one-sixteenth of a grain of bichloride of mercury, in an agate mortar, and each operation presented characteristic evidence of complete reduction and amalgamation with the tin; viz. change of colour, and the viscid adhesive consistence of the mass. Collected and introduced into a narrow tube, and heated in a spirit-lamp, one or two very minute globules, hardly visible with the naked eye, but easily detached by means of a steel wire, and readily distinguished when thrown upon a small tray made of white paper, and a chloride of tin also, sublimed, when the flame of the lamp was urged with the blow-pipe. Upon removing all the metallic mercury, breaking up the tube, and digesting this and the residual sublimate in nitro-hydrochloric acid, analysis of this fluid gave no evidence of even a trace of mercury, which it must have done had not all the bichloride been completely reduced and the mercury removed. Hence, perhaps, it would be a legitimate inference that tin presents us in itself a reducing agent equal at least in power and effect to metallic silver. Tin, however, has this advantage over silver, that it is much less expensive, much more easily procured, and, to my view, much more manageable. It may be urged, that Dr. Frampton's mode of freeing from the newly-formed chloride of silver by washing with ammonia relieves from all embarrassment that might result from the presence of the new chloride. To this I reply, that I have not found

the chloride of tin formed by the reaction at all to embarrass the subsequent reduction. But there are two modes of obviating any inconvenience resulting from this cause. It may be removed by washing with water, or with a caustic alkali, which dissolves the salt; or all the tin and saline may be removed, and the mercury alone left, by dissolving in hydrochloric acid, but feebly diluted with water. And perhaps the latter is the preferable plan when the quantities used are minute, as we then have left metallic mercury perfectly pure, and free from every kind of contamination. For myself, I feel satisfied that the above is equally as delicate, and certainly as manageable, as the process by finely-divided silver. It may be observed, on the question of delicacy, that the proto-salts of tin decompose the salts of silver, and reduce them to the metallic state.

The next question is, the applicability to the mercurial salt in solution. I have been long aware that tin introduced into a solution of bichloride of mercury causes a precipitation of metallic mercury upon its own surface, and there is consequently an amalgamation. It constitutes the fundamental principle of the process recommended by Devergie. He recommends us to treat the mixture supposed to contain mercury with diluted hydrochloric acid till all the solid matter is dissolved. Next evaporate, to expel the greater part of the acid employed. Add water to the remainder, and transmit *chlorine* to coagulate and remove the animal matter.* Filter, boil, and concentrate. Then immerse for ten minutes a small plate of pure tin, which, if mercury is present, will immediately be whitened (*tarnished* ?); immerse another plate of tin for ten minutes; and continue this part of the process till the plates cease to be whitened. Dry the tarnished

* The transmission of chlorine, although as proposed for a mere secondary purpose by Devergie, is the most important part of the whole process. The digestion in hydrochloric acid is quite unnecessary and superfluous, for if it, the mercury, be in any degree reduced, the acid will not affect it; but the chlorine will immediately form a soluble bichloride, which will be held in solution by an excess of chlorine, and the action of any organic reducing agents suspended or counteracted, and the reducing agency of the tin secured and rendered more effectual. A current of chlorine gas passed through a fluid holding an insoluble compound of mercury in suspension, converts it into a soluble bichloride.

plates, scrape off the tarnished surfaces, put the scrapings in a proper tube, and heat over a spirit lamp: the mercury will be driven off from the amalgam, and condense in a ring of globules. Such is Devergie's process.

I have myself frequently used fine grain tin instead of tin plates, and I think the tin in this state preferable, as being more certain. First, by agitation, the grain tin is made to act upon every particle of the fluid, so that no atom of the dissolved salt can so easily escape the reducing agency of the metal. Again, the action is rendered more certain and complete if the solution of bichloride contain a tolerable excess of hydrochloric acid. The acid in proportion to its concentration attacks the tin; protochloride of tin is formed, and which instantly reacting precipitates metallic mercury. Now, all the mercury precipitated by any generated protochloride of tin, no matter whence its origin, subsides and is found principally at the bottom of the vessel holding the solution. This of course is lost in the case of the tin plates, which become tarnished by that mercury only reduced in immediate contact with their own surfaces. Now in the case of tin finely powdered, it falls to the bottom, and immediately amalgamates with any free mercury, and with which too it must of necessity come in contact. But even, should this not be the case, the mercury cannot be lost, because whatever subsides is to be collected, and either heated immediately in a tube, or be first treated as previously suggested, and then heated in a proper tube. Hence, then, it is evident that tin is a more delicate and effectual reagent than silver for mercury in solution, inasmuch as acidulating with hydrochloric acid, and boiling, greatly facilitates the action of tin, but exerts no such effect with respect to silver.

In organic complication, if the mercury be rendered insoluble by vegetable matter, silver cannot possibly act unless the mercurial salt be redissolved, and hydrochloric acid alone cannot effect this. But hydrochloric acid may enable tin to attack and reduce even the *vegeto-organic* compounds of mercury; for proto-chloride of tin will reduce even these, and if the solutions be strongly acid and boiled upon the tin, a proto-chloride of the metal will be formed. The preferable plan, however, in organic com-

plications, will be to insure the solution of the mercury. This is to be effected either by passing a current of chlorine gas through the suspected solution, filtering, and then washing through with diluted hydrochloric acid; or by adding to the suspected matters a mixture of nitric and hydrochloric acids in the proportions to evolve chlorine, filtering and washing through as above. By these means the mercury will be brought again into solution, which will, to a great extent, be freed, by either of the above processes, from organic impurities both vegetable and animal. This, therefore, brings the matter almost to the condition of simple solution; and the grand point at issue is the preferable reducing agent. First, it is necessary to premise that the conditions of solution must be the same throughout, as to concentration, foreign principles, subsequent manipulation, &c. The mercury may be precipitated in the metallic form by the following: finely divided silver; grain tin, or, what is preferable, tin filings, under similar conditions of tenuity; solution of protochloride of tin; phosphorous and hypo-phosphorous acids. In the two first cases, although the mercury is reduced to the metallic state, yet amalgams subsequently form with the respective metals. In the case of the silver amalgam it must be distilled to evolve the mercury; in the case of the tin amalgam mercury may be distilled off; or the tin may be separated by hydrochloric acid, and the mercury thus set free left behind.

The next three reagents are in solution; and each precipitates metallic mercury perfectly pure and unalloyed, although it may be mechanically intermixed with certain impurities, which merely prevent the mercurial particles from coalescing into globules recognizable to ordinary vision. From these impurities, however, it is easily freed by well-known methods. Then the question now is, which are the most delicate and effectual reagents, the solid metals or the liquid tests? When bodies are dissolved in a fluid, the body or solvend appears to be uniformly diffused throughout the solvent; for every the most minute particle of the latter will afford traces more or less characteristic of the former; consequently the liquid reagents seem to act under circumstances of great advantage,

at least as relates to delicacy, extent, and minuteness of division; and experiment proves what reason naturally infers. Nothing, in fact, can equal in delicacy and effect protochloride of tin in solution, and the acids above named; and I am satisfied no one who will take the trouble of comparative experiments, but will give the preference to the three reagents last mentioned.

It may here be made a question as to the bichloride of mercury in the solid state, or the proto-chloride (calomel), which is incapable of solution. But this and many other compounds of mercury, though insoluble in themselves, are readily and immediately converted into bichloride by passing chlorine gas through water holding them in mechanical suspension, or boiling with nitro-hydrochloric acid. Further, dry bichloride, proto-chloride, and many of the other solid compounds of mercury, are immediately reduced by merely pouring upon them solution of proto-chloride of tin, or the phosphorous or hypo-phosphorous acids; and perhaps this plan is the preferable.

Dr. Frampton contrasts the reduction by metallic silver with that by the alkalies. The alkalies present, in every way, the most inconvenient and unmanageable processes in the dry way. It requires some tact, and a great deal of management, to prevent the sublimation of the mercurial salt undecomposed. In other cases a mixture of undecomposed bichloride and red oxide sublimes, and not a particle of metallic mercury. I have frequently verified this by treating the mixture with water holding hydrochlorate of ammonia in solution, that part of the bichloride which had escaped decomposition; and by treating the residue with diluted hydrochloric acid, the red oxide were dissolved and mercury identified. Therefore finely divided silver or tin presents the best, the most effectual, and the most manageable reagents for the reduction of the chlorides in the dry way, and will be preferred by the practised and experienced operator. Of the two metals, tin, if it have no superiority, yet from the readiness with which it can be adapted for use, and the greater facility of obtaining it, will, in all probability, be selected in most instances.

I have now considered, at considerable length, the questions proposed

by Dr. Frampton in his paper published in the GAZETTE. I give Dr. Frampton due credit for the ingenuity displayed in his process; and had it not been for the importance of the subject, but more especially his own invitation to inquiry, I should hardly have entered at such length upon the matter. I trust that what is here advanced will be regarded as emanating from a true desire to promote science, and that the remarks upon Dr. Frampton's proposal, and the methods contrasted with it, should they be thought worthy a place in the GAZETTE, will be found couched in the true spirit of philosophical inquiry and truth; and far from emulating or striving after either mastery or triumph.

London, July 9, 1843.

MEDICAL GAZETTE.

Friday, August 4, 1843.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

PRIVATE TUITION.

It is well remarked by the late Dr. Arnold, in his Lectures on Modern History, that the struggles of a nation or of a party for constitutional privileges, however laudable has been the object or admirable the mode of its pursuit, do not confer lustre on victory, if the success obtained be not used in furthering the nation's real welfare. The proper object of war is peace; of liberty, the power to act rightly; and few things are more lamentable than to see advantages which have been gained at the cost of much suffering, either wasted by being turned to no account at all, or perverted to mean and unworthy purposes. Yet nothing is more common; it would seem, indeed, to be one natural consequence of a prolonged struggle, that the energies and the virtues which are required to reap the fruits of victory

have been exhausted in the contest, and have been succeeded by lamentable indolence, or yet more deplorable abuses. Nor is this proof of the weakness of human nature to be drawn only from public history and from national contests. The lives of private individuals supply ample data for a similar inference. The industrious pursuit of wealth is often followed by avarice or luxury; of power, by tyranny or arrogance: nay, more—

“*Insani sapiens nomen ferat, sequus iniqui,
Ultra quam satis est, virtutem si petat ipsam.*”

“For virtue's self may too much zeal be had,
The worst of madmen is a saint run mad.”

Cases in the wards of Bethlem or St. Luke's are but aggravated specimens of a pathology which may be abundantly studied in private life; nay perhaps each of us may detect a few symptoms in his own person.

The waste of powers in acquiring means without judiciously directing them to an end, is seldom seen more remarkably, and never more lamentably, than in education. To put out of the question those rarer instances of excessive zeal, where youths spend prematurely in the acquisition of science the health and strength which should have supported them through a life of practical usefulness, we shall meet with too many cases where the powers which with the most careful adjustment would barely have sufficed for the purposes of their possessor, have, by early mismanagement, been made useless or detrimental.

The acute writer on history, whose opinion is alluded to above, draws a beautiful and just distinction between the duty of the professor and the educator. The teacher of a special science or branch of education is bound to instruct his pupil to the utmost of his power in the particular branch which he professes. This is to be not merely his prominent object, but his only one; and

in proportion as he does this he discharges his duty. The educator, on the contrary, has to consider the general scope of his pupil's instruction, and especially the duties which he will have to perform in after-life; and with this object in view he has to consider the capacity and powers of his pupil, the nature of his studies, and the degree and mode in which each may be most beneficially pursued.

The author's application of this to the parental duties of the state is not to our present purpose; but the whole work, of which the most evident fault is its brevity, will richly repay an attentive perusal. Our profession is one which has a great influence on the well-being of society; we do not quite agree with those who desire for its members a large share in the national councils, or in the honours and rewards which attend public services, for we believe that our daily private ministrations to the comfort of individuals, though more humble, are more useful; and, moreover, that a frequent competition for public office and public honours would detract from our specific value as professional men; yet as we would have each man in his own circle bring the weight of his personal influence to bear as largely as possible on the public good, so we think it highly important that the general views of each one of us, the tone of feeling and of action, should receive all possible help towards their justness, their elevation, and their purity; and to this end a philosophical study of history will very much conduce.

One of the inconveniences under which a pupil labours on commencing his studies, is that each course of lectures contains much information which, in the present state of his knowledge, he is either quite unable to understand, or which, at least, he cannot apply, and which he can only retain by a mere

effort of memory. This is an unavoidable consequence of each course being complete in itself. The lecturer is addressing two classes at once—the totally uninformed, and those who have already become familiar with much of what he is telling them; to the former, therefore, much must be unintelligible, to the latter much must be wearisome, and, notwithstanding all the skill that may be exerted to give colour and relief to the most important and prominent features, and to point out to each class what parts require the most marked attention, the general effect of a long course of lectures is almost invariably to tire out the patience of many: and though no doubt the emptiness of the benches is mainly due to the mere seductions of indolence or pleasure, yet the smallest show of reason for absence adds incalculably to the force of temptation, and too often not only confirms the unprincipled, who would have done wrong just as much without it, but overcomes the last scruple of the wavering.

Yet the duty of the professor is to make his course complete, and, during the process of composition, his own mind is stimulated, and his labours are made tolerable, by the agreeable task of eliminating first principles from the stores of his knowledge, and arranging them in order and clearness for the *tabula rasa* of the young and uninstructed mind; he is then carried into the more abstruse and intricate parts of his subject, discussing the most difficult and disputed points, stating the various questions with clearness, and summing up the arguments with all the acuteness of which he is master.

But when the lectures, which had satisfied him during their composition, and received attention during their first delivery, come to be repeated, the professor feels internally conscious that one-half of his audience must be aware

of what he is about to say—that the premises he is so carefully stating have already suggested the conclusions—that his most brilliant and startling propositions will be received with coolness, and his very jokes either heard with gravity or laughed at by anticipation. This is an alarming prospect for a man of taste and earnestness; and by and by the absence of his more advanced pupils convinces him that his fears were not unfounded. He retouches his work, and endeavours to revive the flagging interest of the seniors, by discussing points of clinical importance; but he now finds his young pupils, the freshmen of his class, looking puzzled, and he sees that for them he is going too far or too fast.

Every one knows how children are apt to loathe the food of grown-up people when minced and mashed into an unmeaning pulp by over-careful nurses, and how it disagrees with them when they are persuaded to swallow it; no less is the disgust and weariness with which the young receive history when unskilfully reduced to stories. Sir Walter Scott found he had told the first series of *Tales of a Grandfather* too childishly, and improved his style afterwards. The professor who tries to teach in the reading-made-easy style will find, in like manner, that his fare offends the robust, and overloads the weak intellect. It is surely better for students that a man of powerful mind should fling down the hardest propositions, to be worked out by the diligence and ingenuity of his class, than that every thing should be reduced to the very easiest terms. The great practical objection is, that some are apt, after a short struggle with their difficulties, to be left behind, and to acquire the very dangerous habit of imagining that their deficiency will be supplied when the course is repeated. Many have thus consoled themselves

season after season, till, when the time comes for examination, the grinder appears the only person who can set matters to rights. The remedy for much of this evil seems to fall within the legitimate province of the tutor, and to consist in carefully superintending the progress of each pupil, showing him what is elementary and fundamental — what he really must master at the time, and what may safely be left to a future course.

The weekly examinations do much towards raising the average information of a class, but require intelligence, diligence, and confidence; and as it is yet nearly optional with the student to attend them or not, they are soon deserted by the very class who most need them—the slow, the indolent, and the diffident. The directions of public bodies, as to the order in which lectures are to be attended, are meant to ensure a systematic and gradual mode of instruction, and certainly the intention is good, but many parts even of the earlier subjects must, if the professor desire to make his course complete, be evidently beyond the unassisted comprehension of his younger pupils. *Materia medica* and therapeutics, for example, what a wide range does this present; from the commonest acquaintance with the mere physical properties of a drug, to the most subtle application of remedies amidst the complications of disease, the last and always unfinished labour of the most accomplished veteran.

Another difficulty in the student's way, justly alluded to by Dr. Arnold, is the duty no less than the inclination of each professor to insist on the prominent importance of his own special science; the duties of the educator being rather to assign to each its own place and value. The only educators in this sense of the word for medical students, are the licensing

bodies, and the only instruction which they afford is that conveyed in the list of subjects for examination—a concise piece of information, and as puzzling as attempts at condensation generally are, “*brevis esse laboro, obscurus fio.*”

It would be unjust to our ablest professors to forget the admirable advice contained in their introductory lectures: many of these might be quoted as sound and unexceptionable suggestions for the complete education of the student, and useful to him in every relation of professional or private life; but these lectures are heard but once in each course, or, if the maxims they contain are occasionally repeated, they are insufficient to restrain the refractory or to stimulate the indolent; we are inclined, therefore, to believe that there is a difference between the public duties of the professor and the private functions of the educator, which will be beneficially recognised when tuition on something like a collegiate system shall have been more extensively adopted.

FELLOWES' CLINICAL PRIZE REPORTS.

BY ALFRED J. TAPSON.
University College Hospital, 1842.

[Continued from p. 620.]

CASE XIV.—*Delirium tremens*, complicated with, and somewhat masked by pneumonia; and when both these had been cured by the use of opium, calomel, tartar emetic, and leeches, an attack of hepatitis came on, which was successfully treated by cupping, blue pill, and taraxacum.

ARTHUR C., æt. 24, admitted May 24th, 1842, under Dr. A. T. Thomson: a tall thin man, of nervous temperament; pale complexion and light hair; unmarried: a tailor by trade. His habits have been very irregular for several years, always drinking freely, and frequently getting drunk; parents both living, and both healthy, also seven brothers and sisters, all pretty healthy. Previous health always delicate; but he has

never been laid up with any illness, excepting scarlatina.

The circumstances under which the present attack came on were as follows (they were chiefly learnt from his sister, who came with him). On the 16th and 17th inst. he got very drunk indeed; since then he has scarcely drank anything. Nothing was observed amiss till the evening of the 20th, when he appeared very irritable, and says that he felt very stupid and heavy: on the 21st he was attacked with pain in the head, back, chest, and limbs; shivering; shortness of breathing; great thirst; great depression and weakness: on the 22d his manner was remarked to be very strange; he kept pointing about the room with his finger; could not sleep at all from the time he was first taken ill; the breathing continued quick; the skin became very hot; he complained of severe pain in the right side and at the epigastrium, and had a slight cough.

On his admission on the evening of the 24th, the chief symptoms were the heat of skin, frequent respiration, the above pain, tenderness on pressure in the same parts, thirst, depression, &c.; there was a rough sound, resembling friction sound, heard below the right scapula, but no dulness on percussion.

He was ordered — Hirud. No. viij.;
Epigastrio admov.

℞ Calomel gr. v. statim sumend.
℞ Haust. Niger. cras mane.

℞. Liq. Ammon. Acet. fʒss.; Sodæ Tart. gr. xv.; Sodæ Carb. gr. v. Mist. Camph. fʒj. M. f. haust. 8vâ qq. horâ sum.

May 25th.—Has passed a very restless night; crying and frequently attempting to get out of bed. His countenance is very irritable and suspicious; his manner very uneasy, hands and fingers in almost incessant motion, picking about the bed-clothes, &c.: on the least noise he starts suddenly round and looks frightened; talks a great deal in a low tone, and incoherently: he is quite sensible when spoken to, and answers questions rationally, but his memory is so deficient that he frequently contradicts himself. The head feels very hot; the eyes and nose are red, and have been running; the lips are of a bright vermilion colour and dry; the tongue very red along the margin and at the apex; not dry, but covered with a yellowish slimy fur. The surface of the body is hot and dry; he would not allow the thermometer to be placed in the axilla (suspecting, he told me afterwards, that we were going to cut him); but in the bend of the elbow the temperature was upwards of 100° Fahr.; the respirations 54 in a minute, and shallow;

pulse 148, soft, and moderately full; has a slight cough, but no expectoration; there is still pain and tenderness in the epigastrium, and also on the right side of the chest, midway between the sternum and lateral median line. Bowels have been opened twice in the night. In the course of the forenoon he became quite outrageous, and had a straight waistcoat applied for a short time.

℞ Calomel, gr. ij.; Pulv. Opii. gr. j.; Antim. Tart. gr. ʒ.; Mucilag. q. s. f. pil. 6tâ qq. horâ sumendâ. Pergat haust. Lotio refrigerans capito raso ope lintei applicanda.

26th.—Has slept a little during the night for the first time since the attack; and has been much more quiet, though still restless and fidgetty, and constantly talking in a low unintelligible manner. The countenance much improved, the suffusion of the eyes, nose, &c. much diminished; tongue has a more slimy appearance and a brownish tinge; pupils rather contracted; the respirations 36 in a minute; pulse 120, soft; no tenderness at the epigastrium now; bowels not opened since yesterday morning, and has passed no urine for the same time. (The catheter was introduced in the afternoon, and several ounces of high-coloured urine drawn off.)

℞ Calomel, gr. v.; Ol. Crotonis, mʒj.; Mic. Panis, q. s. f. pil. statim sum.

℞ Haust. purgans horâ post pilulam, si opus sit, sumendus. Cont. pil. ex Opio, etc.

27th.—Has passed a much better night, having slept a good deal, and been generally very still and quiet; appears quite sensible, answers questions readily and much more distinctly; face pale, and has a heavy expression; the lips and tongue are very dry; the latter is so dry that it can scarcely be protruded beyond the teeth; the temperature in the axilla is 103° Fahr.; but the head is now cool and comfortable. Respirations 32 in a minute; pulse 112, weak and variable; heart's action feeble, and rather irregular; he complains of the pain in the right side: on examining the chest posteriorly the sound on percussion was found to be dull in the lower two-thirds on the right, with crepitation distinct in the same situation; in the upper third the respiration was loud. Anteriorly in the situation of the pain there was muco-crepitant and some sonorous rhonchus. Bowels have been freely opened; evacuations dark and offensive; urine increased in quantity.

Adde Singul. pilul. Antim. Tart. gr. ʒ; Pergat haustus salin.

28th.—Continues to improve; the pain in the side is less; breathing slower; pulse 96, fuller and softer; tongue moist; gums

slightly tumid and red; thirst less; crepitation distinct in the same situation as before; bowels open; urine plentiful, high-coloured, but clear.

Sumat. pilulum 8vā. qq. horā. Beef-tea a pint daily.

31st.—Countenance is now quite natural; head clear; no confusion of ideas; the memory is improved; tongue moist, and much cleaner; no thirst; appetite returning; the respiration natural in frequency; pulse 78, and rather weak; pain in the side not constant, felt chiefly when he coughs; the cough is frequent and troublesome, and accompanied with scarcely any expectoration; excretions free.

Omitt. pil. Pergat. Haust. Milk diet, and chop every other day, instead of beef-tea.

June 1st.—Complains more of the pain in the lower part of the right side of the chest; there is some dulness on percussion, with bronchial respiration and bronchophony here; and posteriorly the crepitation is still heard at the end of a forcible inspiration, but not in ordinary respiration.

2d.—Omittantur medicamenta.

4th.—The pain in the side is less; the cough better; no expectoration; the head is quite clear; has had no return of the delirium; he feels very weak; the tongue is clean and natural; pulse 100, soft, and easily compressed; appetite good; bowels regular; urine abundant and natural.

℞ Infusi Cascariæ, ʒiss.; Acidi Sulph. Dil. ℥viii.; M. f. haust. bis quotidie sumendus. Full diet.

7th.—Has not been so well since he has had the last medicine; has had headache and more pain in the side; and has been shivering several times; the skin now feels very hot (it is 104° Fah. in the axilla); pulse quick, and he complains of some palpitation of the heart; is thirsty, and has no appetite for food. The physical signs are much diminished in the back; the dulness is almost gone, and no distinct crepitation, either coarse or fine.

Omitt. haust. Admov. Hirudines No. x. parti thoracis dolenti. Low diet.

8th.—Pain much relieved by the leeches; skin moist and cooler (100° Fah. in the axilla).

11th.—Pain is only felt when he takes a deep breath; it is now quite at the margins of the ribs and rather below; there is some tenderness on pressure here, and extending to the epigastrium; the dulness of the liver extends about an inch and a half below the margins of the ribs; the skin is still too hot, but is moist; he feels very weak, and

cannot sleep well at night; cough nearly ceased; appetite returning again; bowels regular; urine natural.

℞ Solut. Morphie Bimeconatis ℥xviii.; Mist. Camph. ʒjss. ft. haust. omni nocte sumendus. Chop daily, and half a pint of porter.

14th.—Has slept much better; feels stronger and better altogether; has less pain; no cough; tongue moderately clean; appetite good; bowels rather confined, and stools dark coloured.

℞ Olei Ricini, ʒss.; Aq. Menth. Pip. ʒj.; Tinct. Camph. C. ʒj. Ft. haust qq. h. sumend.

16th.—Sleeps well and dreams but little; whereas when he came in, if he dosed at all, he had the most horrible dreams, seeing devils, &c.; the pain is not quite gone, and he says he feels as if he had a weight on his stomach when he lies on his back; is much stronger than he was a week since.

To be discharged: cured of delirium tremens, and pneumonia.

July 2d.—The patient was readmitted into the hospital to-day; he states that during the time he has been out from the hospital he has had constant pain in the right side, in the same situation as it was just before he was discharged, viz. about an inch below the margins of the ribs, and it has extended backwards almost to the spine; latterly the pain has been a good deal more severe, it is increased by external pressure, also by coughing, &c.; he has also had pain occasionally at the lower angle of the left scapula: he says, moreover, that he used, about three years ago, to suffer a good deal from pain here, and whenever he got drunk it made him very ill, and caused a severe pain in the right side; whilst he has been out, he has (he says) been very careful as to his diet, and only drank from half a pint to a pint of porter daily, never more; his appetite has been good, but he has vomited occasionally after breakfast, and always brought up a good deal of bile; he has taken a good deal of exercise; the cough is very trifling; he looks heavy.

Applic. Cucurb. cruent. lateri dextro ad ʒxvj.

℞ Pil. Hydr. Ext. Hyos. aa. gr. ij.; Ext. Tarax. gr. v. M.f. pil. ij. Sumatur una 8vā. qq. horā. Middle diet.

5th.—Feels much better; the pain is much less severe; sleeps well; the tongue much cleaner; bowels open; urine free, natural.

Applic. Emplast. Canth. amplum lateri dextro; pergat in usu pilul.

R. Decoct. Tarax. f3iss.; Acidi Nitrici Diluti, m̄x.; Acidi Hydrochlorici, m̄v. M. f. haust. ter die sumendus.

6th.—The blister has risen well, and discharged freely; the pain is nearly gone; it is not increased by a deep inspiration.

7th.—Pain is only felt when he takes a deep inspiration; he feels quite well; pulse natural; tongue clean; gums not tender or swollen; the appetite good; bowels regular. Discharged cured.

REMARKS.—The *diagnosis* in this case was difficult at first, and could scarcely be formed with certainty without a knowledge of the previous history and habits of the patient. Judging merely from the condition that he was in, most would have pronounced it a case of typhus fever, with some inflammatory affection of the chest; but when the previous habits of the patient, with the circumstances under which the attack came on, and the mode of attack, were taken in connection with the existing symptoms and signs, Dr. Thomson at once pronounced it to be a case of delirium tremens, complicated with inflammation of the chest; and the further progress of the case, and the result of the treatment adopted in accordance with this diagnosis, quite confirmed it.

First, in looking at his *previous history* we find he had always been delicate; that he was in the habit of getting drunk; and that on the 16th and 17th of May he got exceedingly drunk, after which he scarcely drank any thing till the attack commenced, viz. on the 20th of May. Now these are precisely the circumstances under which delirium tremens most frequently comes on, viz. a sudden and great diminution of the quantity immediately after drinking an unusual amount.

Second, as to the *mode of attack*. It commenced with a state of great irritability, and a feeling of depression; constant watchfulness, or if he dozed at all he speedily awoke in consequence of some frightful dream; giddiness; a strangeness of manner; pointing about the room, and a very suspicious look; loss of appetite; and the rest of the symptoms before detailed.

Third, the *symptoms which existed on his admission* may be divided into those referrible to the delirium tremens, and those referrible to the pneumonia.

(a). *Those referrible to the delirium tremens* were—the irritable, uneasy, and suspicious appearance of the countenance; the idea that some one was going to injure him; the continual tremulous motion of the hands and fingers; restlessness and inability to sleep; the sudden starting on the least noise; the constant incoherent talking; and with these may probably also be classed, the heat of the head; the slightly contracted state

of the pupil; the suffusion of the eyes; the furred and slimy state of the tongue, &c. We refer the heat of the head, &c. to this class, because they subsided with the delirium and tremor, although the pneumonia was then increasing; and also because, as this was the patient's first attack, and he was young, the delirium tremens would be very likely to produce these phrenitic symptoms, though it was clear, from the softness of the pulse, the tolerance of light, from his answering questions, and the character of the delirium, that there was but little, if any actual phrenitis.

(b). *The symptoms referrible to the pneumonia* were—great heat and dryness of the skin, quick pulse, and exceedingly rapid respiration (the last symptom was probably increased by the state of the nervous system, as it is very rare indeed to see 54 respirations in a minute from pneumonia in an adult); great thirst; pain and tenderness of the right side of the chest, increased by a deep breath or by coughing; a slight cough; a rough respiratory murmur, &c. These do not indicate the existence of pneumonia; indeed that could not be ascertained till subsequently, when the occurrence of fine crepitation, dulness on percussion, &c. were quite conclusive on this point; also the character of the pain, and its situation (*vide reports*), indicated the same thing. The general symptoms of pneumonia were much less marked than usual; the cough was never severe, and there was scarcely any expectoration throughout the disease; also, the physical signs, though distinctive, were not nearly so clear as they often are. In addition to the pneumonia there seemed to be some gastric complication, from the extreme redness of the lips and of the margin of the tongue, the yellow fur along its centre, the great thirst, and the pain and tenderness on pressure in the epigastric region. These all soon went away, and were apparently intimately connected with the delirium tremens or with its cause.

Fourth, considering the *progress of the case* in connection with the *treatment*, we see that it quite confirmed the diagnosis which had been made and acted on. It was evident that a combination of remedies was requisite in order to combat the combination of diseases. Opium was ordered for the delirium tremens; and leeches, mercury, and antimonial salines, for the gastric affection and inflammation of the lungs. The effect of these remedies was the speedy subsidence of all the symptoms referrible to the nervous system and stomach; and then, as the pneumonia had decidedly manifested itself, the quantity of antimony was increased, and the calomel continued, until the gums were slightly affected; and under this treatment the symptoms gradually diminished, and on

the 4th of June, as weakness was the most prominent symptom, he was ordered a tonic draught and increased amount of food. It appeared, however, that it was rather too early; at all events he had a return of feverishness and pain, and the physical signs showed that the inflammation was not altogether removed. This slight return was, however, soon removed by the application of a few leeches, and the substitution of low diet for a few days, and after about the 10th June there were no symptoms referrible to the lungs.

But about this time a new disease began to manifest itself, marked by pain in the right side below the margins of the ribs, tenderness on pressure in this situation, pain in the shoulder-blade, and on percussion the liver was found to descend lower than natural. These symptoms indicated the existence of hepatitis; but without any treatment being specially adapted to this he improved, and was discharged cured of the delirium tremens and pneumonia.

Soon after he left the hospital the pain in the side became more severe, and in a little more than a fortnight he was re-admitted, having the same symptoms as when he went out, only greatly increased in severity, and some new ones had appeared. The pain now extended from the side round to the back; the liver descended fully an inch and a half below the margins of the ribs; he had bilious vomiting, &c.; abundantly proving the existence of a sub-acute form of hepatitis.

The treatment adopted consisted of local depletion by cupping, followed by the application of a blister, with blue pill to act on the liver, and also the extract and decoction of taraxacum, which is a remedy strongly recommended by Dr. Pemberton in chronic hepatitis and incipient cirrhosis, and therefore, we conceive, peculiarly adapted to this case. The nitro-hydrochloric acid was also given. Under these means he was soon well enough to be discharged again.

The *prognosis*, on his first admission, was not very favourable, although a first attack of delirium tremens rarely proves fatal; but there were here serious complications which considerably augmented the danger: the prognosis was much better, of course, when the disease was reduced to simply pneumonia, though this alone is enough to cause serious alarm, especially in such a subject. We have seen, however, that he recovered from this also, and was then attacked with hepatitis, which appeared to have gradually arisen on the subsidence of the pneumonia, as if the inflammation had passed through the diaphragm to the liver. Of this likewise he was cured; but the ulterior prognosis is certainly unfavourable, and we think the chances are that he will be very likely to have tubercles

formed in his lungs, cirrhosis in the liver, and not unlikely, also, granular degeneration of the kidneys, should he not be cut off by a recurrence of the delirium tremens.

The *cause* of the delirium tremens was obviously the sudden diminution in the quantity of spirit drank, after a great excess. His habits of drinking also probably gave rise, in a great measure, to the disease of the liver and stomach; and whether the pneumonia was to be traced to the same or not was doubtful. There was no evidence of his having been exposed to cold or wet, and we know that pneumonia is not at all an unfrequent complication of delirium tremens: thus, it is stated in the *MEDICAL GAZETTE* of May 13th, 1841, by Professor Budd, that "the organs most frequently inflamed, in this disease, are the stomach and the lungs."

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

You were pleased, in April last, to publish a request of mine, that the gentlemen employed under the Poor Law Amendment Act, in charge of the sick poor, would be so good as to send to me such information as might enable me to draw up a paper, or digest, on the subject of the grievances they suffered and wished to have redressed; and I have to thank a great many for the readiness with which they complied with that request. The ninth annual report of the Poor Law Commissioners, laid before Parliament in May last, having stated that the duties of the Union surgeons were much diminished in the North of England, in consequence of the various dispensaries, &c. which gave relief to the sick poor, and from medical men being employed to take charge of poor persons engaged in collieries, factories, &c., it became necessary to write to the surgeons of 112 Unions on these points, which delayed the printing of my report, entitled "Facts and Observations relating to the Administration of Relief to the Sick Poor in England and Wales," until the 27th of June. This report was privately addressed to the Members of the Commons House of Parliament, and I had the honour of sending a copy to you.

The additional matter for inquiry which the Northern Counties furnished, rendered it necessary to refer to some Members of the House of Commons conversant with the affairs of collieries and factories; and Lord Ashley, who takes the greatest interest in the whole subject, finding from the state of public business that nothing could be done this session, gave notice, on Wednesday the 26th, that he should move early in the next session of Parliament "for a select com-

the left groin the appearance of a wound made by a scalpel or some surgical instrument. The body generally exhibited the signs of great decomposition, more rapid than is generally the case, even allowing for the time of year and the period which had elapsed since death. The internal appearances presented on being opened—in the cavity of the chest an effusion of fluid in both pleural cavities, congested state of the lungs at their posterior parts, and some emphysema in the anterior or inferior portions. The heart was flabby, and its left ventricle dilated. I now proceeded to the examination of the abdominal cavity, and found the marks of slight peritonitis over the intestines. On proceeding to separate the stomach from its connections, I found very considerable adhesion between its smaller curvature and under surface of the liver. On breaking through those adhesions, I found a cavity containing grumous blood and portions of fibrine. The cavity extended a considerable way behind the stomach. On removing the stomach and slitting it open, I found about six ounces of coffee-ground fluid in its cavity. There was not the slightest appearance of inflammation or ulceration in the mucous membrane, which was unusually pale. The liver was a little enlarged, congested, and very much disorganized in its lower surface and inferior border. The gall-bladder was literally crammed with biliary calculi, large and small together about 200. The kidneys were extensively diseased, presenting an advanced stage of the malady designated 'Bright's disease.' There are no other morbid appearances. From the morbid appearances discovered, I conclude that the cause of death in the deceased was hæmatemesis and the inflammation of the peritoneum, the result of diseased state of the viscera. The entire absence of inflammation or ulceration in the lining membrane of the stomach, precludes the idea of any deleterious ingredient, mineral or vegetable, having been taken by the deceased. I did not analyse the contents of the deceased's stomach, for I considered it a work of supererogation."

Mr. Field states in his evidence that there was not the slightest appearance in the mucous membrane of inflammation or ulceration, which was more

than usually pale; but what would have been the appearances in the stomach if the vessels had not emptied themselves by secretion during the last stages of life? Would not the retention of coffee-ground fluid within the vessels have presented all the signs of congestion, and conveyed to the mind of the toxicological pathologist unequivocal indications of an irritant poison acting either directly upon the mucous surface, or, what is more probable, indirectly through the medium of the nervous and circulating systems? Did not the icy coldness of the hands indicate that one portion of the spinal marrow had ceased to generate heat, although it still continued to animate the circulation in a feeble manner, for the pulse was scarcely perceptible? and was not this depression of the circulating powers extremely favorable to the processes of secretion, exhalation, and congestion, so strikingly exhibited in the post-mortem examination? Is the icy coldness of the hands a common symptom of disease, or the panting a usual symptom in diseases of the respiratory organs? I put these questions, for I confess I have not witnessed them myself. Can coffee-ground or black vomit be called hæmatemesis, when the essential characteristics of the latter disease are entirely absent, viz. coagula?

Notwithstanding the gall-bladder was stuffed with calculi, I never heard the deceased complain of suffering any inconvenience from them.

As to the wound made by the scalpel, through which the intestine was partially protruding, I shall leave it to the profession to decide for what purpose that was made. A servant swore that he saw a gallon of fluid drawn off; but the surgeon who is said to have tapped the body ought to have been examined upon that point. There was no collapse of the abdominal parietes.

It is not my intention to enter into any controversial discussion; suffice it to say, that I vouch for the accuracy with which all the pathological phenomena have been detailed.

P.S.—I entirely differ with Mr. Field as to the analysis of the contents of the stomach being a work of supererogation. When the slightest suspicion of poison exists, and such a large quantity of fluid is found in the stomach after death, it should undoubtedly be

submitted to chemical analysis. But the proceedings at this inquest were not conducted in a very satisfactory manner.

OBSERVATIONS
UPON THE
NEW PROCESS PROPOSED FOR THE
DETECTION OF CORROSIVE
SUBLIMATE

BY MEANS OF
METALLIC SILVER.

BY FORENSIS.

(*For the London Medical Gazette.*)

DR. FRAMPTON has proposed to use silver as a test for corrosive sublimate, upon the grounds that the affinity of silver for chlorine, and the great tendency of silver to amalgamate with mercury, offer, or at least promise, facilities for detection superior to other methods. Dr. Frampton, at the same time, very liberally and very properly submits his processes to investigation, and courts inquiry. Upon these terms I beg to offer the following for his especial consideration, as well as that of toxicologists in general. Dr. Frampton's first proposition is, that silver triturated with bichloride of mercury effects the reduction of the salt and the liberation of the mercury, which then forms an amalgam with the remaining silver. This is inferred from the change of colour. Upon this it may be observed, that two substances, exerting no chemical action whatever upon each other, by mere mechanical admixture, frequently modify, and sometimes even generate perfectly new and distinct colours. Again, it is a rule of chemical action that bodies do not act upon each other unless one at least be in solution, or contain water of crystallization. Although there are exceptions to this, yet I determined to place this matter beyond all doubt. For this purpose, bichloride of mercury having been rubbed on a plate of metallic silver till it was darkened, the plate was digested in a solution of ammonia. The fluid was now filtered, and the filtered portion boiled in a tube, when it became turbid. On the addition of nitric acid, a white curdy-looking precipitate fell down, insoluble in nitric acid, and which became dark

on exposure to bright light. Ammonia again redissolved it, and, when reprecipitated by hydrochloric acid, a button of pure silver was obtained by reduction and cupellation. Therefore there can be no doubt that silver reduces bichloride of mercury by mere contact, and that a transfer of the chlorine to the silver takes place on mere triture.

Dr. Frampton's next experiment consisted in boiling a solution of bichloride of mercury with very finely and minutely divided silver, when the reduction of the mercurial salt, and the liberation of the metal, were equally the ultimate results. But the third case is the most important, in which bichloride of mercury is complicated with organic matter. Organic matter may be considered in the two-fold relations of animal and vegetable. As regards animal organic matter,—albumen for instance,—bichloride of mercury is rendered insoluble in water by it; that is, the albumen and bichloride of mercury enter into some sort of combination, which is insoluble. Upon this metallic silver exerts no action, nor would any action be exerted even at a boiling temperature. But, although insoluble in water, the compound is easily decomposed by various salines and other agents. Thus, hydrochlorate of ammonia and the alkaline chlorides redissolve the mercury in the form of bichloride. The same may be said of diluted hydrochloric acid, and of an excess of bichloride of mercury, or of albumen. In Dr. Frampton's experiment hydrochloric acid was added to the animal organic complication, by which the bichloride was brought into solution, and the silver thus enabled to act on the mercurial salt.

But although the process by silver, as detailed by Dr. Frampton, may answer for animal mixtures, I fear it will be found quite unsuited to vegetable mixtures. The reason probably is because bichloride of mercury is *reduced* by vegetable organic principles, so that hydrochloric acid will not act upon it, nor redissolve the mercury. Thus: "The solid compounds," says Christison, "formed by corrosive sublimate with animal principles, are either soluble in the hydrochloric acid, or part with all their mercury to it. The matter left does not yield a particle by reduction. But this is not the case with the compounds formed with vegetable

portion which invests the body and cervix behind, and extends from thence with greater or less rapidity, according to the severity of the attack, to the general peritoneal membrane. In some fatal cases the inflammation is in a great degree confined to the uterus, and it is generally most severe in this organ, or in the parts immediately contiguous. Even when it has extended to the other viscera, and affected them most severely, the peritoneum of the uterus most frequently, if not invariably, exhibits signs of recent inflammation. The lymph is for the most part poured out in thicker masses around the uterus than in any other situation; and this viscus has seemed to suffer in the greatest degree from the violence of the inflammation. Sometimes considerable deposits of pus are formed beneath the peritoneal coat of the uterus, which are either prominent and circumscribed, or diffused throughout the cellular membrane. These are most frequently met with at the part where the peritoneum is reflected from the uterus and vagina to the rectum.

Inflammation of the peritoneal coat of the uterus is characterised by great tenderness of the surface of the organ, increased on pressure, and by pyrexia more or less severe. In every instance which has come under my observation, where the patient was seen soon after the invasion of the disease, on a careful examination of the uterine region there has been more or less pain in it, increased by pressure, with constitutional disturbance; though it must be admitted that the pain and febrile symptoms have varied greatly in intensity. When the attack of peritonitis is severe, the patient commonly lies upon the back, with the knees slightly drawn up to the abdomen. At the onset of the disease the abdomen is generally soft and flaccid, and, except in the uterine region, not affected by pressure. Though an enlarged and painful state of the uterus be never altogether wanting, yet the pain often undergoes exacerbations similar to after-pains, and is often mistaken for them by careless observers, and the disease is thus overlooked till a great part of the peritoneal sac is inflamed, and the case in consequence is rendered hopeless. The whole abdomen then becomes swollen and tympanitic, and the pain either wholly subsides, or becomes still more intense than at the commencement. Vomiting of black or dark-green-coloured fluid follows, the pulse becomes extremely rapid and feeble, the tongue dry and brown, the lips and teeth are covered with dark sordes, and diarrhoea frequently supervenes, and death follows at no very remote period. The invasion of pain in the uterus is sometimes sudden; at other times the ordinary increased sensibility of the uterus, subsequent to the efforts of natural labour, or after-

pains, pass slowly into the acute pain, increased by pressure, which is the great characteristic symptom of uterine inflammation at the onset. Most frequently the accession of the disease is marked by rigors, partial or general; sometimes so slight as scarcely to be perceived by the patient, at other times so violent as to produce succussions of the whole body. The cold shivering after a longer or shorter duration passes away, and is succeeded by great heat of the surface, acceleration of the pulse and of the respiration, thirst, sometimes nausea and vomiting, and intense pain across the forehead. The rigors precede, accompany, or follow the increased sensibility of the uterus. In some of the most severe cases there has been no distinct rigor; but a quick pulse, hot skin, and hurried respiration, have rapidly succeeded to the uterine pain. In some of the most unfavourable cases, the extremities have been cold, and the countenance anxious and pallid, after the disease has been completely formed. There is no uniformity in the state of the tongue in puerperal peritonitis. It is sometimes covered with a thin, moist, white, or cream-like film, at other times it is red in the centre, with a thick yellow, or white fur, on the edges. The lochia are often completely suppressed, in other cases only diminished in quantity. The mammæ usually become flaccid, yet in some fatal cases the milk has been secreted till a short period before death. Puerperal peritonitis may be confounded with the irregular contractions of the uterus which constitute after-pains and hystericalgia, and it must be admitted that in some cases it is difficult to draw a line of distinction between them. Where the pulse is accelerated, the remission of pain incomplete, the lochia scanty or suppressed, the fundus uteri felt large and hard, and painful on pressure, or the whole hypogastric region unusually tender when touched, in a large proportion of cases you will arrive at a correct diagnosis by considering the peritoneal coat of the uterus, or its deeper-seated tissues, in a state of congestion or inflammation, and employing antiphlogistic treatment. There are few puerperal women, except those of a feeble and irritable constitution, or who have been previously exhausted by hæmorrhage, or some chronic disease, who are seriously injured by cautious depletion, local or general; and where death has followed the abstraction of sixteen or twenty ounces of blood from the arm the fatal result may fairly be attributed to the disease, and to the neglect of the remedy rather than its abuse. This table, which was published in an imperfect form, without the description of the morbid appearances, ten years ago, furnishes the best proof you can have of the truth of this statement.

TABULAR VIEW (No. 1) OF 100 CASES OF SEVERE INFLAMMATION OF THE UTERUS AND ITS APPENDAGES,
Which occurred to me in London, from March 1827 to the end of December 1830.

No.	Name, Residence, and Delivery.	Date of Attack and Symptoms.	Treatment.	Result and Morbid Appearances.
1	Groom; æt. 28; 13, Little Col- ram Street, Russell Square. Natural labour. 6th March, 1827.	First day after delivery.—Pyrexia; uterine pain; lochia suppressed; diarrhoea; vomiting; tympanites. Died on the 10th.	Opiates and hot fomenta- tions at the commence- ment. V.S. ʒxij. late in the disease, cathartics.	Died. Peritoneal sac extensively inflamed; uterine peritoneum behind coated with lymph; pus in the cellular tissue beneath; uterine appendages on both sides inflamed, and covered with lymph and pus; ʒiv. of a dark- coloured serum in the peritoneal sac; stomach and small intes- tines distended with gas.
2	Marshall; æt. 23; 3, Crown Street, Soho. Natural labour. 1st March, 1827.	Second day.—A violent rigor; headache; vertigo; uterine pain; tongue red and moist; lochia and milk suppressed; pulse 112, feeble; slight diar- rhoea; vomiting; delirium; cessation of pain; enormous distension of abdomen. Died 16th March.	V.S. ʒxiv. third day after attack, leeches xxx., calo- mel, pulv. antim., cathar- tics, opiates.	Died. Extensive peritonitis; in- testines glued together with lymph; uterus and its appen- dages imbedded in lymph and pus; ʒx. of sero-purulent effu- sion; uterine peritoneum red and vascular; ovaria softened and enlarged.
3	Mary Pascoe; æt. 27. Natural labour; 7th child. 15th March, 1827.	Second day.—Severe rigor; acute pain in the back and region of the uterus, increased by pressure; diarrhoea; no sickness; tongue red and moist; pain in the back part of the head, and giddiness; pulse 120, not strong; respiration anxious; face flushed; tremors of the limbs.	V.S. ʒxvj., leeches xxx. calomel, antimony, ca- thartics.	Recovered.
4	Mary Sullivan; æt. 32; 16, Denmark Street, Soho Sq. In labour 52 hours. 25th March, 1827.	Third day.—Rigors; uterus large and painful; pulse 96, sharp; lochia suppressed. Duration of disease eight days.	V.S. ʒxv., leeches xj., ca- lomel, gr. iv., pulv. antim. gr. v. 4ta q. q. h., ca- thartics.	

5	Wilson; æt. 42; 4, Pitt Place, Drury Lane.—Tedious lab. 2d April, 1827.	Eighth day.—Rigors; uterine pain; headache; lochia suppressed.	V.S. ʒiv., calomel and cathartics.	Recovered.
6	Smith. Natural labour. 6th April, 1827.	First day.—Severe pain in right iliac region; slight pyrexia; rigors; pulse 104; pain aggravated and diffused over the whole uterine region. Symptoms relieved by V.S.	Fomentations, tinct. opii gtt. xl., a copious bleeding, saline cathartic, calomel, opium, a blister. V.S.	Recovered.
7	Williams; 34, Drury Lane. Natural labour.	Sixth day.—Uterus enlarged, and painful on pressure; pyrexia; lochia suppressed.		Recovered.
8	Sarah Oulton; 8, Houghton St. Clare Market. Arm presentation; turning. 9th April, 1827.	Third day.—Acute pain of the uterus, succeeded by great tenderness of the whole abdomen; pulse 110; great heat of skin; lochia suppressed; vomiting; tympanites.	Stimulants and opiates at the invasion, copious bleeding and digitalis late.	Died.
9	Leeder; æt. 28; 24, Brownlow Street, Long Acre. Natural labour. 13th April, 1827.	Fifth day.—Severe rigor; headache; pain of back, loins, and lower part of abdomen, increased by pressure; pain afterwards in the left iliac fossa and along the course of left iliac and femoral vein, and slight swelling of left inferior extremity.	V.S. lb. ij., leeches xx., calomel, antimony, cathartics.	Recovered.
10	Haman; æt. 25; 2, St. Ann's Place, Soho.—Nat. labour. 20th April, 1827.	Third day.—Intense headache; no rigor; uterine pain increased by pressure; pulse frequent; tongue white; mammæ flaccid.	V.S. lb. iss., calomel, antimony, diaphoretics, and cathartics.	Recovered.
11	Richards; 20, Stacey Street. Arm presentation; turning. 2d May, 1827.	First day.—Rigors; intense uterine pain and headache; lochia suppressed; pyrexia.	V.S. ʒxxiv., leeches, calomel, opium, cathartics.	Recovered.
12	Hunn; æt. 28; Crown Street, Soho.—Natural labour. 1st May, 1827.	Sixth day.—Severe uterine and abdominal pain; pulse 120, feeble; lochia suppressed; milk secreted.	V.S. ʒxx., leeches xxx., cathartics, and opiates.	Recovered.
13	Carr; æt. 30; Tash Court, Gray's-Inn Lane.—Nat. lab. 12th May, 1827.	Third day.—After drinking porter, rigors; uterus large and painful; pulse frequent, and soft; tongue white and moist; countenance pale and anxious.	V.S. lb. ij., calomel, and cathartics.	Recovered.
14	Mannay; æt. 25; 6, Charles St. Drury Lane.—Nat. lab. 27th May, 1827.	Second day.—Uterine pain; nausea and headache; lochia diminished; pulse 80; heat of skin little increased.	V.S. ʒxij., fomentations.	Recovered.
15	Eliza Corey; æt. 16; 50, King Street, Soho.—Natural lab. 17th June, 1827.	Third day.—Pyrexia; exquisite uterine pain, with great depression of strength; pulse 140.	V.S. ʒxxiv., leeches, xvij., calomel, and cathartics.	Recovered.

16	Groundawell; Ham Yard, Great Windmill Street. 10th July, 1827.	Third day.—Rigors; uterine pain and headache; lochia suppressed.	V.S. xvij., leeches xij., calomel, antimony, cathartics.	Recovered.
17	Shepherd; æt. 33; 39, St. Martin's Street. Puerperal convulsions. 13th August, 1827.	Fifth day.—Rigors; violent pain of uterus; rapid pulse; tongue loaded; followed by severe pains and swelling of left leg.	V.S. twice xxxiv., leeches xxiv.	Recovered.
18	Barton.—Natural labour. 2d September, 1827.	— Acute pain in the region of the uterus; rigors; pyrexia.	V.S. xxxv.	Recovered.
19	Costello; æt. 23; 15, Church Court, St. Martin's. 13th September, 1827.	Fourth day.—Slight uterine pain; rigors; rapid feeble pulse; tongue brown; vomiting; tympanites; delirium.	V.S. not employed; leeches x, stimulants, opiates.	Died.
20	Mrs. Somerville; æt. 40; Orange Street, Leicester Square. Natural labour. 28th September, 1827.	21st Sept.—Severe rigor; acute pain in the hypogastrium and loins; suppression of lochia; nausea; urgent thirst; delirium; pulse 130, weak and intermitting; countenance pale and anxious; tongue white and moist. 22d: stupor; pulse more rapid and feeble; pain in the left iliac region. 23d: stupor; hurried breathing; intermitting pulse.	V.S. xvij., fomentations, opiates.	Peritoneal sac perfectly healthy; no effusion; left spermatic vein from uterus to emulgent vein distended with coagula of blood and lymph, which adhered to the inner surface of the vessel; vein thickened, and inner membrane of a scarlet colour; veins in the fundus uteri inflamed, and muscular coat softened; left ovary and tube soft, of a dark red colour, and coated with lymph.
21	Cantwell; æt. 23; 15, Green Street, Leicester Square. Natural labour. 23d September, 1827.	Second day.—Violent rigor, and uterine pain; pulse 140; headache; sickness; tremors; delirium; great debility; pulse 140; painful and distended abdomen.	V.S. xxxij., calomel, Dover's powder, cathartics, blisters.	Died.
22	Foster; æt. 30; 11, Ogle Street, Middlesex Hospital. Natural labour. 6th October, 1827.	Sixth day.—Pain, gradually increasing from delivery; pulse 140; debility; hurried respiration; lochia suppressed; right iliac region peculiarly tender. Convalescent on the third day.	V.S. xxxvj. (blood buffy), leeches xxiv., calomel, and antimony.	Recovered.
23	Cooper; 6, Moore Street, Seven Dials.—Natural labour. 3d October, 1827.	Tenth day.—Rigor; pain of uterus and right iliac region; pulse 100; lochia suppressed.	V.S. xxxvj., leeches xxiv., calomel, antimony, and cathartics.	Recovered.

24	Wellington; æt. 22; 16, Tower Street, Seven Dials. Natural labour. 16th October, 1827.	Third day.—Severe pain of uterus from the time of delivery; vomiting; pulse 100; lochia suppressed. Convalescent 19th October.	V.S. 3xv., leeches xvij., calomel, and antimony.	Recovered.
25	Hill; æt. 35; 454, Strand. Natural labour. 15th October, 1827.	Fourth day.—Severe pain, increased by pressure, in both iliac regions; abdomen soft; tongue white; thirst; pulse 96. Second day.—Pain of hypogastrium, increased by pressure, since delivery; rigors; lochia suppressed; tongue loaded; pulse 140, feeble.	V.S. 3xiv., calomel, antimony, saline effervescing medicine. V.S. 3xij., calomel, antimony, cathartics.	Recovered.
26	Hughes; 22, Short's Gardens. Natural labour. 29th October, 1827.	Fifth day.—Rigors; headache; intense uterine pain; lochia suppressed; pulse 135, feeble; tongue dry and brown; vomiting; prostration of strength; delirium; painful induration of the left saphena veins; coma; swellings appeared suddenly in the joints of the arms.	Leeches xxiv., powerful diffusible stimuli, quinine, &c.	Recovered.
27	Pope; 7, Feathers' Court, Drury Lane. Flooding. 26th October, 1827.			Died. Saphena, femoral, and iliac veins not examined; small intestines of a bright red; no lymph effused; the left fallopian tube and fundus uteri of a deep red colour; the examination was imperfect.
28	Desmond; æt. 20; 15, Crown Street, Soho. 16th November, 1827.	Fourth day.—Rigors; pyrexia; headache; acute pain of uterus; lochia suppressed.	V.S. 3xx., leeches xvj., calomel, antimony, Dover's powder, cathartics.	Recovered.
29	Manning; æt. 22; 131, Drury Lane.—Arm presentation. 3d December, 1827.	Third day.—Exquisite uterine pain; rigor; thirst; cough; rapid strong pulse.	V.S. (at twice) 3liv., leeches xxiv., fomentations, calomel, antimony, opium, cathartics.	Recovered.
30	Mayes; æt. 20; 5, Vere Street, Clare Market. 7th January, 1828.	Third day.—Rigors; headache; acute pain of hypogastrium; pulse 110; tongue white; lochia and milk not suppressed.	V.S. 3xvj., leeches xxiv., fomentations, calomel, pulv. Jacobi, cathartics, saline draughts.	Recovered.
31	Adams; æt. 24; 10, Ely Court, Holborn.—Natural labour. 10th January, 1828.	Third day.—Severe after-pains; uterine region exquisitely painful on pressure; pulse 90, and strong; tongue white; thirst; lochia flow.	V.S. 3xxx., leeches xvij., cataplasms, calomel, antimony, Dover's powder, cathartics.	Recovered.
32	Atkinson; æt. 32; 5, Shelton Court. Natural labour. 25th January, 1828.	Second day.—Excessive tenderness of uterus; hypogastrium tumid; pulse 100, weak; no rigor or headache; lochia and milk flow; retention of urine. The symptoms continued several days without relief.	V.S. 3xvij., V.S. 3x., leeches xxiv.—xxiv., calomel to salivation, cathartics, cataplasms, blisters.	Recovered.

33	Malton ; æt. 30; 5, New Compton Street.—Natural labour. 1st February, 1828.	Third day.—Rigors; uterus large, and on the right side exquisitely painful; intense pain in the forehead; tongue white; nausea; prostration; lochia flow.	V.S. 3xvj., leeches, calomel, antim., cathartics, opiates,	Recovered.
34	Lawrens; æt. 35; 6, Cumberland Street, Middlesex Hosp. Hydrocephalic foetus; dropsy of amnion. 12th February, 1828.	Second day.—Intense pain of hypogastrium; lochia suppressed; rapid feeble pulse; vomiting; foul tongue; urgent thirst; prostration of strength; tympanites.	Leeches xxiv., calomel, Dover's powder, effervescing draughts.	Died. Intestines, liver, and uterus partially coated with lymph; uterus uncontracted; a fibrous tumor in the muscular coat; lb. ij. of a dark-coloured seropurulent fluid in peritoneal sac; right uterine appendages disorganized by inflammation; ovarium three times the natural size, and softened.
35	Parkhurst; æt. 34; Marylebone Lane. — Hæmorrhage and retained placenta.	Third day.—Acute pain of uterus; lochia suppressed; rigors; rapid pulse; loaded tongue; nausea; yellow suffusion of countenance; crural phlebitis on left side.	Copious venesection, leeches, fomentations, cathartics, opiates.	Recovered after five weeks.
36	—; 5, Monmouth Street. Natural labour. 20th March, 1828.	Second day.—Acute pain of hypogastrium; rigors; pulse accelerated; lochia suppressed.	V.S. 3xviij., calomel, cathartics, fomentations.	Recovered.
37	A Patient in the British Lying-in Hospital. Natural labour. 12th March, 1828.	Fifteenth day.—(First seen.) Violent pain in the lower part of the abdomen; vomiting; rapid feeble pulse; extremities cold.	Opiates, fomentations, leeches xij., vesication, calomel and opium late.	Died.
38	M. Jenkins; 11, Charles Street, Strand. 15th March, —.	Third day.—Exquisite tenderness but no fulness nor hardness in the region of the uterus; headache; rigors; lochia suppressed; pulse quiet, not feeble.	Copious V.S., calomel, antimony, cathartics.	Recovered.
39	—; High Street, St. Giles's. Natural labour. 16th April, 1828.	Fourth day.—Rigor; quick strong pulse; hot skin; great sensibility of the hypogastrium; lochia suppressed.	V.S. 3xx., calomel, pulv. antim., cataplasms, cathartics.	Recovered.
40	Buck; White Horse Yard, Drury Lane.—Natural labour. 8th July, —.	Second day.—Severe rigor; uterus large, hard, and painful; lochia flow; pulse 130; tongue loaded; bowels costive.	V.S. 3xxv., calomel, cathartics, cataplasms.	Recovered.

41	Austin; British Lying-in Hospital.—Natural labour. 1st June, 1828.	Seventh day.—(First seen.) Severe fever, headache, delirium; pulse 130; tremor of tongue and extremities; diarrhoea; pupils dilated; swellings of joints, especially right wrist; exhaustion. Second day.—Rigor; headache; heat of skin; intolerance of light; pulse 140; hurried respiration; no pain of abdomen; pain in the chest, followed in a few days by cough and foetid expectoration. Died eighteen days after delivery.	Leeches xij. to the head, diaphoretics, opiates, wine, ammonia, and other stimulants. V.S. eighth day to xxxvj., blisters to the thorax.	Died.	Died. Abscess in the left ovary; pus in the sinuses of the uterus on the left side; coats of left spermatic vein thickened, its inner surface lined with lymph and pus, and nearly obliterated. These changes occupied the whole course of the vein to the emulgent, the coats of which were in the same condition; venæ cavæ healthy; inflammation and gangrene of the lungs. Cured.
42	Ann Cromer: St. James's Infirmary.—Uterine hæmorrhage from placental presentation. 22d July, 1828.				
43	—; British Lying-in Hospital. 1828.	Third day.—Acute pain in the iliac regions; rapid pulse; rigors; lochia suppressed.	V.S. xxx., calomel, cathartics, fomentations.	Recovered.	
44	—; British Lying-in Hospital. Natural labour. 8th August, 1828.	Sixth day.—Rigors; intense soreness of the hypogastrium; tongue loaded; bowels open; pulse quick; skin hot.	V.S. xxx., calomel, pulv. antim. cathartics.	Recovered.	
45	Vernon; 11, Chapel Street. Droopy of amnion; hæmorrhage. 1st November, 1828.	Second day.—Violent rigor; sudden attack of acute pain of the uterus, which became large and hard; lochia suppressed.	V.S. xxx., leeches xxxvj., calomel, antimony, cathartics, diaphoretics.	Recovered.	
46	—; 26, Little Windmill Street. Natural labour. 3d November, 1828.	Tenth day.—Violent pyrexia; uterus large, hard, and painful, gradually increasing from delivery; lochia suppressed.	V.S. xxx., leeches xxxvi., calomel, &c.	Recovered.	
47	Mrs. Turner; 92, Berwick St. Premature labour. 10th December, 1828.	Second day.—Acute pain in the hypogastrium before delivery; severe vomiting soon after took place, with pyrexia, tension of abdomen, suppression of urine, and tympanites.	V.S. xxxiv., leeches, cathartics.	Died.	Died. Omentum, intestines, and liver coated with lymph; omentum vascular; peritoneum covering uterus, and appendages, red, vascular, and coated with lymph; two pints of reddish serum in cavity of pelvis; muscular tissue of uterus healthy.

48	Gibbs; 41, Broad Street, Golden Square.—Natural labour. 18th January, 1829.	Third day.—Acute pain of uterus; pyrexia; pulse rapid and feeble; lochia suppressed; followed by great tenderness in the left iliac and femoral veins, and general swelling of the whole left lower extremity, of short duration.	Moderate bleeding twice at the onset, leeches xxvj.; fomentations, mild cathartics, opiates.	Recovered.
49	A patient of Middlesex Hospital; 20, Ogle Street. Natural labour. February 1829.	Fourth day.—Pyrexia; acute pain, increased by pressure, in the left iliac region; lochia diminished; tongue white; headache; surface hot and moist. Imperfect relief from leeches.	Leeches xxvj.; poultices, mercury, antimony.	Recovered imperfectly after a considerable period.
50	Greenwood; 4, Stafford Street, New Road.—Tedious labour. 21st February, 1829.	Third day.—Sudden attack of severe pain in the region of the uterus and left iliac region; intense pain of forehead; violent rigors; pulse 116; lochia diminished; tongue loaded; urgent thirst.	V.S. lb. ij. (syncope), calomel and opium, leeches xxiv., cathartics.	Recovered.

[This Table will be completed in the next number.]

By looking over the abstract of the cases contained in it, you will observe that a great proportion of the women, above one half, were attacked on the second and third days after delivery, and that in most of them where the disease proved fatal the symptoms occurred in the following order: rigors, uterine pain, suppression of the lochia, headache, tenderness and distension of the whole abdomen, vomiting, diarrhoea, delirium, and cessation of pain before death.

II. *Inflammation of the uterine appendages, ovaria, fallopian tubes, and broad ligaments.*

I have seen the uterine appendages free from disease in one case only, where the peritoneal covering of the uterus has been inflamed, but frequently the peritoneum has been slightly affected where the appendages of the uterus have been extensively disorganised. The surface of the broad ligaments, ovaria, and fallopian tubes, have been red and vascular, and partially or completely imbedded in lymph or pus. The outer extremities of the fallopian tubes have been of a deep red colour, and softened, and deposits of pus in a diffused or circumscribed form have taken place between their coats or within their canals. Between the folds of the broad ligaments effusions of serous or purulent fluids have also been found. Numerous important changes have likewise been observed in the structure of the ovaria. Their peritoneal surface has often been red, vascular, and imbedded in lymph, without any visible alteration of their parenchymatous structure, or their whole volume has been greatly enlarged, swollen, red, and pulpy; blood has been effused into the Graafian vesicles, or around them, and circumscribed deposits of pus have been often dispersed throughout the substance of the enlarged ovaria. In several cases the structure of the ovaria has been reduced to a soft vascular flocculent pulp, no traces of their original organization being left. These morbid appearances have been represented in several drawings [exhibiting them]. The ovary in one instance was converted into a large purulent cyst, which had contracted adhesions with the abdominal parietes, and discharged its contents exteriorly through an ulcerated opening. In another case, which proved fatal, the inflammation had extended to the cellular membrane exterior to the peritoneum, and had given rise to an extensive purulent deposit in the course of the psoas and iliacus internus muscles, as in lumbar abscess. In two other individuals, who ultimately recovered, the purulent deposit formed in the situation of the psoas and iliacus internus muscle, or about the neighbourhood of the uterus, made its way through an ulcerated opening in the upper part of the

thigh : contraction of the thigh on the trunk took place in both these cases, and continued for several months, but disappeared on the recovery of the patients. In another recent case, a great quantity of pus, after uterine inflammation, escaped through the anterior wall of the vagina, and the patient recovered. In another, after puerperal peritonitis, an ulcerated opening formed in the rectum, and a great quantity of pus escaped, after which the symptoms subsided. In several cases I have seen a great discharge of pus take place through an opening made with the lancet in the walls of the abdomen, between the umbilicus and ilium, and perfect recovery to succeed. Inflammation of the uterine appendages being generally combined with peritonitis to a greater or lesser extent, it is often difficult to establish a diagnosis between these varieties of uterine inflammation. The pain is, however, usually less acute than in peritonitis, and is principally situated in one or other of the iliac fossæ, extending from them to the loins, anus, and thighs. On pressure the pain is chiefly experienced in the lateral parts of the hypogastrium. The constitutional symptoms at the onset of the attack do not materially differ from those which mark the accession of peritonitis, which are often accompanied with strong febrile reaction, which passes speedily away, and is succeeded by prostration of strength, and the other symptoms which characterise inflammation of the venous and muscular tissues of the uterus.

III. *Inflammation and softening of the muscular coat of the uterus.*

The dark-coloured mucous layer, which usually coats the inner surface of the uterus after delivery, has been supposed to be the result of gangrenous inflammation, and has been described as such by some pathologists. This ought not, however, to be confounded with the changes produced by inflammation of the inner membrane of the uterus, when it becomes softened or wholly disorganized, like the mucous linings of the stomach and intestines in certain inflammatory diseases. In several cases the internal membrane of the uterus was soft and flocculent, and had undergone changes similar in appearance to those which are produced in it by long maceration. In other cases, not only has the internal coat been disorganized, but the muscular tissue, to a considerable depth, or even through its entire substance to the peritoneum, has been of a dark purple, greyish, or yellowish hue, and so softened in texture as to be torn by the gentlest efforts made in removing the parts from the body. The peritoneum covering the inflamed portion of muscular coat of the uterus has also been affected, and lymph has been thrown out over its surface as in common

peritonitis; or the peritoneum has become of a yellow, red, or livid colour, no albumen having been deposited on its surface. The peritoneum has also been softened where the subjacent tissue has been little, if at all, affected; more frequently, however, the softening has proceeded from the internal surface of the uterus to its peritoneal, and the muscular has been extensively disorganized without a corresponding lesion of the peritoneal coat of the uterus. Inflammation and softening of the uterus have, in some cases, affected the muscular tissue of the fundus, body, and cervix of the uterus; in others these changes have been limited to the part where the placenta has adhered, which has become unusually thin, and reduced to a pulpy state. Small abscesses have been formed, in a few instances, in the muscular tissue of the uterus, without any perceptible change in the surrounding substance of the organ, while in other cases every trace of muscular fibre has been lost. Pain of the hypogastrium, diminution or suppression of the lochial discharge, and rigors, with rapid pulse, are the most frequent symptoms of the disease. The countenance becomes pallid, and is usually expressive of great anxiety and distress. There is often severe headache, with delirium, and other affections of the brain and nervous system; and so violent have these been, in some cases, that the local affection of the uterus has completely escaped detection during life. The skin is hot and dry, and sometimes of a peculiar sallow tinge; the pulse is rapid and feeble; the respiration hurried, with remarkable prostration of strength; the tongue becomes foul; the lips covered with sordes; occasional vomiting is experienced. The progress of the disease in some cases is rapid; in others it runs its course more slowly, being protracted to the eighth or tenth day. It must be admitted that the diagnosis of this variety of uterine inflammation, particularly where it is complicated with peritonitis or inflammation of the veins, which is frequently the case, is difficult, or even impossible. If the attack of inflammation of the muscular coat be sudden and violent, it becomes so speedily complicated with peritonitis, more or less acute, that the symptoms are readily confounded together, and it is impossible to distinguish with certainty the symptoms which are to be referred to peritonitis, and those which result from the affection of the muscular coat. The prostration of strength, the alteration of the features, which often exists from the commencement, the feebleness and rapidity of the pulse, the irregular foetid state of the lochia, are not such constant symptoms as to be pathognomonic, and may arise from other causes. Hence it will appear that the most attentive consideration of the phe-

nomena will not lead us to any certain conclusion as to the nature of the affection ; and, as in many other diseases, we can only determine its precise character by the history of its origin and progress, and by the alteration of structure discovered after death. In all the cases of this affection which I have observed, the resources of nature and of art have proved equally unavailing in arresting its fatal course. The active inflammatory symptoms which commonly manifest themselves at the commencement of the attack pass speedily away, whatever plan of treatment be adopted, and are rapidly succeeded by symptoms of exhaustion. Where the disease is not complicated with inflammation of the peritoneum the symptoms are not such as to indicate the necessity for the employment of venesection ; and in one case where it was adopted freely the abstraction of the blood was followed by speedy death. In other cases, where the opposite plan of treatment was had recourse to, the fatal result seemed to be less speedy, though equally certain. This destructive form of uterine inflammation has been described by several German and French pathologists ; Astruc, Vigarius, and Primrose, probably refer to it when they state that the uterus is liable to be attacked with gangrene and sphacelus ; Ponteau and Gastellier have related cases in which gangrene of the uterus followed acute inflammation of the organ. In 1750 an epidemic attacked many puerperal women, which was characterized by severe abdominal pain and tumefaction of the hypogastrium. On examining the bodies of two of these women, Ponteau states that the uterus was found very large ; the internal membrane was soft and black, and the substance of the parietes was of a livid red colour, and in a gangrenous state. Boer, of Vienna, has described this affection under the term putrescence of the uterus, and has observed its frequent occurrence in particular epidemics. Luroth and Danyau have more recently published detailed accounts of this destructive disease. Two hundred and twenty-two women died in the Maternité, of Paris, in 1829 ; and in examining their bodies, M. Tonellé found the muscular tissue of the uterus softened in forty-nine. He states that softening of the uterus, after occurring frequently in the first half of the year 1829, and particularly about January, disappeared entirely in the months of July and August, which were characterized in a remarkable manner by the frequency of inflammation of the veins of the uterus. Afterwards it began to occur, often with great violence, in September and October, and again disappeared in November and December. Boer and Luroth have, I think, erroneously described the different degrees of this affection as constituting two essen-

tially distinct diseases. M. Tonellé also states that the disorder at Paris assumed two different forms—the softening of the uterus properly so called, and the putrescence. In one form the softening affected only the internal surface of the uterus, and it presented itself under the appearance of irregular superficial patches of a red or brown colour, which occupied almost all the points of this surface. Its limits were not determined, the diseased tissue passing by insensible gradations or shades into the healthy tissue. In the second species the softening extended deep into the substance of the uterus ; it occupied sometimes the whole thickness of the body and cervix of the uterus. The tissue of this organ was so softened that the fingers could not seize it without passing through all its parts. The superficial softening was combined almost constantly with some alteration of structure, the result of peritonitis, metritis, or inflammation of the veins ; and it did not appear that the existence of these had a very sensible influence on the progress of the symptoms. The softening in the second degree was also sometimes combined with other derangements ; but it formed usually the principal alteration, often the only one, and invariably impressed upon the disease the most decided typhoid character.

The history of uterine phlebitis will form the subject of the next lecture.

REMOVAL OF
DROPSICAL OVARIA, ENTIRE,
BY THE LARGE ABDOMINAL SECTION.

By D. HENRY WALNE, Esq.

(For the London Medical Gazette.)

SECOND CASE.

IN the early part of the present year, Mr. Camplin, of Finsbury Square, called on me, accompanied by one of his patients, whose case he considered to be one of dropsical ovarium, and suitable for the operation of which I had then recently published a case. At his desire I very carefully investigated the circumstances of her state, and agreed with him that there could be no doubt of the nature of her disease, nor of the propriety of ultimately treating it by operation. We however thought that, in deference to the opinion still entertained by a few physicians that internal remedies are not without use in such cases, it would be proper first to give a trial to a course of such as are at present in most esteem. By thus proceeding we should test the efficacy

of active internal agents, and in the event of their failure, find a fuller justification for resorting to surgical means.

Mr. Camplin's patient, Mrs. M. R.—, was a widow of 57 years of age, who had not married till she was 46 years old, had never been in the family way, and whose husband died five years after their marriage. Having always been accustomed to suffer much at the menstrual periods, she yet continued to menstruate till she was 49. Full sixteen years before she applied to Mr. Camplin, she had thought herself larger on the left side of the abdomen than on the right, but until about eight years ago had not felt the slightest inconvenience, nor did she take any notice of the circumstance to any one, being in the enjoyment of perfect health. About the latter period, however, she felt a soreness and tenderness of the lower part of the left side of the abdomen, accompanied by fulness; and a surgeon, to whom she applied, mentioned the ovary of that side as the seat of ailment, and ordered her leeches, iodine ointment, and various other remedies, observing that though her complaint "was not a thing which touched life, it sometimes ended in dropsy." Five or six years back her abdomen was to all appearance flat; but during the last two or three years she perceived a stoutness, which, as her health and condition were good, she thought little of. Something more than a twelvemonth since she began "to droop," to lose flesh generally, and at the same time to increase very remarkably in the size of her abdomen. Having ascribed these changes to flatulency and indigestion, she did not immediately apply for professional advice, but their continuance induced her to refer to Mr. Camplin in November 1842; the above being, in substance, her own history of the case down to that period.

When I first saw Mrs. R., she had the appearance of a healthy person of spare habit, and the size of a woman eight months advanced in pregnancy. There was distinct fluctuation and dull sound over the greater part of the abdomen, with a circumscribed character of tumefaction. A sense of dragging about the cartilages of the ribs, chiefly of the right side, was her principal uneasiness. The uterus appeared healthy, and of moderate size. She had no

symptom of general dropsy. Her health was good, except a little flatulency and other symptoms of feeble digestion. She was directed to take—

Liq. Potass. 3ss.; Potass. Hydriod. gr. iij. ad gr. v.; in bitter infusion, with Tinct. Columb. twice a day, and an occasional aperient.

After a steady trial of the Liq. Potass. and Potass. Hydriod. for more than two months, it was clear that her size was undergoing augmentation, whilst her plight was in no degree improved. Her own opinion was, and Mr. Camplin and I thought it correct, that the disease gained ground faster whilst she was following this plan of treatment than either before or after it. The medicines that were administered subsequently were chiefly directed to the improvement of her digestion, and the lessening an irritability of system and excitability of circulation which had shown themselves.

Finding that the disease continued unabated, and that the inconveniences occasioned by it were becoming greater and greater, the operation was proposed, and Dr. James Blundell consulted, that we might have additional assurance of the accuracy of our opinion and the propriety of the intended measure. We had the satisfaction of his entire concurrence. Various circumstances, however, occurred to postpone the operation till the 30th of May, when, in the presence of Dr. Sewall, of Washington (United States), Dr. Klein, physician to the Crown Prince of Wurtemberg, Drs. Moore and Waller, and other gentlemen, and assisted by Mr. Camplin and those gentlemen (Mr. Vincent excepted, whom accident kept away) whose aid I had been so fortunate as to obtain on the former occasion, I proceeded, after due preparation, to its performance.

The most important preliminary measures were—

1st. Insisting on a few days of absolute rest within the house, our patient having wearied and excited herself several times very undesirably by visiting distant friends and busying her mind; and having, by much walking, brought on a painfully swollen condition of the left leg, with tenderness in the course of the veins. Rest upon a couch, a little aperient medicine, and putting her feet in hot water two or three times, improved her state very

much, reducing the pulse, which had become somewhat quick, and removing her other slight ailments.

2dly. Marking the abdominal skin with solution of arg. nitr. in lines crossing the linea alba, to secure correct adjustment of the wound.

3dly. Clearing the bowels so completely that there should be no occasion to disturb them again for at least 48 hours after the operation. An aperient pill over night, and a large enema an hour before the operation, secured this object, which I consider doubly important; in reference, viz. to the healing of the wound and to the prevention of peritoneal inflammation.

4thly. Supporting her well with nutriment that would leave little residue to load the intestines afresh, and yet should well sustain her through the operation and its immediate consequences. I remembered the cold extremities and low condition of my former patient just after the operation. To this a pint and a half of good beef tea was given about two hours beforehand. She had her usual breakfast, and took nothing but the beef tea after it.

5thly. The temperature of the room was maintained at a little above 70 Fahrenheit.

Tuesday, 30th May, 1843. It was near five o'clock when Mrs. R—— took her seat upon a couch, her feet upon the ground at its end, her back well propt by pillows, and an eight-headed roller laid beneath her back. The steps of the intended operation had been fully explained to all the medical gentlemen when previously assembled in another room, and each of those who had assisted me before was engaged to take his part as in the former instance. Plenty of able assistance was at hand, but this arrangement was the simplest mode of securing what was necessary without confusion. Mr. Camplin was watchful of his patient's condition, and whilst cheering her was ready also with every aid of counsel and of hand that could be useful.

As in the former operation a small incision was first made of an inch and a half in length, and the abdomen cautiously opened to a still less extent in the linea alba. In the course of this proceeding a little clear fluid (probably from the sheath of the right rectus muscle,) having appeared in the wound, gave an impression to some of

the spectators that the sac had been already wounded, or, at all events, the peritoneal cavity entered. The fluid ceased, however, to trickle down, and examination convinced Dr. Blundell and myself that such was not the case; and by a careful division of the tendinous and peritoneal layers the surface of the sac was made visible, when a finger, passed in every direction between it and the peritoneum, discovered no adhesions. I could now proceed in the operation with the confident anticipation that all the circumstances of the case were favourable to its completion, and expediting my movements accordingly, I divided the skin from above downwards to the first wound, and thence towards the pubes, in all to the extent of about twelve inches; then, with a probe-pointed curved bistoury, guided and guarded by two fingers of my left hand, I opened the peritoneum to a like extent. The wounded structures separated on each side, and the tumor being devoid of adhesions steadily advanced through the incision. They were followed by the hands of one of the gentlemen and closed behind the tumor as opportunity offered, so as to cover the viscera with the peritoneum itself as promptly and as completely as possible. Dr. Freund, as upon the former occasion, performed this office, and the tumor was steadied by Mr. Law; whilst I passed two fingers of my left hand behind the left uterine broad ligament, which formed the pedicle, and by their guidance, with a suitable needle, carried a ligature behind and thence through the middle of the pedicle, for the purpose of tying it in two portions. The first half of the ligature was readily and firmly tied, but the second broke.* The entire pedicle was then included in one double ligature, and divided between it and the tumor. The pedicle was very short, and the uterus lay backward in the pelvis, with a part of the distended ovarian sac in front of it. After the division of the pedicle, and the removal of the tumor, there was hæmorrhage, in the suppression of

* It is very desirable to have a strong kind of ligature for tying the pedicle, and of equal strength in all its parts. I had tried beforehand a portion of that used in this case, and found it readily sustained a weight of 28lbs., yet another portion snapped at an untoward moment. I have since had a twist made purposely, and shall not be content with any ligature which will not sustain 60lbs. and is not very even in its fabric, as well as of soft texture.

which the shortness of that part occasioned some difficulty; but on drawing it up by the ligatures I could command the vessels by holding the bleeding part within the finger and thumb of my left hand, and they were, after a little delay, secured by another ligature, which included the pedicle again entirely. The advantage of a free incision was particularly felt at this period.

The coagula being cleared away, the edges of the wound were adjusted as accurately as possible, and nine interrupted sutures served to preserve them in apposition. Long pads of lint were laid down each side of the wound, and over them slips of plaster passed from side to side across the abdomen. The heads of the roller which had been placed behind her were now carried once round her with the requisite firmness and tied. She was conveyed to bed with a firm though frequent pulse, and a warm skin, having been scarcely faint during the operation. She took gr. $\frac{1}{2}$ Morph. Acet. in $\frac{3}{4}$ ss. Mist. Camph. immediately, and again in an hour; and eagerly drank some water, of which she had already taken more than I was aware of. At half-past six o'clock, her pulse was 110; at ten, it was 106, and full, her skin warm and freely perspiring, and she had slept a little. Complained of some pain of the left side and in the back. $\frac{3}{4}$ xj. of urine withdrawn by catheter. Temperature of the room, 75. To have nothing but water, viz. 12 oz. in the night. The temperature to be lowered a little.

31st.—I paid her three visits, at each of which the pulse was noted, and was about 120. She had slept little, but perspired freely all night. No sickness, nor shivering, nor chilliness had occurred, and her mind was perfectly clear. The abdomen was free from distension and from tenderness, except in the line of the wound, and in the left iliac region; but she felt all over her as if she had been beaten, was thirsty, and complained of heat and occasional griping uneasiness. I was surprised at finding $\frac{3}{4}$ xxi. of urine following the use of the catheter in the morning. $\frac{3}{4}$ x. more were drawn off at midday; but before my evening visit she had twice passed it unassisted in considerable quantity: I, however, drew off $\frac{3}{4}$ v. The tongue was moist and clean; short intervals of sleep refreshed her in the course of the day. Her breathing was free; and she could

partially turn in bed, by the aid principally of the lower limb of the side from which she wished to turn. The rectum-tube was passed, but very little flatus escaped. One dose of her anodyne was given at night.

June 1st.—Had a good night. When visited at

	9 A.M.	5 P.M.	11 P.M.
Her pulse was .	117	108	102
Urine withdrawn	$\frac{3}{4}$ vij.	$\frac{3}{4}$ x.	$\frac{3}{4}$ vij.

and some was also voided in the night, and when the bowels were twice spontaneously moved in the course of the day. Her skin was warm and perspiring all day; her tongue moist, and only slightly white. She had no pain, and the wound, where visible on re-adjusting the bandage, had nicely united. In all respects she was going on well. Water had been her only support till five o'clock to-day (forty-eight hours from the operation) when a little beef tea was given, and at night some gruel.

2d.—Having slept a good deal yesterday, her night was not so good, though the anodyne was taken as before. The pulse was about 102 all day; the symptoms much as on the previous evening. The wound being dressed, was found to have united throughout, except for about three quarters of an inch at the lower end, where the ligatures of the pedicle were placed. The stitches were all removed.

Towards evening she became uneasy, and had a sense of sickness; but was free from tenderness of the abdomen. Her bowels not having been moved, an enema was administered, and much flatus followed; and as her pulse intermitted somewhat, beef tea was directed to be given more frequently.

3d.—A pretty good night, but had some unpleasant dreams. Flatulency and occasional griping. Would like an egg for breakfast. To have it, with bread and butter and tea; and then to take gr. x. of Fel. Bov. inspissat. The pulse, 108 in the early part of the day, was 105 later, after having slept a good deal. Having had no movement of the bowels, but being less flatulent, gr. x. of the Fel. to be repeated.

4th.—A better night. Bowels twice moved very comfortably; voided her urine very freely, which hitherto had generally been drawn off; pulse 106, feeble. Some offensive motions passed, and she felt low. A little brandy to be taken in some gruel, and then her anodyne. Arrow-root for supper.

5th.—A good night. Is languid; pulse 105. To have beef tea and a custard pudding for dinner. Tried to sit up after dinner, but felt faint and giddy. A glass of sherry given. Slept in the evening, and became very comfortable. Miliary eruption appeared yesterday on some parts of the skin, and to day was very general. Pulse, towards night, 96. The room to be kept cooler.

6th.—Wound dressed again. Two or three spots only of pus, where the skin was not quite evenly adjusted, but in quantity hardly worth mentioning; the wound, in general, being a cleanly-united line, excepting, of course, where the ligatures lay like the threads of a seton. Pulse 94. Complained of nothing but weakness, being remarkably well for the period of her recovery—one week after the operation. To have some boiled mutton for dinner, with wine and water. Pulse, at night, 88; urine passed freely; no motion, and the bowels a little uneasy, with a sense of weight in the left iliac region.

Capt. Fel. Bov. inspiss. gr. x. h. s.

I have detailed the symptoms to this period more particularly than I should otherwise have done, for the purpose of shewing in how promising a manner every thing had hitherto proceeded.

On the 7th of June she had passed an indifferent night; and there was considerable uneasiness in the left iliac region, with one tender spot feeling like an intestine in a state of contraction. She had a copious motion in the morning, with partial relief. Instead of meat, took some sago pudding for dinner, which she enjoyed. Was free from sickness, but complained more than hitherto of pain.

℞ Extr. Hyoscyam.; Fel. Bov. inspiss. aa. gr. v.; Aloes Barb. gr. j. M. Ft. pil. iij. statim sumend.

As no motion followed this dose, and her uneasiness was increased towards night, though she had passed urine of pale colour freely, and the wound near the ligatures looked well, an enema was used, followed by the anodyne, with Morph. Acet. gr. ss. Fluid diet.

June 8th.—Bowels copiously relieved, and she felt much easier, even before taking the anodyne, but after it slept and perspired very much. To-day she complains of rheumatic pain in her arms and shoulders, with a stiff neck, and says she has taken

cold. Tongue furred, but moist; urine passed without difficulty, but of higher colour. There is uneasiness in the iliac region as before, and a little soft fulness. I examined the left leg, fearing inflammation of the veins from the symptoms complained of. It was larger than the other, but so it had been before the operation; no shivering nor sickness, but the pulse 110. The miliary eruption much renewed. Towards night, the pain in her limbs increased, but the abdomen easy, and there was less tenderness in the iliac region; the right leg had become somewhat painful, particularly on being moved, and her pulse was higher; a hot enema was given, viz. of 108 Fahr. and an anodyne.

June 9th.—Passed an indifferent night, and feels very ill this morning, her sleep having been disturbed by pain in the limbs, particularly the left leg, which is more swollen, and now pits sensibly, though it did not on examination last night; there is some tenderness in the course of the blood-vessels in the groin; the shoulders and neck are easier; pulse 125, feeble; urine more red; bowels well relieved, and motions not unhealthy; tongue foul, but moist; no shivering; skin perspiring; leeches to the groin.

℞ Infus. Cinchon. ℥jss. quartâ quâque horâ sumend.

2 P.M. Leeches have not sucked well, nor the bites bled much, yet she says she is better. Being put on milk diet, she finds it support her very well; her pulse is, however, 130. At night, leg more swollen and very painful; leeches renewed; a hot enema.

℞ Sulph. Quin.; Pil. Hydrarg.; Ext. Conii, aa. gr. ij. M. ft. pil. ij. quartâ quâque horâ sumend., in lieu of the infusion. An anodyne.

Dr. Blundell concurs in her case being now one of mild phlegmasia dolens, or inflammation of the veins, as Mr. Camplin and myself considered it.

June 10th.—Had a better night, and is freer from pain; pulse 138; to be again leeches.

Towards night her pulse fell to 119, and though very uneasy, particularly in the left leg, her pain was less. She took an excessive quantity of milk last night and this morning, and caused herself a great deal of distension and discomfort. A little brandy and water had to be given; her pills were con-

tinued, and at night an anodyne enema administered, which not being wholly retained, her usual anodyne was also given, and the two produced an inconvenient drowsiness.

June 11th.—Excessively heavy, languid, and somewhat confused. Pulse 145. It even rose to 150 in the course of the morning, but towards the afternoon fell to 130, and gradually came down from this time for the next two days, being then 100; the leg followed the like course of improvement, as did her general state, except that a cough distressed her at times, and her feebleness and emaciation had become extreme: the quinine was continued, but the Pil. Hydrarg. omitted: her diet was made more generous as the symptoms permitted. At one time the right leg became painful and slightly swollen, but not for a continuance. There was tenderness also in the right groin in the course of the blood-vessels. Her convalescence was very gradually established; some tenderness in the situation of the veins in both groins was experienced for many days; clammy sweats broke out at times, and pains like those of rheumatism were often complained of during her recovery. As to the wound, what was chiefly remarkable was, that from the peeling of the skin, occasioned by the innumerable little blisters of the miliary eruption, its whole line was made raw for a couple of days, and at the part where the ligatures hung forth, a discharge, just about the time of the subsidence of the worst symptoms of venous irritation, was observed in greater quantity than at other times, and then it was offensive, but in general it was healthy and not at all profuse.

The ligature first tied, which included half the pedicle, came away in about five weeks. The others which embraced the whole pedicle, although they have been very tightly twisted, remain to the present time.

The tumor removed in this case was rather less solid than that which I removed in November last. It weighed sixteen pounds and three quarters, imperial weight, and, when laid in a dish, measured in horizontal circumference 2 feet 11½ inches; in vertical circumference 2 feet 6 inches lengthwise, and 2 feet 3½ inches across. The engraving of the former tumor (LONDON MED. GAZ. Dec. 23, 1842,) will convey a better notion of this than any description I can

give; the chief differences being in the position of the fallopian tube, which stretched wide away from the solid part, and its being a disease of the left, whilst the other was of the right ovary.

Guilford Street, Russell Square,

TREATMENT OF FRACTURES

BY MEANS OF THE STARCHED BANDAGE.

To the Editor of the Medical Gazette.

SIR,

I BEG the favour of the insertion of the enclosed letter in your GAZETTE, should you deem it worthy of a place in its columns.—I am, sir,

Your obedient servant,
H. B. NORMAN.

9, Holles Street, Cavendish Square.

In your number of the 21st of July, I have read a detailed account of a fracture of the forearm, unsuccessfully treated by the starched bandage, given by Mr. M'Cash, from which the author proceeds to draw inferences, which I cannot but regard as unjust, as grounded on insufficient experience, and as calculated to bring into disrepute a practice of exceeding value to the surgeon in the treatment of fractures. The author details the case, the substance of which is as follows:—"A boy, of 12 years of age, and of slender conformation, had fallen from a wall, and so had received a fracture of both bones of the forearm. There was a considerable displacement of the broken bones, a good deal of deformity around the seat of fracture. All the patient's members were agitated by the intensity of his sufferings; the muscles of the limb affected by such violent spasmodic movements, that when the displaced bones were reduced to their proper position there was very great difficulty of keeping them so. This the author considered a *favourable case* for the trial of M. Velpeau's method of treatment by means of the early application of the starched bandage (*le bandage immobile* of that justly celebrated surgeon.) Accordingly, after fomenting the limb and administering the Sulphate of Magnesia c. Tart. Antim. he proceeded to apply the apparatus. The patient suffered for the first day or two a good deal of pain in the in-

jured limb; this, however, subsided, and every thing was believed to be going on well for *seven or eight weeks*, at the end of which time, the apparatus being removed, the bones were found perfectly in apposition and firmly united, but such an alteration had taken place in the muscles of the limb that it was rendered useless, all power of flexion and extension, &c. being lost. The author rightly, I think, attributes all this to the effect of acute inflammation, followed by deposition of organizable lymph among the muscles. Beyond this I cannot agree with him, nor follow him in his censure of the mode of treatment as the cause of this effect.

In the first place I would remark, that the case itself was an unfavourable one for this or any other method of treatment. The patient is described as of "slender conformation." If this description means any thing in the account of the case, I conceive that it is intended to convey the idea of delicacy of constitution, and the opposite of that state of health which usually belongs to that age. If this idea be just, I see in it at the outset a ground for an unfavourable prognosis. For though it may be urged that, in such a subject, reaction would be more moderate than in one of a more robust constitution, and consequently that there would be less danger of any unfavourable result on this ground, I answer that this is only in part true. The reaction will be less violent, perhaps; but I believe the power of the constitution to resist the destructive or injurious consequences of this state, and to convert it into a reparative and favourable process, is possessed in much greater degree by the robust than by the delicate. The whole system is better enabled to resist the effects of, and to rally from, both internal diseases and external injuries.

Secondly, I regard the great degree of displacement of the broken bones as a complication of the case likely to render its management more difficult than usual, inasmuch as fresh violence must be resorted to, to overcome it, and to prevent its recurrence, and, further, likely to interfere seriously with the favourable progress of the case, from the extensive injury received by all the soft textures around the seat of fracture. Such displacement as is de-

scribed in this case could not have happened without much laceration of the muscles and the smaller blood-vessels of the limb; and I am further inclined to think that the *violent spasmodic muscular contractions* described are attributable to serious injuries of the nerves as well. Are we, then, to look to these causes, or to the early application of the immoveable apparatus, for the unfavourable result in this case? or are we to take a middle course, and to say,—to the serious nature of the injury must the unexpected consequences be attributed; but they might have been counteracted had the case been treated on another plan? I am inclined to think that the real cause of the unfortunate result is the serious injury received by the soft parts, and it is not to be attributed to the use of the immoveable apparatus at all. I would not, however, be understood to say that I should in general be prepared for an unfavourable result in such a case as the one under consideration. By no means. I believe that 80 out of 100 such cases would do well under this or any other well-conducted treatment; and further, that the most careful treatment cannot prevent occasional unfavourable consequences in the simplest cases. We cannot always foresee evils; and when we can, we are not always able to cope with them.

There is one point in Mr. M'Cash's treatment of his case which I consider decidedly wrong, namely the warm fomentation of the fractured limb. It is, according to Mr. M'C.'s opinion, and that of all other surgeons, a desirable thing to moderate the reaction consequent upon fractures, and to prevent as much as possible effusion of blood into the soft textures. How, then, is this to be done? By warmth, which must accelerate the determination of blood to the part, and by this means favour the occurrence of hæmorrhagic effusion? I should say no, but by cold, which is calculated to have the very opposite effect, and further by a raised position of the limb, so as to favour the return of blood by the veins. These, added to the early reduction of displacement, and coaptation of the fractured bones, and the early application of some efficient apparatus, are the means to prevent any evil consequences arising from fractures. In one more

point the treatment of this case is to be blamed; rather, I may call it, the neglect. For what purpose was the confinement of the limb in the apparatus maintained for eight weeks? This seems to me a very unnecessary length of time to keep the limb unused, and confined in a fixed position; certainly much longer than fracture of the bones of the forearm requires, and sufficiently long, in some cases, to lead to great rigidity of the joints and atrophy of the muscles. May not this even have had some share in producing the unfortunate termination of the case? On the strength of this, Mr. M'Cash's first trial of the "bandage immobile," and the unsuccessful issue of his case, this gentleman proceeds at once to subvert the position taken by Gendrin and Velpeau, that "on the earliness of the application of the immoveable apparatus in fractures depends, in great measure, its utility." Of the truth of this position I am myself as confident as Mr. M'Cash is incredulous. I first saw the practice in the Hôpital de La Charité, under M. Velpeau's own directions, about two years ago. The simplicity and neatness of the method at first struck me, and induced me to make inquiries about it. During a short visit to Paris, though daily at the hospital, I could come to no very certain opinion as to the value of the practice, but was assured repeatedly by a friend, then *externe* to M. Velpeau, that it was most successful. This declaration I held to be the more valuable as my friend was an Englishman, and consequently not likely, from national prejudice, to overrate the practice of his great master. On returning to London, and receiving the appointment of House-Surgeon to Mr. Liston, in the University College Hospital, I determined, with his permission, to put the practice to the test. This I did as occasion offered a suitable case. I treated several cases of fractures of the forearm and leg, one fracture of the thigh, and one or two of the humerus, by this method. It is a subject of regret to me now that I did not keep careful notes of the cases. The result, however, was so far favourable, that whenever opportunity recurs I shall again have recourse to it. In one instance only do I remember to have removed the apparatus before the completion of the cure; in the instance of a *sidgety*, nervous, female patient,

who had received fracture of the bones of the forearm. I have never seen a case in which there was any defect in the action of the muscles on the removal of the apparatus. On the contrary, one of the advantages of the practice has always appeared to me to be the plump and firm condition in which the limb is found.

In using any other appliances, the bandages must be removed several times in the course of treatment: at each reapplication they are accommodated to a limb diminished by pressure and rest, until at the end of six or eight weeks the limb is miserably diminished, shrivelled, and weak. The immoveable apparatus is applied once for all to a limb of at least its natural size. At first there is some uneasiness occasioned by the resistance to the swelling of the parts enclosed; this soon subsides. The circulation is carried on readily in parts but moderately compressed, and the nutrition of the limb consequently is more complete. The plan I have adopted is as nearly Velpeau's as possible, substituting starch only for the dextrine. The fractured bones being placed in apposition, and the limb raised considerably above the level of the body, it is encased lightly and carefully in a broad roller. Two straight splints of thick pasteboard, such as is used by bookbinders, are *starched* and laid along the inside and outside, or fore and back part of the injured limb. These are to extend beyond the articulations above and below the fracture so as to fix them. A strong starched roller is then carried pretty firmly round the limb to fix the splints, and the apparatus is completed, unless in some cases the additional security of a wooden splint be resorted to while the apparatus is drying. The apparatus should be applied with very great care, and the limb for some time kept considerably raised. The earlier it is done the better; very little swelling follows a fracture carefully managed and early reduced. All antiphlogistic treatment until this is accomplished is in vain. Cold may be applied with advantage for the first eight-and-forty hours, and in most cases all will do well. I do not say all, but most, I strongly believe, would. Sufficient attention I am convinced in general is not paid in the treatment of fractures and other injuries attended with inflammatory action, to the position of

the affected part. In the University College Hospital, where, under the auspices of Mr. Liston, it has received a good deal of attention, the use of leeches, evaporating lotions, &c. is entirely dispensed with, and found unnecessary. I would request Mr. M'Cash to withhold his decision on the value of the practice he strongly condemns until he has given it a further trial; I do not ask him blindly to follow any one's theories or practices, but only to form his own on sufficient grounds. Let him give the plan he condemns a fair trial, and he will be convinced of its value.

MODIFICATION OF DR. ARNOTT'S HYDROSTATIC BED.

To the Editor of the Medical Gazette.

SIR,

I BEG to transmit to you a description of a modification of Dr. Arnott's hydrostatic bed, which I think will be found more convenient than those now in use.

A bed-frame is prepared, with feet, sides, and ends, similar to those of ordinary beds. At three or four inches within the side bars two others are placed parallel to them, leaving in the centre an open space at least two feet broad. A sheet of strong canvas is stretched over the whole, and laced with a cord to the ends and external lateral bars, sufficiently slack to allow the part between the two internal bars to be depressed nine inches in the centre, and only two or three inches at each end. In the cavity of this depression is placed a sack of water-tight Macintosh cloth, large enough to allow the introduction of twenty or thirty gallons of water, without producing any tension; it must remain perfectly flaccid. The sack which I use is six feet long by three feet wide, with a narrow neck about a foot long; but it is larger than is absolutely necessary. The neck is brought through the foot-board of the bed, to the outside, where water is introduced; sufficient being employed to fill the sack to within half or three-fourths of an inch of the level of the frame of the bed. The apparatus now presents the appearance of a nearly level surface, consisting of two lateral planes, rigid and tense, and one central plane of the greatest possible softness. A thin mattress ($1\frac{1}{2}$ to 2

inches thick) and bed-clothes now being laid on this surface, the bed is ready for use.

The advantages of this bed over those hitherto in use are as follow:—

First and chiefly, much greater facility of ventilation. Ten years ago I had one constructed on Dr. Arnott's plan, and have had frequent opportunities, during that time, of knowing the very great relief afforded by it, in the practice of several medical gentlemen who have used it, to persons in the last stages of illness, and also to some who have even ascribed their recovery to it. But there has generally been some difficulty in preventing the accumulation of condensed perspiration in the hollow of the trough upon the Macintosh cloth. This has been remedied to a certain extent by interposing between the mattress and the water a network of corks strung together, with the view of forming a stratum freely permeable to the air; but the ventilation so obtained has seldom been perfect. In the bed which I now describe there is a smaller surface for the condensation of moisture, and there are no upright sides impeding ventilation. A small stratum of corks may be used, but even that is not always necessary; and the most of the bed requires none at any time.

Second, superior portability. There being no metal work, nor wooden box to contain it, the whole is much lighter and more manageable,—an object, however apparently trivial, always of some importance, especially in a sick chamber.

Third, less water is sufficient. The quantity can be reduced almost to the minimum which will float a man, by lacing the canvas proportionally tight. When the patient is large and heavy, more water is required to float him, and the lacing can be slackened accordingly.

Fourth, less expense. I do not know the price for which hydrostatic beds are made in London, but that which I have now described was only half the expense of the other made with the zinc trough.

There is no necessity to close the orifice by which water is admitted; it requires simply to be turned upwards, and supported with a loose string, to prevent the water from flowing out by the movements of the patient: the un-

dulations never exceed a few inches. For discharging the water when it is desired to remove the apparatus, a siphon is introduced at the orifice to the deepest part of the sack.

In pouring in the water, a quantity of air is liable to be carried along with it, which elevates the upper side of the sack, and accumulates there. Although more yielding even than water, it defeats the whole design, and forms salient and tense protuberances. It is easily discharged by drawing the arm, with a little pressure, over the surface of the sack from the bottom to the neck.—I am, sir,

Your obedient servant,
H. OGDEN, M.D.

Sunderland, Aug. 5, 1843.

DEATH OF THE CORNEA FROM CHEMOSIS; ADVANTAGE OF MERCURY IN IRITIS; SIZE OF THE IMAGES ON THE RETINA.

To the Editor of the Medical Gazette.

SIR,

In your number for July 28, Dr. J. C. Hall inquires—

1st.—If the priority of "*the notion, that in purulent ophthalmia the cornea dies from the pressure caused by the chemosed conjunctiva*," does not belong to Mr. Middlemore, to whom it belongs.

2d.—If the priority of the "*demonstration of the advantage of mercury in iritis*" does not belong to Dr. Farre, to whom it belongs.

The two following extracts may, perhaps, assist Dr. Hall in solving these questions.

"Other causes, no doubt, concur, in the puro-mucous inflammation of the conjunctiva, to produce opacities of the cornea, detachment of its conjunctival covering, and ulceration, and, in particular, the maceration of the cornea in a flood of purulent fluid, not sedulously removed by injections. But the destruction of the cornea by infiltration of pus and sloughing I am disposed to refer in no small degree to the pressure of the chemosed conjunctiva, and the consequent mechanical death of the cornea."—*Mackenzie's Practical Treatise on the Diseases of the Eye*, p. 331. London, 1830.

"*Wenn der Arzt am Ende des zwey-*

ten Zeitraumes, &c." In English, thus—

"When the practitioner observes at the end of the second stage, that the lymphatic effusion in the posterior chamber (though not preventing, still greatly limiting vision), does not diminish by the treatment which is pursued, so as to allow a hope for the complete restoration of sight; but on the contrary, that there is reason to dread that the lymphatic effusion will remain in the same state after the second stage has terminated; then not only external, but internal alterative medicines must be had recourse to, in conjunction with the other remedies proper in this stage of the disease; that is, the preparations of mercury must be employed, which in such circumstances will never disappoint, if properly managed. Calomel, united with opium, is to be given internally. Frictions once a day, over the eyebrow, with mercurial ointment, opium being added to it, very much contribute to the absorption of the lymph effused into the posterior chamber.

"Whoever has not witnessed the striking effect of such a method of treatment of iritis in this stage, cannot possibly form any idea of the extraordinary and rapid improvement, which, when properly conducted, it often in a few days produces. I have repeatedly seen a whitish net-work in the pupil, and which was distinguishable at a distance, disappear in eight or ten days."—Beer's *Lehre von der Augenkrankheiten*, vol. i. p. 449. Vienna, 1813.

These extracts will probably satisfy Dr. Hall's inquiries. I may mention, however, that Beer recommended mercury in 1799 for iritis, although the *term* was not used till 1801, which it was first by Schmidt.

Since I have the pen in my hand, I may say I am sorry Mr. Mayo has not seen fit to return any answer to a query I used the freedom to propound to him some months ago, through the MEDICAL GAZETTE.

The sages say, Dame Truth delights to dwell,
Strange mansion! at the bottom of a well.
Questions are then the windlass and the rope
That pull the grave old gentlewoman up.

In his "*Nervous System and its Functions*," Mr. Mayo announced what I conceived an important optical discovery, viz. that the angular breadth and height of the inverted picture on the retina were one-half of those of the object so represented. He says (p. 130)

that this is *easily shown* to be the case. What I wanted to know when I sent my former query, and what I still feel anxious to discover, is the proof of Mr. Mayo's doctrine. If Mr. Mayo can give no proof, but has hurriedly published a statement which does not bear investigation, it would only show a becoming respect to the purchasers of his book at once to say so.

I remain, sir,

Your obedient servant,

A MEDICAL STUDENT.

August 4th, 1843.

OBSERVATIONS
UPON THE
NEW PROCESS PROPOSED FOR THE
DETECTION OF CORROSIVE
SUBLIMATE

BY MEANS OF
METALLIC SILVER.

BY FORENSIS.

(*For the London Medical Gazette.*)

[POSTSCRIPT TO PAPER IN No. FOR AUG. 4.]

SINCE my former remarks were written, the whole of the facts have been reconsidered, and the experiments upon which they are founded repeated, while other new ones have been instituted, not only with a view to revision, but also to greater accuracy and superior delicacy. The following may be stated as the additional results. First, it may be observed of *tin*, as a reducing agent, that a portion unites to the chlorine disengaged from the mercury, while another amalgamates with the latter. The newly formed chloride should be removed by solution, or otherwise it will sublime together with the reduced mercury, and obscure the globules. Secondly, the fusing point of tin is inconveniently low, being only 442° Fahr., or somewhat less than two-thirds of that required for the volatilization of mercury: therefore, it is advantageous to separate the tin previous to sublimation. If the amalgam be distilled, the boiling tin is apt to sputter, and be thrown into the upper part of the tube, and reamalgamating with the mercury, renders it pasty, and incapable of assuming its characteristic globular

form. The same facts also give rise to a source of error: the tin, during fusion, is frequently formed into very minute globules, which, thrown out upon a tray of white paper, roll about, presenting to the naked eye the appearance of very minute black spherules, and which may readily be mistaken for mercurial spherules, more especially as they present the metallic lustre when examined by a lens, and indeed, in all appearances, so closely resemble the mercurial globule, that, in many cases, they cannot be distinguished, unless the eye be aided by an achromatic glass. The mechanical properties, however, will enable us to distinguish them. The tin, pressed by the point of a penknife, feels firm, hard, and resists the pressure, and when pressed by the extreme point, bounds from under it. The tin globules, collected and placed in contact with each other, do not coalesce, nor unite into a single globule, but remain separate and of the original number. The mercurial globules, on the contrary, present the very reverse of these characters. When the globules consist of a mixture or amalgam of tin and mercury, if pressed by an iron blade they will be found to be pasty and viscid, and without any, or at least a great deal less, tendency to preserve the globular form; nor will it divide into a number of minuter spherules, as pure mercury invariably does under similar circumstances.

The fusing point of silver (1873° Fah.) in part frees it from some of these inconveniences, especially those more immediately dependent on the lower fusing point of tin. Still, however, it is liable to other inconveniences, and which seem to be essentially connected with, and indeed inseparable from, all capability of amalgamating with mercury. For example, the globules sublimed from the silver amalgams occasionally fall back again upon the silver, and reamalgamate. When the quantity of mercury is sufficient, this perhaps is a matter of little moment, as enough of the sublimed metal may generally be secured for complete and satisfactory identification; but when the quantity is extremely minute, and scarcely sufficient for appreciation by the unaided sense, the most trivial circumstance, as a rough handling, shaking, or jerking of the reducing tube, will throw back the

globule, and give rise to reamalgamation. Since the first part of the present paper, I have seen this happen more than once; and the purer the mercury, the more free from all contamination, and the cleaner the subliming tube, the more likely an accident of this description, especially in rough hands. In the silver amalgam the silver cannot easily, as in the case of tin, be separated, so as to leave the mercury free and pure. Heating and subliming the mercury presents the only practical method.

I was induced, in consequence of the above, to try clean, bright, and very fine iron filings. So far as I have been able to determine they are equally delicate with the agents already considered, and at the same time free from all the objections just noticed, inasmuch as they form no amalgam, and are wholly infusible in a tube. It is a familiar fact, that iron reduces bichloride of mercury to the metallic state, and if a drop of a solution of bichloride supported upon a piece of gold be transfixed by a clean iron wire, so that the gold be touched with the wire through the fluid, *metallic* mercury is instantly deposited at the point of contact, and for some distance around, and an amalgam formed. If iron filings be rubbed with either bichloride of mercury or calomel, and the mixture heated in a tube of hard glass, mercurial globules sublime. Even when the quantity is very minute, the $\frac{1}{100}$ of a grain, if the mass, after ignition, be thrown out upon a tray of paper, minute globules of mercury may be detected, by the aid of a good lens, amongst the particles of iron, and may be removed by the point of a steel wire or pen-knife moistened with saliva, and when all collected may be united into a single globule. With the globules of mercury, the *chloride of iron*, formed by the decomposition of the mercurial chloride, sublimes; but this inconvenience may be avoided by digesting with hydrochloric acid, or dilute sulphuric acid, by which the *whole* of the iron will be removed, and pure mercury only remain behind for subsequent sublimation.

From the foregoing facts, which I have considered sufficiently important to justify this postscript, I think it will appear that when we wish to reduce corrosive sublimate in the dry way, *iron filings* present the best reduc-

ing agent; that in organic complication the solution of the mercurial by converting it into *bichloride* either by a cement of chlorine, or by nitrohydrochloric acid, forms an essential preliminary. Having effected this, that the precipitation of metallic mercury either by solution of proto-chloride of tin, or by phosphorous, or hypo-phosphorous acid, is superior to every other method hitherto proposed, and the only one that can be *safely* practised in medico-legal analysis.

August 6, 1843.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO

WOMEN AND CHILDREN AS AGRICULTURAL LABOURERS.

IN our late articles on this important subject, we confined our comments to one only of the reports made by the four special assistant-commissioners. We will now, before dismissing the subject, briefly touch upon a few points in the remaining three reports.

Mr. Vaughan pursued his inquiries in the counties of Kent, Surrey, and Sussex.

It is remarkable that he thought it incumbent upon him to take the evidence, or the greater part of it, upon oath. We have always been of opinion with Paley, that the multitude of oaths taken in England are highly unfavourable to morality; and we are happy to see that of late years the current of legislation has set against them. A pound of tea can now pass through the Custom-House unaided by the half-dozen oaths which it required in Paley's time; and we think that the duties and rewards of hop-pickers and fruit-gatherers might have been ascertained without so solemn an appeal.

The great formations of the wealden (*i. e.* woodland), the sand, and the chalk, belong to all these three counties. The wealden is girt with a belt of chalk hills; while a fringe of sand unites the two; and "the sand," says the reporter, "as it rises into the chalk, furnishes some of the most celebrated hop-gardens and orchards."

Field-labour appears to Mr. Vaughan to be generally beneficial to the health of women and children. As to the kinds of labour performed by women, local customs vary even within a short tract of country. Thus, "about Tunbridge Wells, women are rarely employed in opening the hills* in the hop-grounds. At Maidstone and Farnham it is their common occupation. At Maidstone, again, the woman opens the hills, and the man cuts the plants; at Farnham, the man opens the hills, and the woman cuts the plants. In some places the woman does not bind the corn, but only makes the bands; in others, the binding is generally assigned to her."

To the general healthiness of their occupations there are a couple of exceptions. If the hop-picking season proves a rainy one, the women and children suffer from standing for hours upon the wet ground, and diarrhœa is a common consequence. The heavy boots worn by young boys to walk over corn lands, produce great weakness about the ankle-joints.

Mr. Vaughan believes that in the hop districts a woman earns thirty shillings during the tying season, and twenty pence a day while the picking lasts. At ordinary times her wages are far less, say ten pence a day.

The labourer, in many districts, suffers from the high prices of village shops, where he is obliged to buy

inferior articles at extravagant rates, or else go to an inconvenient distance after a hard day's toil. If a labourer has run up a score at the village shop, he has not even this painful alternative left him. In vain he complains of the dearness of his creditor's goods: "deal here, or pay your debt, is the practical argument."

Henry Duppa, Esq. of Frimingham House, near Maidstone, has, in consequence, changed the hour of paying his labourers on Saturday, from 7 P.M. to 9 A.M. and they have all quitted the village shops for the better and cheaper ones of Maidstone. This evil of dealing at bad shops is aggravated in certain districts by the mode in which wages are paid. In some of the villages towards the north-east of Sussex (about Brede and Sedlescomb) the unfortunate husbandman is often paid by checks drawn on the shopkeeper or miller. It is unnecessary to comment upon this; the statement of the fact is sufficient.

But let us turn to brighter scenes. The allotment system, though not general throughout these countries, has been tried in a majority of districts, and is productive of a hundred advantages.

"Allotments may be looked upon as an attempt to aid the industry of the man by that of his wife and child, to divert both from a closed or unprofitable market, as well as to exempt money from the toll of village prices. They especially affect the wife and children, both as employment and as wages, giving them a light and profitable agriculture, and furnishing them with articles of common consumption untaxed by any intermediate profits between the soil and the cottage larder. * * * In some parts there are allotments especially devoted to children."

An agriculturist in the west of Sussex says that an allotment enables the wife to improve her cookery, and revives

* In the language of the hop-garden, "to open the hills" means to open the elevated surface round the plants, in order to get at and prune the lower part of the last year's shoots.

the use of vegetables, almost lost, by eating, for a series of years, little but bread and butter and cheese from the village shops.

Next to the allotments in importance come clothing and benefit clubs. The former are in part a charity, as the savings of the labourer are met by equal subscriptions from his wealthier neighbours; the latter clubs are generally unassisted.

In hop districts the morals of the resident population appear to be tainted by the recruits during the season of picking. Thus the parish of Farnham contains about 7000 inhabitants; but during the hop-picking there is an accession of between 4000 and 5000 strangers. They come chiefly from towns and villages within twenty miles; but some are labourers without a settled home, and some are gipsies.

In the parish of Farlegh, near Maidstone, a great number of the English hands come from St. Giles's, Saffron Hill, &c.; and they are the most vicious and refractory. The Irish, though dirty in person and habits, indelicate in conduct and appearance, and frequently bringing contagious disorders with them, are more controllable.

As to education, it is at a very low ebb indeed. Those of our readers who recollect our papers on the employment of women and children in mines, and on the reports of the Registrar-general, will not be surprised at the testimony of Mr. Vaughan on this point. "Great ignorance, if it does not prevail, is at least to be met with, where no special pains are taken to discover it. It is quite common to meet with boys engaged in farms who cannot read or write. The unity of God, a future state, the number of months in the year, are matters not universally known."

In quitting the instructive and well-written report of Mr. Vaughan, we must not omit a point in the evidence

of one of his witnesses painfully characteristic of the age in which we live.

Henry Edwards Payne, Esq. deposes upon oath that he is secretary to the Rye Agricultural Association, and informs us that prizes are given by this society to labourers thirty years of age, *who shall have remained single up to that time*, and shall have worked for the longest period on the same property, or in the same service.

The legislators of old thought very differently on this point:—

——— fuit hæc sapientia quondam,
* * * *

Concubita prohibere vago, dare jura maritis.

"To make men husbands, and to keep them so," was the aim of the Pagan lawgiver; your Rye Association is only eager "to prevent imprudent marriages," careless of the *concubitus vagus*.

Mr. Denison reports upon the state of Suffolk, Norfolk, and Lincoln. The wages of women in the two former counties are, on an average, eightpence a day; in Lincolnshire he thinks that tenpence is now the average: for this they usually work eight hours in winter, and ten in summer. The labouring classes in Lincolnshire are much better off than in Suffolk and Norfolk.

Mr. Denison appears to lean to the opinion of the farmers, that "education is being carried too far." But, assuredly, the evidence poured upon us from all quarters would rather show that education has yet to begin. Even the number of the months not universally known!

All the persons (with two exceptions) to whom Mr. Denison applied for information respecting the allotment system, spoke strongly in its favour.

The gang-system is the very antipodes of this. The labourer possessed of an allotment almost rises into the rank of a petty farmer; and the culti-

vation of a separate piece of ground has often converted the slovenly pauper into a diligent husbandman. The headquarters of the gang-system, in its full-blown state, are at Castle Acre, near Litcham, in Norfolk, and the system itself is as follows. A farmer who wishes to have a piece of work done, contracts with a gang-master, who, in his turn, hires a miscellaneous group of men, women, and children. The gang-master, scarcely, if at all, above the rank of a labourer, squeezes his profit out of the gang, by grinding down their wages to the lowest possible rate, uninfluenced by the motives of compassion or decency, which might be found in the ranks above him; while the superabundant population of Castle Acre gives full scope to his thirst of gain. In a word, the gang-master "regards the labourer solely as a living instrument, valuable only in proportion to its available power;" bad character is no bar to admission into a gang; and the promiscuous assemblage of men and girls in these gangs is unfavourable to virtue; "I should not like myself to take a wife out of the gang;" says one of their overseers!

Sir F. H. Doyle reports upon the condition of Yorkshire and Northumberland. In Yorkshire, the wages of women are 10d. a day at one season, and 1s. at another; but as their work is partial and uncertain, its remuneration is not, on the average, more than 2s. a week, or £5. 4s. a year.

We are glad to find that Sir F. H. Doyle stands up for the cottager's pig. "Of such a pig, the first product of allotment, garden, or potatoe head-land, it is the fashion among political economists to speak disrespectfully. Now, whatever might be the superior profit of the cottager, of saving the money which he spends upon his pig, and buying his bacon in the market, this, as it never

has been, and never will be so saved, we may dismiss."

Moreover, the pig, besides being a profit, is a pleasure to its keeper, and we feel, with Sir F. H. Doyle, that to discourage the practice would be an act of consummate cruelty to the cottager.

We have barely room to notice the prominent feature of Northumbrian husbandry. The hind (or labourer) has a yearly instead of a weekly engagement. He is provided with a rent-free cottage and garden, and is paid four or five pounds a year in cash, and the rest of his wages in kind. Thus Mr. Grey, manager of the Greenwich Hospital estates near Hexham, gives each of his hinds 36 bushels of oats, 24 of barley, 12 of peas, 3 of wheat, 3 of rye, from 36 to 40 of potatoes, 24 lbs. of wool, a cow's keep for the year, coals carrying [carried?] from the pit, and £4. in money. In return for this, the hind, besides his own work, is bound to provide a female labourer, to work for his master at stipulated wages. This woman, who is called a *bondager*, is usually the hind's daughter or sister, and her wages are commonly 10d. a day, or 1s. in harvest.

A great objection to this plan is the wretchedness of these rent-free cottages; for they generally contain but one room, perhaps 17 feet by 15; in construction and ventilation they are most miserable; and the want of separation between the sexes implied by their single apartment is utterly indefensible. Improvement in this point has begun, but it is not so rapid as it ought to be. "I hope, however, and believe," says Sir F. H. Doyle, "that the landowners of Northumberland,—and not of Northumberland alone,—are becoming every day more deeply impressed with the feeling, that some sacrifice of time and thought, and even of amusement, in order to promote the general well-

being of their dependents, is not a charity, but a duty,—the moral rent-charge attached to their properties by the state, from which they were derived.”

PRESENTATION OF A GOLD MEDAL TO SIR BENJAMIN BRODIE.

ON Thursday last a dinner took place at Willis's Rooms, King Street, St. James's, for the purpose of presenting to Sir Benjamin Brodie a Gold Medal as a testimonial of esteem and respect on the occasion of his resigning (two years since) the office of surgeon to St. George's Hospital. Sir Charles Clarke presided. About 120 sat down to dinner, including many of the most distinguished members of the profession.

After the health of Her Majesty had been drank, the Chairman proposed that of Sir Benjamin Brodie, to whom he then presented the Medal, with an address, in which he highly complimented his distinguished friend. Our limits, however, oblige us to confine ourselves to Sir Benjamin's reply, which he delivered with a great deal of feeling.

Mr. President: It is, sir, no affectation in me to say that I really want words to express what I feel on this occasion; for whilst, sir, on the one hand, I am sensible of the honour you have conferred upon me, considering it as the proudest distinction of my life—while I am gratified to see so many of my old friends, so many of my pupils, so many individuals distinguished in the world, not disdaining to be here this evening—while I am gratified, also, by the favourable sentiments expressed by yourself, and which others have not less cordially responded to—Sir, I cannot but feel that all this is more than really belongs to me: that I am indebted to the kindness and partiality of my friends, rather than to my own merits; and that there are other individuals who have laboured in the same vineyard, far more worthy than myself, and to whom the profession owe obligations greater than they owe to me. The consequence of this is, that at this moment a feeling of humility is united in my mind with that of gratified ambition. But out of this, sir, arises another feeling, in which there is no complication, which, pure and unalloyed, will descend with me to the grave,—that is, gratitude to you, sir, and my other friends, for your generosity and kindness. Sir, when I first entered on the profession to which I belong, that profession became to me my world, in which I lived and moved and had my being. I thought of no distinction that was unconnected with it. I had no hope, I desired no

further reputation, and there was no object nearer to my heart than that of having the good opinion of those with whom I was associated. Sir, a long lapse of years, and a more extended intercourse with the world, and a more varied acquaintance with men and manners, have made no alteration in these my sentiments. I have never wished that I could retrace my steps, and begin my career in another sphere of life. I know no profession which, after all, is preferable to ours. I know of no profession which possesses so honourable an independence; Sir, I know of none. I know of no order of men who are more disinterested, or who are more ready to perform gratuitous acts of kindness, than the members of the medical profession; and who, in addition to their moral qualifications, are more distinguished for their good sense, and freedom from prejudice, as well as for their general knowledge and attainments. And, sir, having mixed a good deal with other portions of society, I am only too happy to fall back upon my own profession as affording me the best examples of moral character, the most prudent counsellors, and the kindest friends.

Sir, you have been pleased to revert to my publications connected with physiology and surgery. With respect to the former, I consider the chief merit they have is, that they may have led others to work in the same field; and my ambition respecting them will be fully satisfied if they have been found of any use in getting my professional brethren through the difficult labyrinth of surgical practice.

But, sir, you have been also pleased to speak of me in connexion with St. George's Hospital, and of my services there, and you have alluded to a meeting at the Hospital for the foundation of this medal on the occasion of my resigning my office; and thinking it my duty to speak on this occasion of St. George's Hospital, I beg to say that, to St. George's Hospital, to the Medical School attached to it, to my colleagues and pupils there, I am mainly indebted for the advantages I have possessed in my profession. The name of St. George's Hospital is associated with my most interesting recollections; with hopes and fears, and joys and sorrows, which have long since passed away, with my young ambition,—the anxieties and aspirations of my early life. Sir, it was my good fortune to be elected to the office of assistant-surgeon to St. George's Hospital at an unusually early period, and to hold it for a considerable time. It was in St. George's Hospital I was enabled to lay the foundation of what little knowledge of pathology and surgery I may now possess, and there the happiest hours of my life have been passed. Everything there, sir, tended to my improvement. The study of the patients

cases, the observation I had to make in the wards, the discourses and conversations I had with others, and last, sir, but not least, my friendly intercourse with the pupils, among whom I am happy to say I have preserved a large proportion as my friends, I hope, for life. Then, sir, in common with others, I had this advantage, that St. George's Hospital always presented to my mind the names of some of the brightest examples of professional skill in former times—the name of Cheselden among the proudest. It was there Sir Cæsar Hawkins rose, and there that John Hunter pursued those eminent researches in physiology that were destined to alter the condition of the human race. There, sir, I find the names of both the Heberdens, father and son, distinguished alike as practical physicians, accomplished scholars, and gentlemen. There I found the names of many distinguished for their private worth, integrity, and virtues. But, sir, it would be ungracious in me, on such an occasion as this, if I did not also recur to the name of another individual, to whom, as a living example at the time I was student, and afterwards assistant-surgeon at St. George's Hospital, I am still more indebted—I mean Sir Everard Home, who, at that time, devoted his whole energy, every hour in the day, to some useful undertaking in the performance of the duties of a surgeon. Sir, he had this great quality, which it would be well not only for the members of his own profession, but persons in all situations, to imitate, that when a difficulty occurred to him, instead of shrinking from it, it seemed to be the object of his mind to meet and to surmount it. But, sir, his name has long since been added to the list of those who belong to the times that are past; and when that circumstance accidentally comes to my mind it recalls the scenes of my early life, and I am sometimes startled when I recollect all at once that I am so far advanced in my worldly course. This, sir, is no vain sentiment, and among the numerous debts of gratitude I owe, I know of none greater than this, that the friends and associates of my early life are my friends and associates still, and many of them have done me the honour of being present on this occasion. To that list of friends I have been enabled to add another and greater pleasure, that they are taken from those who were my pupils.

Sir, much as I am indebted to those who have done me the present great honour, I am still farther indebted to them for having allowed me to receive this gift from the hands of one whose conduct has gained the respect of every member of the profession, and to whom I have myself been bound by a long and an uninterrupted friendship."

Sir Benjamin was often interrupted in the

course of his speech by marks of applause, and sat down amid long-continued cheering.

Before sitting down, Sir Benjamin proposed the health of the chairman, after which that of Dr. Chambers was drank with the warmest cordiality. A few other toasts were given, but we have not space left to allude to them.

UNIVERSITY OF LONDON.

BACHELOR OF MEDICINE.—PASS EXAMINATION, 1843.

Monday, Aug. 7.—Morning, 10 to 1.

Anatomy and Physiology.

Examiners, Mr. KIERNAN & Prof. SHARPEY.

1. A vertical section of the Skull being made in the median plane, and in the dry state, and the septum nasi being removed, describe the parts brought into view. Commence the answer by enumerating the bones divided in the section, and proceed with the description in the following order, mentioning the processes, depressions, and foramina,—1st, the inner surface of the cranium; 2nd, the roof, floor and outer wall of the nasal cavity; 3rd, the roof of the mouth and the inner surface of the inferior maxillary bone. The attachments of muscles not required.

2. Commencing the dissection at the Integuments, and proceeding with it as far as the outer surface of the Internal Pterygoid and the Styloid muscles, describe the parts successively exposed in dissecting the space bounded above by the Zygoma, below by the base of the inferior maxilla, in front by the anterior margin of the Masseter, and behind by the Meatus Auditorius, Mastoid process, and upper part of the Sterno-Cleido-Mastoideus.

3. Give the anatomy of the external circumflex artery of the Thigh; state the steps of the dissection required to display it in its entire course, and describe the parts exposed in the dissection.

4. Describe the soft parts met with in dissecting the anterior and outer region of the leg, and the dorsum of the foot.

5. Give a description of the Duodenum, comprehending its form, situation, connections and structure, its vessels and nerves, Brunner's glands, and the mode of opening of the ciliary and pancreatic ducts.

Afternoon, 3 to 6.

1. The Vertebral Column and the rami of the lower jaw being removed, describe the external surface of the Pharynx, the attachments of its muscles, and the course of their

fibres; and the muscles of the soft palate as far as they can be seen in this stage of the dissection. The pharynx being opened from behind, describe the parts then brought into view; the description to include that of the posterior nares, the soft palate, its arches and muscles, isthmus faucium, the dorsum of the tongue, its glands and papillæ, the Epiglottis and its folds, and the superior aperture of the Larynx.

2. Give the dissection required to expose the internal pudic artery and its branches, after it has turned round the spinous process of the ischium; commencing the dissection in the perineum, and describing the parts which successively appear in the progress of it.

3. Commencing the dissection at the inner surface of the lower portion of the anterior superior spinous process of the Ilium to the mesial line, and dissecting from above downwards, and from the peritoneum to the integuments, describe the parts successively exposed, particularly with reference to the Inguinal canal, its contents and boundaries.

3. Give the structure and chemical composition of Muscular tissue, the arrangement of its nerves and blood-vessels, and the difference in structure between voluntary and involuntary muscles.

5. By what mechanism is air introduced into and expelled from the lungs in respiration? Enumerate the muscles which are constantly, and those which are only occasionally employed in inspiration and expiration.

Tuesday, August 8.—Morning, 10 to 1.

Chemistry.

Examiner, PROFESSOR DANIELL.

1. A saline powder will be placed before you with a blow-pipe, lamp and charcoal: test the powder, state its composition, and describe the phenomena which it presents by the application of the flame, and explain their causes.

2. A saline solution will be placed before you marked A, with appropriate tests: explain the changes which will take place upon their application, and name the acid and base of which the salt has been composed.

3. What was the great fault of the thermometer as originally constructed by the Italian philosophers at the beginning of the 17th century? and how was it corrected by Sir Isaac Newton?

4. Describe the processes by which uniformity of temperature is brought about in a system of bodies originally of different temperatures, and the principal circumstances which influence each.

5. Describe and explain the principal phenomena of electric induction.

6. What were the respective shares of

Galvani and Volta in the discovery of galvanism or voltaic electricity? Describe and explain the fundamental experiments of each.

7. What are the principal advantages which the science of Chemistry has derived from the establishment of Dalton's atomic theory?

8. How may the presence of nitrogen be detected, and its amount be ascertained in an organic compound?

9. What is phosphorus? State its principal physical properties, its equivalent number, and describe its combinations with oxygen.

Afternoon, 3 to 6.

Materia Medica and Pharmacy.

Examiner, DR. PEREIRA.

1. Describe the method of preparing the *Antimonii Potassio tartras* according to the London Pharmacopœia, and explain the chemical changes which attend the process. State the composition, effects, uses, and doses of this salt, and also the tests by which its presence may be recognized.

2. Give the botanical characters of *Aconitum Napellus*. Mention the peculiarities of its action on the system; name the diseases for which it is especially adapted; and state the best mode of using it externally as well as internally.

3. How would you distinguish *Liquor Sodæ effervesens*, Ph. L., from mere carbonic acid water? With what metal is the soda water of the shops frequently contaminated, and how would you detect the impurity?

4. What are the appropriate doses, for an adult, of the following substances:—Benzoic acid, sal ammoniac, trisnitrate of bismuth, biniodide of mercury, and bromide of potassium?

5. How would you detect the adulteration of balsam of copaiba with castor oil?

6. Enumerate the principal cathartics. In how many groups or orders may they be conveniently arranged? What are the peculiar effects and uses of each group?

Afternoon, 3 to 6.

Structural and Physiological Botany.

Examiner, Prof. HENSLow.

1. Compare a campanulate with a rotate corolla: and a corymbiform with an umbelate inflorescence. Illustrate your comparison by a slight sketch of each.

2. Whence does the arillus originate? Name two good examples of plants of different families in which it occurs.

3. How do you explain the formation of central and parietal placentæ? Name an example of each.

4. What is the nature of vegetable albu-

men? Is it found in the seeds of *ranunculus*, *pisum*, *sinapis*, *primula*, and *geranium*?

5. What is a stipule? Are the plants in *rosaceæ*, *leguminosæ*, *cruciferæ*, generally stipulate or not?

6. How is the genus *cuscuta* supplied with nourishment? What peculiarity is observable in the structure of its embryo?

7. What are "adventitious buds"; and how do you suppose they have originated?

8. 9. 10. Describe these specimens.

COMPOSITION OF MILK.

M. DONNÉ has read a memoir on this subject before the Academy, in which he has established the existence of a striking analogy between milk and blood, an analogy not contradicted by experiments on animals. In each is found serum containing, in solution, a specially azotised matter, coagulable spontaneously, and a great number of substances representing all the materials for organization. In suspension are found concrete particles called globules, which are of very complex structure in the blood, much more simple in milk. Milk owes its whiteness and opacity to its globules of fatty matter, as blood owes its colour to the red particles. Milk may be said to be a sort of emulsion, in which is suspended fatty or buttery matter in a state of extreme division. Filtering, so as to separate nearly all the fatty particles, deprives milk of its whiteness and opacity, leaving it a clear fluid, transparent or only slightly opaline. In pursuing the analogy between milk and blood, M. Donné has injected considerable portions of the former into the veins of animals: not only does this injection of a fluid, which cannot be called inert, produce no disturbance to the state of functions of animals, excepting, from some cause unknown, the horse, but its globules seem to perform the part of the chylous globules, being changed, like them, directly into blood globules. M. Donné relates the different experiments made by him in the nourishment of young animals by means of milk and of soup; and having shown the great difference to health from their respective use, infers that the consumption of milk is a subject of great hygienic interest, especially in populous cities, and inquires if it be possible to increase the consumption, and amend the qualities of this valuable aliment, and thereby to render a signal benefit to public health.

PARIS MILK.

SPEAKING of the milk in Paris, and especially the supply to the hospitals, M. Donné says, "the state of the milk in the hospitals, as to its alimentary qualities, is truly de-

plorable. At most, if not all, the different establishments for the sick poor, the milk will be found so poor in substantial elements as to furnish hardly three or four per cent. of cream, instead of eight or ten per cent., the average proportion. Even this milk is diluted with water, and has generally been boiled before it is supplied; and although, in the present state of science, this process seems indispensable for the preservation of milk during hot weather, yet it has the great disadvantage of making it less easy of digestion. Not only the milk used for puddings, rice milk, and other cookeries, is of this wretched quality, which would be of less consequence, but that given in its simple state to the sick, the convalescent, the lying-in women, and even to children, whose chief nourishment is derived from it. There is no effective and real inspection of this article, and the abuses in its supply may be inferred from the following avowal of a dealer, speaking of the dearth of forage this year, and the consequent rise in the price of milk. "In general, we add some water to our milk, but this year we shall only add some milk to our water." The guardians of public health, in fact, are not quite in possession of the causes on which this state of things depends. The easiest classes, and the most enlightened, and those most alive to their own interest and welfare, are not out of the reach of the circumstances above mentioned, but share in the consequences of the general ignorance, and the imperfect means applied to the examination of milk. The best directed public establishments, schools, and even colleges, in which the diet has been improved even to luxury, are hardly better supplied with milk than the hospitals. In hospitals and such places the bad quality depends, no doubt, on the low prices imposed on the contractors. It is absolutely impossible to give, not to say good milk, but *passable* milk, at 19 centimes the litre, the hospital price; 30 centimes is the lowest price at which milk can be had of a quality not first rate, but good. M. Donné thinks another cause of the evil is the want of easy, ready, and exact means for appreciating the quality and real value of milk, and that he has found such means in an instrument of his invention, which he calls a *lactoscope*. Most of the milk sold in Paris comes from within a circle ten or fifteen leagues only from the centre, and is purchased of the farmers at 30 cents the two litres, sold to dealers in the capital at 40 or 50 cents, and by them to the consumer at 50 to 70 cents—the price varying according to the quality, the extent of dilution, and the neighbourhood. Certain wholesale dealers sell from 4000 to 5000 litres a day. The difficulty of preserving and carrying milk is an obstacle to any great diminution of price that might be obtained.

by bringing it from greater distances. The most simple, sure, and economical method is by an apparatus consisting of two concentric cylinders, the inner one containing ice, and the outer, of double the capacity, containing the milk; both communicate with the exterior by means of stopcocks, and convenient openings for supply. The whole apparatus, made of tin, is contained in a wooden case. With this precaution, milk may be kept fifteen days through all states of temperature, atmospheric and electrical variations.—*Gazette Médicale*.

THE SALE OF ALUM TO BAKERS.

ON examining the Acts of Parliament, it appears that chemists and druggists are not liable to a fine for selling alum to bakers, although bakers are subject to penalties and imprisonment for using it in the manufacture of bread, or even having it on their premises. The law on this subject is particularly stringent on the bakers, who are liable to have their premises searched in case of any suspicion arising, and are prohibited, under severe penalties, from offering any resistance to such search. Nevertheless the law is inoperative, as bakers' bread is seldom if ever free from alum. We have been informed by some of the trade that it is *absolutely necessary* in the quartern and half-quartern loaves, which would otherwise adhere together on being withdrawn from the oven, instead of separating with facility, which is generally the case. In cottage-loaves, and other fancy-bread, the bakers admit that alum is not so necessary, and its use, in these cases, is much less frequent.

Various contrivances are adopted to evade the law. Alum is called by bakers "*stuff*," or "*the doctor*." It is usually bought by the master, who deposits the proper quantity for each batch in some corner of the premises, where the foreman finds it at the proper time. In some houses the master is subject to a fine in case of his neglecting to provide "*the doctor*;" which fine is the perquisite of his journeymen. By these and other precautionary regulations, the inconvenience of detection is avoided; and although every person knows that alum is always used, no one is in possession of positive evidence of the fact, and all parties concerned keep their own counsel, being bound by that kind of "*honour*" which prevails "*among thieves*." The masters are interested in using "*the doctor*," because they can by this means improve the appearance of an inferior flour; and the men are equally interested in the matter, as the bread is made with less trouble. The parties aggrieved by this practice are those who *consume the bread*. Dr. Pereira, in his *Treatise on Food and Diet*, observes—

"Whatever doubts may be entertained as to the ill effects of alum on the healthy stomach, none can exist as to its injurious effects in cases of dyspepsia. Bread which contains alum is objectionable, not merely on account of this salt, but because it is generally made from inferior flour, which, when mixed with yeast and water, and formed into dough, quickly passes through the stage of vinous fermentation, and becomes acid."—*Pharmaceutical Journal*.

PATHOLOGICAL STUDIES ON MENSTRUATION.

BY DR. A. RACIBORSKI. PART II.

Academy of Science, July 24.

THE following are the conclusions drawn by the author in this memoir:—

We believe that we have shewn in this part of our memoir—1st. That the course followed by the Graafian follicles during their progressive development in women, exactly resembles that which they follow in other mammiferæ, as we may easily assure ourselves, especially by examining the ovaries of the sow.

2d. The rutting seasons offer the greatest analogy, anatomically considered, to the menstrual periods. Both are coincident with the highest degree of development of one or more follicles, and terminate by their rupture, and the expulsion of the ovum, or of a true foetation. They have also in common a greater or less congestion of the uterus, vagina, and external organs.

3d. The menstrual periods, like those of rutting, are closely connected with the reproduction of the species.

4th. The organs described by authors under the name of *corpora lutea*, or glandular bodies, are nothing but the follicles of Graaf, in a stage of development more or less advanced.

5th. The tumefaction of the Graafian follicles, and their elevation on the surface of the ovaries, seems to be an indispensable condition for fecundation of the ova.

6th. The orgasm accompanying coition may of itself suffice to produce this state of the follicles, without its having been previously prepared by the instinctive impulses of nature: only, as in that case this state and disposition of the follicles is not completed till a longer or shorter time after coition, conception is thereby retarded, and is moreover, far less certain than when connection has taken place while the follicles were already swollen and prominent, as they are at the rutting season, and at the approach of the menstrual period.

7th. That, as regards the faculty of reproduction, woman seems to occupy a place intermediate between female animals which

have seasons of heat or rutting, and those which are always capable of fecundation from the mere orgasm excited by coition, without other preparation on the part of nature. Their nature, however, approaches more nearly to that of the former class, our statistical researches having informed us that of 100 women, six or seven at the most become pregnant after sexual intercourse at a distance from the menstrual period; while in most women conception dates evidently from such intercourse *at the moment of the catamenial evacuation (sic!)*, or some days before or after the menstrual period.

PAINLESSNESS OF A MORTAL WOUND.

GREAT wounds stupify the nervous system, and there is no pain, from the impossibility of reaction. Nature is then without force, art without power, and the surgeon without hope. Here is an instance. In 1812 a regiment was marching along the sea-shore of Catalonia: being covered by a slight fog, it faced the English gun-boats, which were lying off the coast. On a sudden a wind sprung up, the fog dispersed, and the enemy's gun-boats immediately poured a very brisk fire upon our soldiers, but so badly aimed that but few were wounded. Nevertheless, a ball, making a *ricochet*, struck a soldier obliquely, and completely opened his abdomen. The skin and muscles were carried away with astonishing precision; but this enormous wound had apparently not touched the abdominal viscera, which were escaping in every direction. There was not the shadow of hæmorrhage. I had the wounded man transported to a neighbouring village, called Tor d'en Barre. He was placed on the ground, with his head on his knapsack, and the wound was merely covered with linen. Some compassionate soldiers came to give him brandy, to help him to die, according to their expression; and he swallowed it very well. Ten times, twenty times, I asked him if he was in pain, and he always answered with a weak but clear voice, that he was quite free from pain, though he saw that certain death awaited him. He died, or rather, he was quenched, at eight in the evening, having been wounded by the ball at seven in the morning. We see that pain is not in proportion to the greatness of the hurt; and one might say that nature employs this mean only with the hope, more or less founded, of subduing the disease; otherwise what would be the advantage of it? It is moral pain alone which remains to the last breath of life.—R. P. in the *Gazette Médicale*.

PILULA FERRI COMPOSITA.

SEVERAL methods were proposed some time ago, by members of the society, for preparing this pill in such a manner as to preserve the carbonate of iron undecomposed, and to insure the uniform consistence of the mass. Some of the plans recommended were, to a certain extent, deviations from the formula of the College. We have found, as the result of experiment, that the mass can be made according to the directions of the Pharmacopœia. and free from any of the objections which have been pointed out, by an attention to the following particulars:—

Dissolve the sulphate of iron, finely powdered, in the treacle, with a moderate heat, and add the carbonate of soda, stirring constantly until the effervescence has entirely ceased and the mixture has become cool; then add the myrrh gradually, and incorporate the mass. As a little evaporation takes place at the commencement of the process, a small excess of treacle is requisite to supply the deficiency. This mass retains its colour and consistence remarkably well.—*Pharmaceutical Journal*.

ON COLLECTING AND PRESERVING ROOTS FOR MEDICINAL PURPOSES.

IN a communication recently made by Dr. Houlton to the Royal Medico-Botanical Society on the above subject, he states, that all roots should be taken up at the time that their leaves die, as they then abound with the proper secretions of the plant. This rule has no exception; it applies to the roots of trees, shrubs, herbs, rootstocks, bulbs, cormi, and tubers, and it includes that curious plant, colchicum, whose flowers only appear in the autumn, and its leaves and fruit the following spring and summer. Biennial roots must be taken up in the first year of their duration; as, when the leaves decay in the second year, their roots are either decayed, or merely dry woody fibre. Roots intended to be preserved should be dried as soon as possible after they have been dug up; the large tree roots, especially the more juicy, dry better in their entire state than when sliced.—*Ibid*.

DR. TODD'S CYCLOPÆDIA OF ANATOMY, PART XXV.

To the Editor of the Medical Gazette.

SIR,

WILL you oblige me, and, doubtless, many other purchasers of the *Cyclopædia* of

Anatomy, by asking the Editor, Dr. Todd, what he is about? On the cover of Part XXIV. was an announcement that Part XXV. would be published in October,—and where is it?—I am, sir,
Your obedient servant,
JAMES DOUGLAS.

Glasgow, July 27, 1843.

ON THE
SENSIBILITY OF THE GLOTTIS
AFTER THE PERFORMANCE OF
TRACHEOTOMY,
WITH THE DESCRIPTION OF A NEW
INSTRUMENT.

To the Editor of the Medical Gazette.

SIR,

WILL you allow me through your journal to call the attention of Mr. Erichsen to a little circumstance of which he appears either ignorant or forgetful?

It is this: that six years ago, M. Magendie, of Paris, proved the relative sensibility of the larynx, glottis, and of the bronchial extremity of the trachea, by performing, *mirabile dictu*, the very same experiment as Mr. Erichsen has done on these parts in the same animal, the dog, and with the same instrument, a probe! And may I ask Mr. Erichsen if he ever read Will. Shakespeare's "Much Ado," &c.?

Magendie's experiment is given in the Lancet for 36-37, Vol. 2, p. 505.

I am, sir, your reader,

E.

University College,
July 15, 1843.

BOOKS RECEIVED FOR REVIEW.

Neurypnology; or, the Rationale of Nervous Sleep, considered in relation with Animal Magnetism. Illustrated by numerous cases. By James Braid, M.R.C.S.E. &c.

Some Account of the African Remittent Fever, which occurred on board Her Majesty's Steam Ship Wilberforce, in the River Niger, and whilst engaged on service on the Western Coast of Africa; comprising an inquiry into the Cause of Disease in Tropical Climates. By Morris Pritchett, M.D. &c. &c. &c.

Report upon the Phenomena of Clairvoyance, or Lucid Somnambulism (from personal observation); with Additional Remarks. By Edwin Lee, Esq. &c. &c.

Letter to the Right Hon. Sir Robert Peel, Bart. on the Responsibility of Monomaniacs for the Crime of Murder. By James Stark, M.D. F.R.S.E. Fellow of the Royal College of Physicians in Edinburgh.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXXIX.

*On Inflammation of the Veins and Absor-
bent Vessels of the Uterus in Puerperal
Women.*

INFLAMMATION of the venous system was first described by Mr. Hunter, in the Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, in 1793. "I have found," he observes, "in all violent inflammations of the cellular membrane, whether spontaneous or in consequence of accident, as in compound fractures, or of surgical operations, as in the removal of an extremity, that the coats of the larger veins passing through the inflamed part become also considerably inflamed, and that their inner surface takes on the adhesive, suppurative, and ulcerative inflammation. I have found in many places of the veins adhesions, in others matter, and in others ulceration. Under such circumstances the veins would have abscesses formed in them, if the matter did not find in many cases an easy passage to the heart, along with the circulating blood, so as to prevent the accumulation of the pus; but this ready passage of the matter into the common circulation does not always happen. It is in some cases prevented by the adhesive inflammation taking place in the vein between the place of suppuration and the heart, so that an abscess is formed, as will be further observed: where the inflammation is most violent, there we find

the vein most inflamed; there, also, after suppuration, we find the purest pus, and as we trace the vessels from this part either further from or nearer to the heart, we find the pus more and more mixed with blood, and having more and more of the coagulated parts of the blood in it. As these appearances are only to be seen in dead bodies, they cannot be described but from thence; but it is so common a case, that I have hardly ever seen an instance of suppuration in any part furnished with large veins, where the appearances are not evident after death. I have found them in the bodies of those who have died from amputation, compound fractures, and mortification." These circumstances led Mr. Hunter to suspect that the fatal effects sometimes succeeding to venesection, which had usually been attributed to injuries of tendons and nerves, depended on inflammation of the internal coats of the veins. He observed similar appearances in the veins of the arm after bleeding; and he states that in many cases the inflammation and suppuration are not confined to the part, from the adhesion not having taken place, and that an abscess is frequently formed which occupies a considerable length of the vein, both between the wound and the heart, and between the wound and the extreme parts." Upon examining the arm of a man who died in St. George's Hospital, Mr. Hunter found the veins, both above and below the orifice, in many places united by the adhesive inflammation. He also found in many parts of the veins that suppuration had begun as on inflamed surfaces, but had not arrived at ulceration, and in several other places ulceration had taken place, so as to have destroyed that surface next the skin, and a circumscribed abscess was formed. The veins near to the axilla had taken on suppuration, beyond which adhesion had not formed, and thus had given a free passage for the matter into the circulation, of which, most probably, the patient died. "Many horses," he says,

die of this disease, but what is the peculiar circumstance which occasions their death I have not been able to determine; it may either be that the inflammation extends itself to the heart, or that the matter secreted from the inside of the vein passes along the tubes in considerable quantity to the heart, and mixes with the blood. I am inclined to believe that the exposure of cavities of the larger veins, in cases of accidents and also of operations, is often the cause of many of the extensive inflammations which sometimes attend these cases, and, indeed, may be the reason why inflammations extend or spread at all beyond the sphere of continued sympathy." It does not appear that Mr. Hunter was aware of the resemblance which exists between the part of the uterus where the placenta adhered, and an amputated or wounded limb, and their liability to the same diseases, and that he had ever observed inflammation of the uterine veins in puerperal women. It is singular that this important variety of uterine inflammation should have altogether escaped his notice, considering the accuracy of the description which he has given of puerperal peritonitis, and the correct opinion he had formed respecting its nature. "The peritoneum," he says, "is more subject to spontaneous inflammation than most membranes, but not so much so as the pleura. The symptoms are great pain, and soreness upon pressure, fever much higher than in an affection of a common part; the disease also runs much quicker through its stages; it has been often taken for a fever, and the pain, &c. looked on only as a symptom; in some cases a diarrhoea comes on, and at others costiveness: both these, I am inclined to think, may be set down as sympathetic affections. It is difficult to say at first whether it is simple inflammation or erysipelalous; if it is the latter, the pulse will soon sink, although at first it might have been otherwise, from nature having been roused at the first consciousness of disease attacking so important a part. In simple inflammation of the peritoneum I need say nothing of the importance of early and plentiful bleeding; in the erysipelalous, some consideration must be had; as on the one hand, this species of inflammation sinks the patient, and on the other, death must be the consequence of suppuration. If we were confident of its being erysipelalous, how far bleeding lessens erysipelas I do not know; peritoneal inflammation happens a few days after childbirth, which has been called puerperal fever; the fever is only a sympathetic affection, in consequence of the inflammation of the peritoneum, although this last has been thought only a symptom of fever."

In a volume of *Essays on the Management of Pregnancy and Labour*, and on the *Inflammatory and Febrile Diseases of Lying-in*

Women, published by Dr. John Clarke in 1793, he observes that, "upon cutting into the substance of the uterus, pus is often found, which, in all the cases I have met with, is situated in the large veins of the part." In dissecting the body of a woman who died several weeks after delivery, Mr. Wilson found the uterine veins thickened and partially obliterated; the iliac, emulgent, and spermatic veins, exhibited the usual effects produced by inflammation; the coats of the vena cava were thickened and adherent to the surrounding parts, and the vessel, which was contracted below the entrance of the hepatic, contained about 3iv. of pus. Mr. Wilson met with similar appearances in the bodies of two women who died soon after parturition, and the uterine veins also contained pus. These facts were stated in the third volume of the same work in which Mr. Hunter's paper appeared in 1793. In 1797, the attention of pathologists being now directed to the subject, Meckel communicated to Sasse the history of a case of puerperal fever, in which he found, on dissection, "all the veins which surround the uterus, the hypogastric trunks, and the vena cava, enlarged in volume; the place where the placenta had adhered was distinguished by a fungous mass. The veins, whose exterior appearance had arrested the attention, were examined with care; they were separated from the surrounding cellular substance, and in this state the whole system of uterine and spermatic veins presented an extraordinary augmentation of the calibre of the vessels and thickness of their coats; when opened, there escaped from them a true purulent fluid. The vena cava, where the right renal vein entered, presented a resisting tumefaction, and when opened, its coats were double the natural thickness, and the cavity was filled with pus, and a polypus formed of pseudo-membranous and puriform concretions. "Many circumstances," Meckel observes, "might contribute to render the disease mortal; but is it not fair," he inquires, "to attribute the occurrence of the fatal termination of the case to the profound lesion of the veins?" Uterine phlebitis, from this period till 1820, appears to have almost completely escaped observation, when it was thus described by Dr. Burns: "Pus is often contained in the ovaria and tubes, and sinuses of the uterus: he says, mortification is an extremely rare termination. This is a fact of which my dissections convince me, and it is further confirmed by the opinion of Dr. Clarke. Little or no scrous effusion takes place into the abdomen. In some cases the veins participate very extensively in the disease, and become inflamed to a great distance. Thus inflammation may spread to the heart or liver, or down along the veins of one or both thighs. This is attended with great and

debilitating fever, and much pain in the course of the affected veins, which, after death, are found inflamed, thickened, or filled with pus. The treatment of this complication must be conducted on the antiphlogistic plan, and a knowledge of the nature of the disease will call for early attention to local pain attended with fever." In 1825, Ribes described a fatal case of puerperal peritonitis in which the abdominal veins were filled with a sanious pus, and it was the presence of this purulent fluid in the veins, he thought, which rendered the diseases of the uterus, in puerperal women, so rapidly fatal. In 1826, M. Louis observed a fatal case of uterine phlebitis; and in the same year M. Dance published the histories of several cases, in his *Inaugural Dissertation at Paris*. If you look at this tabular view (No. 1) of 100 cases of uterine inflammation, you will see that 18 occurred between the 6th of March and the middle of September, 1827, and that in the greater number of these there was acute pain of the uterus, with strong febrile symptoms, and that recovery generally followed the early and speedy adoption of the antiphlogistic treatment. I was induced to believe, from what I observed at this period, that inflammation of the peritoneum, and the disease termed by authors puerperal fever, child-bed fever, the epidemic disease of lying-in women, were the same affections, and that blood-letting, mercury, antimony, opium, and cathartics, would generally succeed in procuring relief. But in the month of September of the same year, Case No. 19 occurred, and the symptoms and appearances on dissection completely overturned this opinion. On the second day after a natural labour, 28th September, 1827, and when apparently recovering favourably, this patient (Somerville) was attacked with a severe rigor, which was speedily followed by acute pain in the hypogastrium and loins, suppression of the lochia, nausea, urgent thirst, and increased heat of skin. She was soon delirious and slightly comatose, and made no complaint when roused, but of pain in the left iliac region. The abdomen was unusually distended, but neither hard nor tense, and pressure produced no uneasiness, except between the left ilium and umbilicus. The uterus was still felt above the brim of the pelvis, large and hard, and painful on pressure. The milk and lochia were suppressed, the countenance pale and anxious, pulse 130, weak, and intermitting. On the 22d the stupor continued to increase, the abdomen was more distended and painful, the respiration more hurried and laborious, and the pulse extremely quick, feeble, and intermitting. A vein was opened in the arm when she was first attacked, but a tea-cupful of blood could not be procured. On examining the body on the 23d, the intestines were

seen slightly distended with gas, but there was no trace of inflammation on any part of their peritoneal surface, and no fluid effused into the sac of the peritoneum. On turning aside the intestines, the left spermatic vein, from the uterus to its junction with the left emulgent vein, was seen distended to nearly the size of the vena cava itself. The cellular membrane surrounding it was highly vascular, and adhered closely to its external surface. On laying open the vein, a dark-coloured firm coagulum of blood filled it throughout its whole course, but it did not adhere to its internal surface, except near its termination, where it was lined with a layer of lymph. The coats of the vein were thicker and firmer than usual, and the internal membrane was of a bright scarlet colour, as was that lining the veins of the uterus near the fundus on the left side, the part to which the placenta had been attached. The substance of the uterus in this situation was of a dark livid colour, remarkably soft in its texture, and easily torn with the fingers. The corresponding ovary and fallopian tube were also very soft, and of a dark red colour, and shreds of coagulable lymph adhered closely to their surface. The left renal vein was in the same state as the spermatic, and the substance of the left kidney was soft and vascular. The connection between the constitutional symptoms in this case, and the veins of the uterus, was too obvious to escape detection.

On the 22d July, 1828, I was requested by the late Mr. Baker to deliver Ann Cromer, a patient of the St. James's Infirmary, who was eight months pregnant, and had been attacked with profuse uterine hæmorrhage from placental presentation. On the evening of the following day her pulse rose to 140, with headache, heat of skin, and intolerance of light; on that of the 24th, she had a slight rigor, and again on the 25th another exacerbation of fever, the pulse and breathing hurried. For some days subsequently she had less fever, and without evening exacerbations; the pulse ranged from 100 to 120. No pain was felt on pressure of the abdomen, although some mischief was evidently going on. On the 2d of August her breathing had again become much oppressed, with slight cough and no expectoration. The next day there was pain in the left side of the chest, and 3xvj. of blood were drawn from the arm. On the 4th the pain was relieved, and on the 5th entirely removed, but the pulse was 120, the skin hot and dry, and there was slight expectoration of a foetid mucus. On the 6th there was less fever, she was excessively weak, the features were sharp and anxious, and the breath was very offensive. On the 7th the expectoration was more free, thick, and purulent, and although the linen of her bed had been changed, the unpleasant smell was not

diminished, and was evidently caused by her breath. Death took place on the 9th, eighteen days after delivery. I examined the body with Mr. Baker, when the following appearances were observed. On opening the chest an extremely foetid odour issued from its left cavity, in the lower part of which were contained between three and four pounds of a turbid serum, mixed with portions of coagulable lymph. Superiorly the lung was glued to the parietes of the chest by recent loose adhesions; inferiorly the pleura pulmonalis and corresponding pleura costalis were covered with a dense coating of coagulable lymph. In addition to this there was on part of the surface of the inferior lobe of the lung a quantity of the same substance in a loose flaky form, on removing which there presented itself a portion of the lung in a state of complete gangrene; this, about the size of a walnut, forming a black pulpy-looking mass of very foetid odour, was contained, with some dark coloured fluid, in a cavity formed by its separation from the sound lung. On making a section of the parts passing through the gangrenous slough, one half of this fell out of the cavity in which it was situated, the other remaining attached to the parietes by a few thread-like adhesions. The cavity itself was lined by a layer of coagulable lymph, having the appearance of a uniform membrane. On cutting into the uterus, which was reduced as much in size as usual at the same period, a few drops of pus flowed from one of the divided sinuses, which, being traced, I found to communicate with an abscess in the left ovarium. I felt the left spermatic vein unusually large and hard before it was laid open, when it was found to contain pus, and its coats were seen thickened, and its inner surface lined with a layer of coagulable lymph which nearly obliterated the cavity. These diseased changes occupied the whole course of the vein to its junction with the emulgent, the coats of which were also thickened, and the cavity lined with lymph. The cava was healthy. There was no trace of inflammation in the peritoneum of the uterus, or general peritoneal sac. The inflamed state of the spermatic vein would here have wholly escaped detection had I not observed the appearances described in the previous case. I felt greatly at a loss to account for the production of so acute and destructive an inflammation of the lungs in an individual who had, previous to delivery, never suffered from any affection of the chest. I was disposed to attribute the attack to the general shock communicated to the system by the operation of turning and hæmorrhage, when I accidentally met with the following remark of Laennec, who gave a different explanation of the occurrence. "It is not uncommon to find the veins in the neighbourhood of a cancerous breast filled with

pus, either pure or mixed with blood, sometimes fluid, at other times of the degree of consistence of an atheromatous tumor. An additional consequence of the presence of too much pus in the blood is the production of inflammation in different organs, and especially in the lungs, which runs rapidly into suppuration. It is from this circumstance that the subjects of surgical operations, and those labouring under extensive suppurations, are frequently cut off by peripneumonies, which, according to the observations of M. Cruveilhier, are usually lobular, that is, commencing at several points at once. This, in my opinion, is the mode in which we must explain the occurrence of metastasis of pus, at least in the majority of cases." Mr. Arnott, to whom I related these cases, had adopted the same view, and had collected 17 cases of phlebitis, which all went to prove that the suppurations which take place in different viscera after external injuries and surgical operations, do not depend upon any shock communicated to the system, but upon the purulent matter formed in the veins mixing with the blood. Mr. Arnott stated to me, at the same time, that he considered this to be the cause of the suppuration of the eyes, and the painful swellings in the joints, sometimes observed in puerperal women. But there was no pus in the spermatic vein in the first case now related, and I have since seen others where these secondary affections occurred without inflammation of the uterine veins or absorbents. The connection between inflammation of the uterus and these secondary abscesses is undoubted, but it may be explained in different ways, and I am satisfied that the intimate part of the process requires further investigation. Whatever the *modus operandi* may be, the following cases, which occurred soon afterwards, established a certain connection between inflammation of the uterine veins and fever, inflammation of the lungs and eyes, and painful swellings in the joints and extremities of puerperal women. The relation of these cases, and an examination of the appearances presented by the inflamed veins in the preparations and drawings now upon the table, will give you a better idea of the changes of structure, and the local and constitutional symptoms of uterine phlebitis, than a general description of the disease.

Mrs. Keene, æt. 31, No. 6, Draper's Place, Euston Square, after a protracted labour of three days, was delivered on the 14th July, 1829, by artificial aid, of a still-born hydrocephalic child. Immediately after the expulsion of the child, she was seized with a fit of the most intense shivering, which continued upwards of an hour, notwithstanding the exhibition of the most powerful stimuli, and the exhaustion which followed was alarming. She rallied, how-

ever, and passed a quiet night. On the following, and two or three subsequent days, the shivering fits returned at irregular periods, sometimes in a slight form, at others in that of a severe rigor, followed by a flush of heat, and partial or general perspiration. During this time the effects consequent to parturition proceeded as usual. The uterus slightly painful on pressure; lochia natural; bowels open; pulse 133 to 140, and extremely feeble. No complaint of uneasiness, with the exception of a troublesome cough and hoarseness, with which she has been afflicted during the latter months of pregnancy. On the 4th day from delivery the secretion of milk appeared for a short time, and afterwards receded. From this day to the 10th, the following were the symptoms: pulse rapid; skin universally of a dusky yellow colour, and the heat of surface increased; respiration hurried; thirst; tongue dry but not furred; great prostration of strength, sallow and haggard countenance; restless and sleepless nights; mental faculties undisturbed. The uterus had gradually subsided, and no pressure, however great, either on it or on the parts in its vicinity, caused pain, except in the right iliac region, where some uneasiness was felt; the flow of lochia natural; bowels regular. At this period the hacking cough which had so long troubled her became more frequent, and it was with difficulty she expectorated the ropy mucus which followed it, and which in the day amounted to an ounce. From the 11th day the respiration became more short and hurried; the pulse more rapid; occasional flushes of heat, thirst, extreme debility, diarrhoea. Pressure over the whole abdomen gave no uneasiness, nor was pain felt in any part of the chest, though auscultation plainly indicated the existence of disease, particularly on the right side. The patient made no complaint but of weakness and the cough. She died exhausted on the 12th. Dr. John Prout, who had carefully observed the progress of the symptoms from the period of delivery, was present with me when I opened the body. The uterus being removed from the body for more minute examination, an incision was made into the right superior angle, to which the placenta had been attached, and here its veins were discovered to be empty, and their internal surface of a scarlet colour. On tracing them towards the trunk of the right spermatic vein, they were found to contain a sanious purulent fluid, and were contracted in their diameters and coated with false membranes. The veins of the right ovary and fallopian tube were all plugged up with firm coagula. The spermatic itself was lined throughout its whole extent with dense membranes of a reddish, or of an ash-grey colour. Its coats, independent of these membranes, were of extraordinary thickness

and firmness—more like those of a large artery than a vein. The whole cavity was contracted; in some parts occupied by a dark-coloured fluid, in others quite obliterated by adhesions formed between the surfaces of the membranous layers deposited within it. At the termination of the spermatic in the vena cava, its orifice was scarcely large enough to admit a crow-quill. Traces of inflammation extended beyond this orifice, the vena cava being partially lined, from two to three inches above it, with an adventitious membrane strongly adherent to its coats, which were at this part double their natural thickness. In its passage upwards the inflammation had extended a short distance into the right emulgent vein, which, near its orifice, was coated with a pellicle of lymph. On opening the thorax a stream of air escaped from the right side; the lungs were collapsed, and upwards of ten pints and a half of red-coloured serum were found in the sac of the pleura. The right inferior lobe was coated with lymph, and a portion of the pleura on the anterior surface was destroyed, and a black gangrenous slough exposed in the substance of the lung. The pulmonary texture around was condensed, and of a deep violet or red colour. The left inferior lobe was also partially coated with a thin layer of lymph; and the pleura, at one point on the anterior surface, was elevated as if by a hard globular substance underneath. When this was laid open, it appeared to consist of a thick yellow-coloured cyst or capsule, containing a soft black matter like a gangrenous eschar. The substance of the lungs around was unusually dense, and of a dark livid colour. The appearances of the portions of lung affected with gangrene, and of the right spermatic vein and vena cava, now described, are well preserved in these preparations of these parts [exhibiting them].

By looking at this preparation attentively, you will not only be able to form a clear idea of the changes produced upon the uterine veins by inflammation, but of the manner in which the disease originates, and the course it usually pursues, where the placenta has adhered to the superior part of the uterus. The veins in that part of the uterus where the placenta had been attached, and the spermatic, which had conveyed the blood from the placenta back to the system of the mother, are those alone affected, the veins in the lower part of the uterus, and the trunk of the hypogastric, being generally in a perfectly healthy condition. But I will show you another preparation [exhibiting it] in which the inflammation has run down along the lining membrane of the branches of the hypogastric into the common and external iliac and femoral veins, and upward along the vena cava to the point where the hepatic veins enter, and produced the same alterations of structure that you have seen in the

other preparation, viz. injection and condensation of the cellular membrane in which the veins were imbedded, thickening, induration and contraction of their coats, and the deposition of lymph mixed with pus and coagula of blood within their cavities. Extensive inflammation of the lungs had likewise taken place in this woman, and, what is more rare, destruction of both eyes by violent inflammation. The details of this case have been minutely related in vol. 15 of the *Medico-Chirurgical Transactions*, and many other cases of uterine phlebitis in which fatal inflammation of the lungs, eyes, puffy swellings around the joints, ulceration of the articular cartilages and symphysis pubis, and gangrene of different parts of the body, took place in the progress of the disease. In some cases extensive inflammation and suppuration took place in the veins ramifying in the muscular coat of the uterus, and death followed with many of the symptoms of typhus fever, rapid feeble pulse, delirium, nervous tremors, the tongue and teeth covered with black sordes, vomiting and diarrhoea, before the inflammation had extended beyond the confines of the uterus. By examining the tables of all the cases which have occurred to me during the last fifteen years, you will be fully aware of the frequency and fatality of uterine phlebitis.

In these drawings [exhibiting them] you have represented the peculiar beaded appearance of the uterine absorbents when filled with pus. The symptoms are the same as in cases of inflammation of the veins of the uterus. The first example of this disease occurred in St. George's Hospital in the month of July 1829, and is thus described by Mr. Caesar Hawkins. A woman, æt. 30, in an advanced stage of pregnancy, had sloughing of the skin over a diseased burn of the patella. The removal of the burn by an operation was followed by great constitutional disturbance, and labour came on fourteen days after. Uterine inflammation took place on the second day after delivery, and death took place on the fourth. Some puriform lymph was found in the pelvis, but with no increase of vascularity in the peritoneum. In the broad ligaments some fluid also was effused, and on each side numerous large absorbent vessels were discovered passing up, with the spermatic vessels, to the receptaculum chyli, which was unusually distended. All these vessels, and the reservoir itself, were quite filled with fluid pus; but that in the receptacle was filled with lymph, so as to be more solid; the vessels themselves were firmer and thicker than usual. The thoracic duct above this part was quite healthy. The uterus was scarcely contracted, and the internal surface of the lower half was soft and shreddy, and in a state of slough.

TABULAR VIEW (No. 1) OF 100 CASES OF SEVERE INFLAMMATION OF THE UTERUS AND ITS APPENDAGES,

Which occurred to me in London, from March 1827 to the end of December 1830.

[Continued from p. 697.]

No.	Name, Residence, and Delivery.	Date of Attack and Symptoms.	Treatment.	Result and Morbid Appearances.
51	Case, British Lying-in Hospital. Natural labour. 1st March, 1829.	Fifth day.—Pain in left side of hypogastrium, followed by rigors and headache; pulse 120; skin hot; tongue red and glossy; exquisite tenderness of the whole uterine region. Second day.—Great pain; swelling and tension of hypogastrium; rapid feeble pulse; tongue brown; vomiting; delirium. Died on the seventh day after delivery.	V.S. ʒi. calomel gr. iij. pulv. Dover. gr. v. 3tia q. q. h. The relief from bleeding instantaneous. Leeches xxiv., calomel, and Dover's powder.	Recovered.
52	Davies; æt. 20; deformed pelvis; Orange-Street, Leicester-Square. A protracted labour and artificial delivery. March 27, 1829.			Died. Large intestines vascular, but not covered with lymph; peritoneum of uterus inflamed; posterior portion of os uteri in a sloughing state; muscular tissue of uterus softened.

53	Case, Queen Charlotte's Lying-in Hospital.—Natural labour. March 4, 1829.	Fourth day.—Slight abdominal pain; diarrhoea; brown tongue; vomiting; rapid feeble pulse; great prostration of strength. Not seen during life; seen after, with Mr. Sweatman. Fourteen days' duration.	V.S. not employed; leeches, vesication, &c.	Died. Omentum small; intestines and uterus strongly adhering together by lymph; uterine appendages much inflamed; several pints of sero-purulent fluid in peritoneal sac.
54	Mayhew; æt. 33; British Lying-in Hospital. Natural labour. March 2, 1829.	Fourth day.—Pyrexia; pulse 130; great debility; delirium; dusky yellow complexion; no pain of abdomen; cough; excruciating pains in the joints of the upper and lower extremities. Duration of disease twenty-two days.	Powerful diffusible stimulants, and opiates.	Died. Uterus reduced to its natural size; no morbid appearance in its peritoneal coat; a portion of placenta the size of a nutmeg, in a putrid state, adhering to the uterus, which was soft and black around; sinuses of the uterus full of pus at this part; 3vj. of pus in right knee-joint; cartilages eroded. Recovered.
55	Aldridge; British Lying-in Hospital. Natural labour. May 25, 1829.	Third or fourth day.—Severe uterine pain; pyrexia; suppressed lochia; after recovery became maniacal.	V.S. ʒviij., cathartics, fermentations.	Recovered.
56	Airey; 43, Clipstone Street. Natural labour. 23d May, 1829.	Second day.—Severe uterine pain; no general abdominal tenderness; pulse 100; tongue white; lochia suppressed.	V.S. ʒxvj., calomel, antimony, cathartics.	Recovered.
57	Case after natural labour; Bloomsbury Market. 15th June, 1829.	Fifth day.—(Not seen at the commencement.) Vomiting within 24 hours after delivery; rapid feeble pulse; no pain of abdomen, or swelling; headache and delirium. The history of the early symptoms imperfect.	Head shaved, cold lotions, cathartics.	Died. Left ovary much inflamed, enlarged, and softened; left fallopian tube red and vascular, and filled with pus; two pints of reddish serum in peritoneal sac; vessels of brain gorged; fluid in the ventricles. Died.
58	M'Sweeney; Falconberg Court, Soho Square. Natural labour. 6th July, 1829.	Fourth day.—Slight uterine pain; delirium; rapid feeble pulse; great debility; vomiting; yellow skin; offensive lochia.	No remedies employed, the case being hopeless when first seen.	

59	Tiffin; 18, Mencer Street, Long Acre.—Natural labour. 7th July, 1829.	Second day.—Uterus large, hard, and exquisitely painful; lochia scanty; pulse 110; pain gradually diffused; sickness; vomiting; delirium; rapid pulse and breathing. Died on the fourth day.	V.S. 3xv., leeches xij., V.S. xxiv., leeches xvij., calomel, opium, cathartics, blisters.	Died. Intestines distended with air, their peritoneum red and vascular; peritoneum of uterus coated with lymph; in the cellular tissue beneath, a sero-purulent and gelatinous fluid; pus in the lower part of the walls of the uterus, and between the folds of the broad ligaments; right ovary the size of a hen's egg, and disorganized, left ovary in a slighter degree; fallopian tubes red, soft, and filled with pus. Recovered.
60	Stockin; 4, Tottenham Court Road.—Natural labour. 8th July, 1829.	Third day.—Pain in the region of the uterus, increased by pressure; lochia scanty; pulse rapid; asphena veins of right side hard and painful.	V.S. 3xij., calomel, antimony, &c.	Recovered.
61	Millam; 4, Tudor Place. Natural labour. 12th July, 1829.	Second day.—Rigors and headache, followed by excruciating pain of uterus; pressure cannot be endured; lochia suppressed; pulse 160; tongue white and moist. Second or third day.—Rigors; slight uterine pain; lochia natural; pulse 133 to 146; sallow dusky skin; respiration hurried; tongue dry; great debility; pain in right iliac region; cough; expectation; diarrhoea; great dyspnoea.	V.S. 3xxiv., leeches xvij., fomentations, calomel and opium, and antimony.	Recovered.
62	Keene; æt. 34. Protracted labour: hydrocephalic child. 14th July, 1829.		V.S. not employed; anodynes, diaphoretics, blisters to the chest.	Died. Veins of fundus uteri right side inflamed; right spermatic vein, through its whole extent, thickened greatly, its inner surface lined with a false membrane, and its cavity filled with a sanious purulent fluid; vena cava above and below the entrance of spermatic vein lined with a closely adherent false membrane; right emulgent vein inflamed; two pints of serum in the pleura; portion of right inferior lobe of lung inflamed and in a state of complete gangrene.

63	Mary A. Hale; æt. 25; British Lying-in Hospital. Natural labour. 25th July, 1829.	Second day.—Severe rigor, followed by great tenderness of hypogastrium; rapid pulse; white tongue; whole abdomen became intensely painful, without swelling or tension; cough; dyspnoea, and pain in right side of chest. Died on fifth day after delivery.	V.S. 3xvij. (syncope), leeches, calomel, Dover's powder, cathartics.	Died. Peritoneum of the uterus and appendages coated with false membrane; peritoneal coating of intestines inflamed and glued together; two pints of whey-coloured fluid in abdominal cavity; muscular coat and vessels of uterus healthy; traces of recent inflammation in the pleura and lungs on the left side. Recovered.
64	Luff; æt. 26; British Lying-in Hospital.—Natural labour. 11th August, 1829.	Sudden acute pain of the uterus; right side exquisitely tender on pressure; uterus large and hard; pulse 112, small; rigors; lochia scanty. The relief from bleeding was most striking in this case.	V.S. 3xxvj., leeches xxxvj., calomel gr. vj., pulv. antim. gr. v. 3tia q. q. h., Dover's powder.	
65	M'Creevey; æt. 25; British Lying-in Hospital. 29th August, 1829.	Second day.—Vomiting during labour; recurred a few hours after delivery, with pyrexia and severe abdominal pain; tympanites; rapid pulse.	V.S. 3xiv., leeches xxiv., calomel, opium, &c.	Died. Partial inflammation of small intestines; a turbid fluid in the peritoneal sac: ovaria inflamed and coated with lymph, and also fallopian tubes; the omentum, adhering firmly to the posterior part of cervix uteri, formed a thick band, stretching over and firmly compressing the intestines. Died.
66	Case at Chelsea.—Nat. labour. 29th August, 1829.	Fourth day.—Diarrhoea; rapid feeble pulse; yellow tinge of skin; great debility; loaded tongue.	Stimulants.	
67	Clarke; æt. 34; 57, Monmouth Street. Natural labour. 6th September, 1829.	Seventh day.—Pyrexia; headache; vomiting; no uterine pain; pulse 150; swellings around the joints; rigors; delirium; brown tongue; great debility; left forearm swollen, and of a dark red colour; gangrene of the back part of hand.	Stimulants.	Died. Uterus contracted; peritoneum of fundus and back part of uterus of a yellow colour, soft, and easily torn; the muscular and mucous coats at the upper and back parts reduced to a soft pulp of a dark red and ash-grey colour.

68	Mason; æt. 42; 3, Little Vine Street, Piccadilly. Twins. Hæmorrhage. August, 1829.	A few days after delivery.—Pyrexia, with great uterine pain; rapid pulse; loaded tongue; diarrhoea; delirium; pulse 140; crural phlebitis in both lower extremities.	Leeches, fomentations, poultices, and diffusible stimulants.	Died. The vena cava, common external and internal iliac veins, and right femoral, inflamed and obstructed. The appearances presented by these veins have been represented in Plate 7, Vol. XV. Med. Chir. Trans.
69	—; 7, Denmark Street. Protracted lab.; perforation. 14th September, 1829.	Second day.—Pyrexia; acute abdominal pain; swelling of labia; quick pulse; tympanites; gangrene of internal parts.	V.S. 3xvj., leeches xxiv., calomel, opium, &c.	Died. Fallopian tubes of a dark red colour, and containing pus; ovaria enlarged and softened, and covered with lymph; 3xij. of red serum in the abdominal cavity; veins of uterus, where placenta adhered, gorged with pus.
70	Mills; æt. 30; British Lying-in Hospital. Natural labour. 7th October, 1829.	Second day.—Pain and hardness in the superficial veins of both legs and thighs, with a diffuse swelling and erysipelatous redness around, with violent fever; tongue red; face flushed; respiration hurried; jactitation; delirium; suppuration in the cellular membrane around the vein at different points. Duration of disease 14 days.	Fomentations and poultices, stimulants.	Died. Trunks and branches of saphena veins inflamed and obstructed; abscesses beneath the skin in the calf of the leg and interstices of the gastrocnemii muscles; coats of femoral veins thickened and contracted; intestines inflamed, portion of ascending colon in a state of sphacelus.
71	Hickson; British Lying-in Hospital. 14th November, 1829.	Eighteenth day.—(Late in the disease.) Exquisite uterine pain; pulse 130; breathing hurried; features sunk; vomiting; brown tongue; yellow tinge of the skin.	Leeches and stimulants.	Died. Right uterine appendages inflamed; veins at the right side of fundus uteri filled with pus, also the right spermatic vein three inches from the uterus, the inner surface of vessel being coated with lymph; a pint of pus in the cellular membrane at the brim of pelvis; two small abscesses under peritoneum of uterus.

72	Cox; Marylebone Street, St. James's. Protracted labour. 1st December, 1829.	Fifth day.—Pyrexia; acute uterine pain, but chiefly on the right side; vomiting; rigors; lechia suppressed; stupor; delirium; loaded tongue; abdomen puffy; pulse 140, feeble.	V.S. 3vij., leeches xxiv., calomel, and opium.	Died. Several small abscesses under the peritoneum of the uterus at the left superior angle, and the veins in this part filled with pus; the ovaria soft and enlarged, and glued with lymph to the fallopian tubes, their stroma converted into a dark, red coloured, pulpy substance.
73	Long; æt. 29; British Lying-in Hospital. Natural labour. 18th December, 1829.	Fourth day.—Headache; pulse 130; delirium; great tympanites; tongue dry and brown.	V.S. 3vij., V.S. xij., cathartics.	Died. Abdomen distended; gas in peritoneal sac; the ovaria, tubes, and broad ligaments on both sides, imbedded in lymph and pus; ovaria large, soft, and vascular; the coats of the uterus healthy; omentum, small and great intestines, and surface of liver, coated with lymph.
74	Gilland; æt. 29; British Lying-in Hospital. Natural labour. 24th December, 1829.	Fifth day.—Pyrexia; rigors, alternating with flushes of heat; pulse 150; headache; giddiness, slight delirium; tremors; face flushed; eyes red; tongue foul; urgent thirst; vomiting; abdomen soft and distended; hypogastrium painful on pressure; tympanites. Died 9th January.	Leeches x. to the temples, cinchona wine, brandy, opium, beef tea.	Died. Peritoneal sac perfectly healthy; the right spermatic vein contracted, its coats thickened, and the cellular membrane around it vascular and condensed, its interior lined with false membranes and partially filled with lymph and pus; the veins proceeding from the right ovary and fallopian tube in the same condition; thin shreds of lymph coated the vena cava around the entrance of the spermatic vein; right ovary and tube glued together with lymph.
75	Mrs. Allan; æt. 20; 11, Noel Street, Berwick Street. Puerperal convulsions. December, 1829.	Fourth day.—Great uterine tenderness; lochia suppressed; pulse rapid; delirium; vomiting; sallow skin; crural phlebitis. The limb remained stiff and swollen long after.	V.S. 3xiv. leeches, calomel, antimony, fomentations, anodynes.	Recovered.

CASE OF THE SUCCESSFUL
REMOVAL OF A DISEASED
OVARIIUM,

Of 17 Years' duration, in which Paracentesis had been ten times performed.

BY DR. FREDERIC BIRD,

Lecturer on Medical Jurisprudence at the Westminster Hospital; Physician to the Metropolitan Free Hospital; and to the Westminster Maternity Charity.

(*For the London Medical Gazette.*)

MRS. GELSTHORPE, aged 35, residing in Chelsea, of general healthy appearance, and good muscular development, the previous history of whose case runs thus:—Prior to attaining her eighteenth year she enjoyed uninterrupted health; at that age menstruation became established, its periodical recurrence during the succeeding twelve months marking intervals of not more than a fortnight. When 19 years old she was, after some comparatively slight exertion, attacked with acute pain in the right iliac region, which, lasting for three days, gradually abated in violence, and in a month she had quite recovered. Since that period, however, she has continued to experience occasional recurrence of the pain at irregular intervals. Immediately after the subsidence of the acute pain, she observed that the abdomen began to increase in size, and continued to do so during the following two years, her general health suffering but little impairment, and menstruation being much more regularly performed. She then placed herself under the care of Mr. Dally, of Syson, Leicestershire, who, having allowed four months for the exhibition of general remedies, removed by paracentesis abdominis three gallons of colourless fluid. For fifteen months she experienced no re-accumulation of the fluid; but at the expiration of that time abdominal enlargement again presented itself, and in less than three months she had acquired her former size. Paracentesis was again performed, and repeated on three subsequent occasions, the intervals between the four last tapplings being about twelve months. Her recovery from the previous operations had been rapid and complete; but the last was followed by the occurrence of acute pain diffused over the whole of the abdomen, greatly increased by pressure; vomit-

ing; febrile action; and all the ordinary indications of inflammation, which slowly yielded to blood-letting, blisters, and internal remedies. Her recovery was tardy, but she ultimately regained her usual state of health, and experienced no return of the original disease during the succeeding seven years; towards the end of which time she married, but has never borne children. Abdominal enlargement again took place, though slowly, and she did not acquire her previous state of distension until two years had elapsed, when paracentesis was performed by Mr. Dickinson, of Sloane Street, on which occasion about two and a half gallons of fluid were removed, the secretion having assumed totally different physical characters, being of nearly a black colour, and remarkably viscid. In six months the operation was again called for, the evacuated fluid being of a dark yellow colour. In eighteen months she was again tapped; again after the lapse of twelve weeks; and for the tenth time on January 11th, 1843, after an interval of seventeen weeks. The fluid, removed on the three last occasions by Mr. Wooley, of Brompton, presented the same colourless state observed during the earlier periods of the disease.

A few weeks prior to the last operation of paracentesis the patient had applied to Dr. Hamilton Roe, who at once pronounced the disease ovarian, and believed that however much the previous history might oppose the employment of the operation for extirpation, yet that her general health, and the non-malignant and probably unilocular character of the tumor, afforded considerable probability of success. With this view Dr. Roe very kindly referred her to me, and thus afforded an opportunity for watching the progress of the disease, and examining it at its several stages of development.

The increase in size of the tumor since the last tapping has been very irregular, weeks sometimes having elapsed without any apparent increase, whilst occasionally a few days have sufficed for very considerable augmentation of bulk. This irregularity was associated with, and probably dependent upon, the irregular performance of menstruation. She had frequent attacks of profuse menorrhagia, during the persistence of which no increase in

size ever took place, and it was not until the use of the *secale cornutum* had completely arrested the hæmorrhage, that the cyst began to refill with the same quickness as on the last occasion. About this time pain on the right side of the abdomen frequently occurred; the pressure of the tumor upon the bladder obliged her to pass urine at very short intervals, and often with much pain; her bowels were inactive, her spirits depressed, and she was most anxious to submit to any treatment that might afford a probability of relief.

The nature of the operation for extirpation of the ovary, with all its attendant dangers, were very strongly (perhaps more so than really necessary) impressed upon her; and she was informed that the chances of success were in her case but few. Possessed of an unusual share of moral courage, these objections availed nothing, and she steadily persisted in her desire that the operation should be performed. Anxious to obtain the most accurate diagnosis of the case, I requested Dr. Roe to again see her, which he did, and after a careful examination did not hesitate to recommend the operation. I also solicited the opinions of my friends, Mr. B. Phillips, Dr. Andrews, Dr. Lever, and Mr. B. Lucas, all of whom were so kind as to assist me with their views of the case. Mr. Walne was also so obliging as to favour me with his opinion on the propriety of performing the operation. The opinions of these gentlemen accorded in all the more prominent points, the majority rather opposing than favouring the performance of an operation, partly from the fact of the patient having passed through a long term of years without having suffered any permanent derangement of health, and that the intervals between the tappings had been considerable, and appeared to be increasing; and partly from a belief in the existence of peritoneal adhesions of greater or less extent. Although most fully concurring in the degree of importance attaching to the first of these objections, I was induced to believe it probable that there did not exist any extensive attachments to the peritoneum, having had an opportunity, which these gentlemen had not had, of examining the abdomen immediately after the last

operation of tapping. This impression, coupled with the very favourable condition of the general health of the patient, induced me to acquiesce in her urgent desire that she might be allowed the chances of the operation; and Monday, June 26th, was fixed for its performance. The only preliminary treatment consisted in the withdrawal for a few days of animal food, the exhibition of eight grains of compound extract of colocynth, with five of hyoscyamus, on the preceding day, and an enema of gruel two hours before the operation. Great care was taken to regulate the temperature of the apartment, which was maintained at 85°, but subsequently lowered as convalescence approached.

June 26th.—In the presence of Dr. Hamilton Roe, Mr. B. Phillips, Dr. Andrews, Mr. Cantis, and Mr. Brown of Chelsea, the patient having been drawn down sufficiently low in the bed to admit of her legs hanging over its end, and thus rendering the abdominal walls more tense, I first made an exploratory incision a little below the umbilicus; a few careful strokes of the scalpel quickly laid open the peritoneal cavity sufficiently to allow of the introduction of the finger, which soon assured me of the non-existence of adhesions at that part. With a bistoury the incision was then enlarged to about three and a half or four inches; the blue cyst of the tumor immediately advanced, closing up the abdominal opening, and thus preventing the entrance into that cavity of the blood escaping from a few divided vessels. A few minutes were occupied in arresting the little hæmorrhage, during which it was observed that the position of the tumor was changed at each respiratory movement of the diaphragm, affording satisfactory evidence of the absence of extensive adhesions. The cyst was next seized with a pronged forceps, constructed to grasp without contusing, an incision made into it, an elastic tube introduced, and the greater portion of the fluid contents evacuated. At each inspiration the cyst became protruded, and continued to escape until retarded for a moment by two very slight adhesions, which separated without difficulty, and the great bulk of the tumor was soon lying on the outside of the abdomen. The left hand was then introduced for the pur-

pose of examining the pedicle, which, though thick from the increased development of the broad ligament, was quite free from morbid attachments to the viscera of the pelvis. The uterus was drawn as high up towards the incision as possible, without producing pain, and a strong curved needle, fixed in a handle, and carrying a very stout silken ligature, was passed through the centre of the pedicle, then withdrawn, and the ligature tied on either side. A third ligature of equal strength was also made to encircle the entire stalk, just below the insertion of the other two. Much pain was now complained of, and some tendency to faint: relief to the latter was quickly afforded by pressing upon the lower part of the chest and scrobiculus cordis, thus giving to the diaphragm a substituted support for the loss of that previously afforded by the tumor. The broad ligament was next divided by a probe-pointed knife; a second application of which cut through the fallopian tube, leaving not more than half an inch of the latter attached to the uterus. All the vessels being now seen to be secure, the uterus was replaced in its proper position, and the ends of the ligatures left hanging out from the lower margin of the incision. Before closing the wound I examined the opposite (left) ovary, which appeared healthy. The lips of the incision were then brought together by a few interrupted sutures, cold water dressing applied, and a flannel bandage lightly drawn around the abdomen.

Shortly after the operation she complained much of lumbar pain, and became faint; the pulse ranged at 80: she was placed in a more comfortable position in bed; a little brandy and water given her, and a flannel roller tightly drawn around the lower part of the chest, with marked relief to the faintness; and was then ordered—

R. Morphine Acetatis, gr. ss.; Aquæ Flor. Aurant. ʒss. Fiat haustus statim sumendus. All food strictly prohibited; allowed a little rough ice and cold water occasionally.

11 P.M.—Has slept a little; the pain in the back continues undiminished; has twice vomited; heat of skin increased; pulse 88, sharper; a little bleeding has taken place from the wound.

Repetatur haustus.

27th, 2 A.M.—Vomiting has recurred, but is now restrained by the ice, which she takes freely; has slept for three hours; skin perspiring; pulse 92.

5 A.M.—Complaining much of pain at the lower part of the abdomen; ʒxij. of high-coloured turbid urine drawn off by the catheter. On looking to the wound I found that the effort of vomiting, together with a rather frequent cough, had displaced one of the sutures, and a large fold of intestine had escaped through the opening and was lying on the abdomen; it presented no appearance of congestion, and had certainly not been long protruded: some little trouble attended its reduction, after which two additional sutures were introduced, and the cold water dressing re-applied.

9 A.M.—Cough troublesome; slight pain about the wound; pulse 92; is anxious for food.

R. Syr. Papav. ʒss.; Ox. Scillæ, ʒij.; Aquæ, ʒx. M. Sumat cochleare min. p. r. n. Continue the use of the ice and cold water, and to be allowed two ounces of thin water gruel.

1 P.M.—Is sleeping; skin moist; pulse the same.

10 P.M.—Heat of skin increased, and pulse accelerated, probably from having been awakened by an accidental noise; ʒxij. of urine drawn off by catheter; no local pain; is inclined to sleep.

28th, 2 P.M.—Slept well during the night; coughs less often; skin moist; pulse 102; ʒviiij. of urine withdrawn by catheter; wishes for food.

Allowed a cup of tea and a small rusk; to persist in the use of the ice.

8 P.M.—Pain in the loins returned this evening, but ceased about an hour ago, when the catamenia appeared; bowels have been once relieved without medicine; is cheerful, and begs for an improved diet; her request is not granted, but having become tired of the ice, toast and water is substituted.

29th.—In the middle of the night was suffering much from pain in the hypogastrium, which subsided on withdrawing about ʒxij. of urine by the catheter; the pulse is 96; catamenia still present.

Allowed a cup of arrow-root with water.

30th.—Much improved, being altogether free from uneasiness; has passed urine naturally; skin and tongue as in

health; pulse 84; menstruation has ceased.

Vespere.—Not so well; complaining of frequent tenesmus; impeded respiration from flatulent distension of the abdomen; pulse 96.

℞ Pil. Rhæi • Co. gr. viij.; Pil. Hydrarg. gr. iss.; Olei Cassiæ, ℥j. Fiant pilulæ duæ statim sumendæ.

July 1st.—Found her much depressed in spirits; suffering from frequent syncope, but no local symptoms; urine 3xij. passed in two portions, once naturally, and once by the aid of the catheter; bowels freely relieved; pulse 100.

Allowed a little veal broth and vermicelli.

2d.—Was summoned to her in the night, at which time she presented the following symptoms. Severe pain at the epigastric and left hypochondriac regions, increased by pressure; respiration hurried; countenance anxious; pulse 110, small and irritable; tongue white; surface of the lower extremities cold; percussion in the painful abdominal regions indicated much flatulent distension, and flatus could be heard traversing the intestinal canal. On inquiring, I with great difficulty ascertained that one of her relatives had most injudiciously informed her of some domestic infelicity, and which had been immediately followed by the symptoms described.

Small quantities of brandy, diluted with hot water, at frequent intervals.

In about an hour heat was diffused over the body; pain was somewhat lessened. She was then ordered—

Morphiæ Acetatis, gr. iss. statim in formâ pilulæ.

After the lapse of half an hour the opiate began to exert its influence; the pulse fell to 96, she was soon sleeping, and did not awake for seven hours, when she expressed herself as quite free from all her former symptoms, and had forgotten the unpleasing intelligence which had been so indiscreetly communicated to her.

3d.—Improving; pulse 96; urine passed naturally; bowels not open. To be allowed a small quantity of boiled rabbit for dinner.

℞ Potas. Tart. ʒij.; Rhei Pulv. gr. viij.; Tinct. Card. Co. 3ss.; Syr. Zinzib. 3iss.; Aquæ, ʒj. Ft. haustus cras mane sumendus.

5th.—Bowels open four times; pulse 96; is progressing favourably.

6th.—Complaining of a little irritation about the bladder, with difficulty in micturition; the urine is turbid from the presence of urate of ammonia, and also contains a rather large quantity of free uric acid; pulse 100.

Liquor. Potas. Efferves. Oss. ter quotidie.

8th.—Is free from vesical irritation; urine natural; sleeps well; spirits excellent; pulse 78. For the last two days she has been sitting up in her bed, amusing herself with needle-work. The bowels not having acted during the last three days, she is ordered to repeat the aperient pills formerly given.

9th.—The bowels have thrice acted; appetite good; pulse 78; has sat up whilst taking her food, which, during the last six days, has consisted of one mutton chop, an egg, rice pudding, tea, and a biscuit, daily, divided into four meals. The greater part of the wound has quite healed; a few small granulations have sprung up around the lower edge of the incision, through which the ligatures, still firmly attached, pass. During the first four days after the operation the temperature of the room was kept at 75°, after which it was lowered to 70°, and now averages at 65°.

31st.—During the three weeks that have now elapsed since the date of the last report, nothing has occurred to retard the rapid convalescence of the patient. One of the ligatures came away some days since, the others yesterday. The wound has quite healed, excepting at the lower end, where a few redundant granulations exist. She is in excellent health and spirits, has for some days been actively employed, keeping her room from precaution, not necessity. The bowels act with regularity, and she expresses herself as being in better health than for many years past.

The dimensions of the abdomen prior to the operation, and at the present time, are the following:—

	Before operation.	After operation.
From ensiform cartilage to pubes 18 inches	11 inches.
Circumference of abdomen 37 inches	24½ inches.

A small portion of the tumor only presented a solid structure, in size not exceeding that of an orange, and appeared to consist of the remaining portion of the ovary not involved in the formation of the cyst. The fluid contents amounted to about two gallons, having an unusually low specific gravity, 1.004, quite colourless, scarcely viscid, and differed from the fluid commonly secreted in this disease in being quite neutral: examined by my brother, Dr. Golding Bird, it was found to consist of—

Animal Extract	}	40
Alkaline Lactates		
Chloride of Sodium		
Water		960
Albumen		a trace.
		<hr/>
		1000

The shape of the cyst when filled was irregularly spherical, and did not at all partake of the balloon-like form frequently observed; from its depending portion a secondary cyst arose, which appeared to have been moulded to the shape of the cavity of the bony pelvis in which it had been placed. The broad ligament measured more than six inches in breadth, and in it passed four arterial branches of rather large size, with some smaller ones, which running along its ovarian attachments terminated by minutely ramifying all over the surface of the diseased mass. The fallopian tube was long, dense in structure, and thickened. Two small patches of roughened and granular membrane, more vividly injected than the surrounding parts, corresponded to the two adhesions observed during the operation. The total weight of the tumor was rather more than 20 pounds.

REMARKS.—The case I have related is illustrative of several important practical points, and also assists in negating some of the objections supposed to attach to the performance of the operation in those who have been previously subjected to tapping. The disease in the present instance, had existed for a long period, and paracentesis had been frequently performed, to which on one occasion succeeded symptoms of inflammation, and as the result would seem to prove, of the cyst; it was therefore inferred that adhesions existed, more particularly at the spot at which the trochar had been introduced; none,

however, were found at that part, and not any of extent or importance elsewhere. The fact of a patient having been previously tapped would, therefore, seem to offer no real objection to the performance of the operation of extirpation, and this being granted, the partial or complete emptying of the cyst may be employed for the purpose of affording an additional means of diagnosis in certain cases in which it is difficult to determine with sufficient accuracy the character of the tumor, or the presence and extent of peritoneal attachments. The diagnosis of adhesions is at all times difficult, and is commonly but little more than conjectural; the introduction of a trochar in doubtful cases, in order to lessen the distension of the abdominal walls, may therefore be received as a method of greatly facilitating an examination, and furnishing new and important data for arriving at a correct opinion. During the first two or three weeks after the last time of tapping it was by no means difficult to grasp the then flaccid abdominal walls, and cause them to glide with freedom over the surface of the ovarian mass; whilst at a later period the distension of the abdomen rendered such examination difficult and uncertain. The very successful termination of the case, is, I believe, in a great measure attributable— Firstly, to the precautions taken to prevent the action of cold air upon the exposed peritoneal surface, by artificially raising the heat of the room in which the operation was performed, and maintaining a high temperature so long as there existed any liability to inflammation. Secondly, to the after treatment, which partook more of a dietetic than medical character, its chief feature consisting in the exclusion as far as possible of all internal remedies, and thus allowing the most complete repose to the organs in the immediate neighbourhood of the wounded parts. A grain of morphia and a little syrup of poppies were the only remedies given during the earlier period after the operation, and the only ingesta consisted of ice, cold water, and a very small quantity of thin water gruel. By these means all sources of irritation were avoided, and thus the chief cause of inflammatory action.

Thirdly, to the form of operation adopted, which I believe to be that presenting all the chances of recovery the extirpation of the ovary is calculated to afford. Hitherto I have but described the steps of the operation, and I would now venture to make a single remark on the cause which induced me apparently to profit so little by the recorded cases of Dr. Clay and Mr. Walne.* It was, however, from their careful perusal, that I was led to arrive at a somewhat different conclusion from that expressed by those gentlemen. The cases of Dr. Clay, and still more his useful practical observations, have sufficiently demonstrated the amount of danger which attends the attempt to perform extraction through a very small opening: the truth of which I saw exemplified in a case that occurred some years ago, in which the failure of the operation and the death of the patient (for failure in these cases seems to amount to death,) were undoubtedly to be attributed to the smallness of the abdominal incision; a secondary cyst of inconsiderable size having formed the obstacle, and which could readily have been removed by a somewhat more capacious opening.

Whilst thus according in the disadvantages said to attach to the small abdominal incision, I cannot but believe that important objections apply with equal justice to the very large section, the chief of which undoubtedly is the question of necessity. Is an incision from pubes to ensiform cartilage, in cases in which the ovarian tumor is wholly or in part fluid, really required? There can, I conceive, be no valid objection to evacuating the liquid contents partially or entirely, and thus causing so great a reduction of bulk as to allow of the removal of the ovary through an opening of less size than that constituting the *major* operation; for if an incision be made sufficiently large to admit of the cyst rising from out of the abdominal cavity without any forcible traction—if it also be sufficiently large to allow of the introduction of the hand of the operator into the abdomen, and thus enable him to apply with facility the necessary ligatures, or remove any abnormal attachments to the pelvic viscera—every end is answered, every indication fulfilled, and the

making a large peritoneal section can confer no further benefit to the patient, unless the removal of an unpunctured cyst can be deemed such. It may be urged that a large incision into the peritoneum is less likely to be followed by inflammation than a smaller one, and this I am by no means disposed to deny; but were it proved, it would still be very questionable whether an operator would be justified in making an unnecessarily large incision solely with a view of enhancing the probabilities of ultimate success. I would not, however, dissent from the employment of a larger incision in cases in which the partially solid state of the tumor might prevent its sufficient reduction by puncture, but from the cases I have seen I am inclined to believe that it rarely happens that an ovarian tumor will not be found to be in part fluid, and therefore capable of being lessened in size by the introduction of the trochar. Many important points remain to be determined with regard to the relative value of the operation, and the number of cases yet recorded have not been sufficient to decide whether the chances of success exceed the chances of the occurrence of disease in the remaining organ. The observations of Mr. B. Phillips,* tend to turn the scale of probabilities against the ultimate safety of the patient, and to show that disease in a less developed form commonly exists in the opposite ovary. This, together with some other points in the pathology of ovarian disease, I purpose, when my inquiries shall have been completed, making the subject of a future communication.

38, Craven Street.

PAINLESSNESS OF MORTAL WOUNDS.

To the Editor of the Medical Gazette.

SIR,

THE extract from the *Gazette Médicale* which appeared in your last number, detailing the case of a man who died from the effects of an extensive injury, without suffering pain, recalls to my recollection a similar instance which occurred some years ago at a public institution in Berkshire. A decrepit old woman was admitted into the wards

* Vide MEDICAL GAZETTE: the cases of Dr. Clay are contained in another journal.

* Vide MEDICAL GAZETTE.

of the Wallingford Union Poor-house, and soon after her admission, by some accident, her clothes caught fire, and, before assistance could be rendered, were almost consumed. The bed, also, upon which she threw herself in the agony and fright of the moment, was set on fire.

On examination, it was found that the poor creature was mortally injured, the vitality and organization of large portions of the cutis in various parts of the body having been so deeply destroyed as almost to lay bare the subjacent muscles.

In consequence of this sudden and extensive violence, no reaction ever occurred, nor the slightest hæmorrhage; the mental faculties were unimpaired; and in about sixteen hours from the receipt of the injury she died from sheer exhaustion, occasioned by the irrecoverable shock the nervous system had sustained. She declared with her latest breath, that from first to last she had been *totally free from pain*.—I am, sir,

Your obedient servant,

R. H. ALLNATT.

Parliament Street, Whitehall.

OBSERVATIONS ON SOME OF THE MORE IMPORTANT DISEASES OF CHILDHOOD.

By CHARLES WEST, M.D.

Member of the Royal College of Physicians;
Physician to the Royal Infirmary for Children;
and Physician-Accoucheur to the Finsbury
Dispensary.

(For the Medical Gazette.)

I.—On Endocarditis in Childhood.

INFLAMMATION of the lining membrane of the heart is an affection of which no notice is taken in any treatise on the diseases of children, with the exception of the recent work of MM. Rilliet and Barthez. Incidental mention of its occurrence as a complication of scarlatina is made by Professor v. Ammon, in his account of a malignant epidemic of that disease at Dresden in the year 1832*. Dr. Copland devotes a few lines to it in his Dictionary, and speaks of its occasional occurrence as an idiopathic affection. Some of the French journals contain observations on hyper-

trophy of the heart and diseases of the valves in childhood, but I believe that none of the writers allude to acute idiopathic endocarditis in the young subject.

The cases of acute endocarditis mentioned by MM. Rilliet and Barthez are three in number. In one of these cases the heart symptoms came on in the course of an attack of acute rheumatism; in the second slight febrile symptoms coexisted with a distinct *bruit de soufflet* and some pain at the heart; and in the third the auscultatory signs only were present, unattended either by fever or by pain in the precordial region. They do not, however, detail the particulars of any of these cases. They met likewise, in the course of their observation at the Hôpital des Enfants Malades, with thirteen cases of chronic organic lesions of the heart of various kinds; and they relate the history of one of these cases in which acute endocarditis supervened on chronic valvular disease, and destroyed the patient.

My attention was first called to this affection in the spring of 1841, when I saw

Margaret Thomas, aged 3 years and 4 months, living at 86, Union Street, Lambeth Walk.

She is the delicate child of a phthisical mother, but her health was good till within the past year, since which time she has had two attacks of convulsions, and her general health has seemed less good.

She was, however, as well as usual until a few days before she came to me, when she was attacked by slight febrile symptoms, complained of great uneasiness, could get no rest at night, and began to suffer much from shortness of breath and palpitation of the heart; symptoms which have continued up to the present time.

A very loud *bruit de soufflet* accompanies and overpowers the first sound of the heart. It is heard both at the apex and at the base, but loudest in the latter situation, and is continued into the aorta. The second sound is clear. The heart's impulse is increased, and its sounds are heard over the whole chest, both before and behind.

Unfortunately I have preserved no record of the daily progress of the child, who recovered from her more urgent symptoms under an antiphlogistic plan of treatment. The bruit, however, continued, and the child remained short-

* *Analekten ueber Kinderkrankheiten*, 11tes Heft. Seite 42.

breathed and liable to occasional returns of palpitation, which subsided on strict quiet being enforced and a mild antiphlogistic plan being pursued. I saw her last in May 1842, when the signs indicative of valvular disease continued unmodified.

Now, although in this case the patient was not seen at the very commencement of her attack, yet there does not appear to me to be any reason for supposing that the affection of her heart dated further back than the few days previous to her being brought to me, when she first complained of dyspnoea and palpitation of the heart. The following case was probably one in which acute endocarditis supervened on some chronic lesion of the heart.

George Cole, 43, Easton Street, Spa Fields, aged 5 years and 2 months, one of seven children, of whom five are still living, but one died while teething, and one of small-pox.

His father is strong and healthy; his mother is not strong, and phthisis is hereditary in her family, though she has never shown any symptoms of it.

George has usually had good health, except two years ago, when he was taken ill with symptoms similar to those from which he is at present suffering, and did not recover for some weeks. He has not had any of the usual diseases of childhood.

For some months he has had a slight cough, but was in other respects in good health, when he was attacked on February 13, 1843, with fever, thirst, and swelling, first of the face, afterwards of the limbs, and on the 14th his heart began to beat much, and whenever he attempted to lie down in bed so much dyspnoea came on as compelled him to resume the sitting posture.

On February 17th he was brought to me at the Finsbury Dispensary, when I ordered three leeches to the heart, a purgative every night to relieve his bowels, which were constipated, and a saline mixture, with six minims of tincture of digitalis, every four hours.

February 21.—The leeches greatly relieved his palpitation, though he still has considerable difficulty in assuming the recumbent posture. The anasarca was completely disappeared, and he makes water more freely than before, though his urine is still scanty, high coloured, abounding in the lithates, and loaded with albumen. He has a trouble-

some cough, unattended with expectoration, no appetite, considerable thirst, a dry harsh skin; bowels open, tongue pale and moist. The pulsation of his carotids is very evident; pulse 70, hard, thrilling, unequal in force about every fourth beat, but not irregular in rhythm.

On auscultating the chest a good deal of rhonchus and creaking sounds are heard, but the air seems to enter both lungs equally well.

The apex of the heart beats lower down, and more to the left of the nipple, than natural, and there is also extensive dulness over the heart. Its sounds are not clear, but have a muffled character, and a harsh bruit accompanies the first sound, and is heard most distinctly about half an inch below and a little to the left of the nipple, but is not continued into the aorta.

The digitalis was now discontinued, and a saline mixture, with small doses of tartar emetic, was given in its stead.

24th.—Breath less laboured; child can lie down more easily, and the palpitation is less troublesome. The medicine has caused much sickness; the urine continues scanty, high-coloured, and albuminous, and the inequality in the beats of the pulse, and the bruit with the first sound, remain as before.

The antimony was now discontinued, and small doses of liquor potassæ were given instead. The boy improved daily, and the note of March 10 is—Child very much improved; can now lie down easily; has but very slight difficulty in breathing; very little cough, and no palpitation. The bowels act regularly. The urine is abundant, natural, and free from albumen.

Pulse 100, the same inequality in its strength, and sometimes a distinct pause about every fourth beat. The action of the heart is not exaggerated, and there is no longer any bruit, but merely a roughness accompanying the first sound, and heard only near the apex.

The boy was soon afterwards discharged.

I observed a third case only a few months since.

Daniel Bain, aged 11 years, living at No. 37, Thomas Street, Stamford Street; is one of 12 children of healthy parents. Nine children are still living, one died while teething, one of scarlatina, and one of pneumonia. There does

not appear to be any phthisical taint in the family.

Daniel has had good health, with the exception of mild attacks of measles, hooping-cough, and scarlet-fever; and was as well as usual until May 8, 1843, when he complained of feeling cold, and began to cough. The chilliness was succeeded by fever, and he continued gradually getting worse till the 13th, when I visited him for the first time. He had had no other medicine than a purgative powder.

May 13th.—I found him lying in bed; face dusky, rather anxious; eyes heavy; respiration slightly accelerated; frequent short cough without expectoration; skin burning hot; pulse frequent and hard. The child makes no complaint except of slight uneasiness about the left breast.

There is slight tenderness on pressure over the heart, with very extended dulness. The heart's impulse is not increased. A very loud and prolonged rasping sound is heard in the place of the first sound; it is loudest a little below the nipple, though very audible over the whole left side of the chest, and also distinguishable, though less clearly, for a considerable distance to the right of the sternum. Second sound heard clearly just over the aortic valves, not distinct elsewhere, being obscured by the loudness of the bruit.

Respiration good in both lungs.

I ordered the child to be cupped to $\mathfrak{z}\mathfrak{v}\mathfrak{j}$. between the left scapula and the spine; and gave gr. j. of calomel, with the same quantity of Dover's powder, every four hours.

May 14th.—Sense of discomfort at the chest relieved by the cupping. He slept well during the night, and to-day looks less anxious, though his eyes are still heavy and suffused; the skin is less hot and less dusky; pulse 114, thrilling, but not full; tongue moister than yesterday, red in the centre, coated with yellow fur at the edges; has had one copious watery evacuation; slight prominence of the cardiac region. The heart's sounds are obscurer and more distant than yesterday; the bruit of yesterday is now manifestly a friction sound, which is louder at the base than at the apex of the heart; the first sound is altogether obscured by it, and the second is heard only over the aortic valves.

The child has had four powders. To

continue taking them every six hours.
3j. of strong mercurial ointment to be rubbed into the thighs every six hours.
Six leeches to be applied over the heart.

15th.—There was considerable difficulty in stopping the bleeding from the leech-bites, which was so profuse as to make him rather faint. He slept tolerably during the night, and until 6 A.M., when he became light-headed, and continued so until 9 o'clock this morning, but has since lain quiet, though troubled by a dry cough.

His appearance is much as yesterday; skin dry and hot; pulse 120, possessing the same character as before, but with less power; tongue coated at the edges, with a dry, red, streak in the centre; bowels open twice, motions green and watery.

Auscultation yields the same results as yesterday. Same treatment continued, with the addition of a saline draught containing small doses of the liquor antimonialis every four hours.

16th.—General condition much as yesterday, but on the whole seems slightly improved; pulse 120, softer.

The friction sound is no longer audible, but a loud rasping sound is heard in the place of the first sound. The second sound can now be distinguished at the apex of the heart as well as over the aortic valves, and is quite natural.

On the 17th the gums were slightly affected by mercury, and the bruit was thought to be softer and rather less loud. The dose of calomel was now reduced to gr. ss. every four hours, and the child was allowed a little broth.

On the 22d his mouth was very sore, and all active treatment was discontinued on that day. The child gradually regained his strength, but the bruit accompanying the first sound continued, and was heard a month afterwards with no other change than being rather softer and more prolonged.

I have notes of another case, in which a very loud *bruit de soufflet* accompanied the first sound of the heart, and was heard with greatest intensity below and somewhat to the left of the nipple. In this instance the disease was probably of long standing, since the heart's impulse was considerably increased, its apex beat considerably lower than natural, and there was extended dulness in the precordial region. While the boy was under my care, his parents removed

from London, and I consequently lost sight of him.

The results of endocarditis appear to be, in the child as in the adult, either very distressing or comparatively slight, according as it is succeeded or not by hypertrophy and dilatation of the heart. It has seldom occurred to me to witness greater suffering than in the case of—

Anne Leach, aged 10 years, living at 50, Turnmill Street, Clerkenwell, who first came under my notice in March 1842. She was one of five children of healthy parents, but her own health had always been delicate. For the last year she had been growing thinner, and had suffered from palpitation of the heart, and for three months had had cough; but I could not ascertain that any very marked febrile attack had ushered in her illness. Her parents, however, belonged to that class of poor who seldom pay much attention to their children's ailments.

When brought to me she was greatly emaciated; her face was anxious and distressed, her breath short, so that it was with difficulty that she walked even a short distance; she had frequent short cough without expectoration, and she suffered much from palpitation of the heart and a sense of discomfort at the chest.

The heart's action was violent; dullness in the præcordial region was very extended; a very loud, harsh, rasping sound accompanied the first sound of the heart, loudest towards the apex and to the left of the nipple, but heard over nearly the whole of the chest, both before and behind.

Various remedies brought slight but temporary relief to her sufferings, and she grew worse every month. She became more and more emaciated; the distress at the chest and the palpitation of the heart increased, her cough became more violent, and once she had an attack of hæmoptysis. For about a month before her death the cough altogether ceased, but she was now unable to leave her bed, from increasing weakness; the palpitation continued unmitigated, and her extremities became slightly anasarcaous. During the last week of her life her respiration was extremely difficult, and became increasingly so till she died, on October 10th, 1842.

On a post-mortem examination, made thirty-six hours after death,—

Very little fluid was found in either pleura; both lungs were very emphysematous, and much congested, but neither they nor the bronchial glands contained any tubercle.

The heart was extremely large, but its right cavities did not exceed the natural size; the pulmonary valves were healthy; the edges of the tricuspid valve were slightly thickened; the left auricle was enormously dilated, but its walls were not at all attenuated; the pulmonary veins were much dilated; the left ventricle was dilated, and its walls were thickened; the chordæ tendineæ of the mitral valve were greatly shortened, so that the valve could not close; the valve itself was shrunk, thickened, and cartilaginous; and there existed likewise slight thickening of the edges of the semilunar valves of the aorta.

The other organs were healthy, except the mesenteric glands, many of which contained tubercles, which, in several, had undergone the cretaceous transformation.

In another somewhat similar case general dropsy came on, and the patient died of ascites and hydrothorax. In this instance, however, though the mitral valve was diseased, and dilatation, with hypertrophy of the left auricle and ventricle, existed, yet the symptoms, though greatly aggravated by the valvular disease, could not be altogether attributed to it. There existed in this case that narrowness of the aorta to which Meckel and Andral have called attention as a congenital malformation, occasionally giving rise to hypertrophy of the heart. It was not, however, till six months before the death of the child—a girl aged ten years—that her health was perceptibly affected, but she then began to suffer from palpitation of the heart, which at first was attended with febrile symptoms, afterwards with phenomena similar to those which occurred in the case of Leach, and which were terminated, as already mentioned, by ascites and hydrothorax.

In a third case I found the chordæ tendineæ much shortened, so as to keep the valve permanently open; and the valve was opaque, thickened so as to resemble cartilage, and presented a puckered appearance as if shrunk by the action of boiling water. The patient was a phthisical boy, five years

old, in whom no symptom or physical sign of disease of the heart existed till five months before his death, when he had an attack of inflammation of the left pleura, terminating in effusion into its cavity. A loud *bruit de soufflet* accompanying the first sound then became audible, and continued so till his death; but the general indications of cardiac disease were masked by the graver phenomena which attended the pleurisy and the extension of the tubercular disorganization of the lungs.

These cases, which are all that have at present come under my notice, are, I think, sufficient to shew that inflammation of the lining membrane of the heart does occasionally occur in children as an idiopathic affection, and wholly independent of rheumatism. It has so happened, indeed, that though I have had the opportunity of observing the diseases of above 5000 children at the Children's Infirmary, since May 1839, I have met with but one case of affection of the heart occurring in the course of rheumatism. This circumstance, however, I regard as merely accidental, and do not by any means infer that idiopathic endocarditis is more frequent in children than endocarditis as a result of rheumatism. I could not connect the occurrence of endocarditis with any attack of scarlatina, though I directed my inquiries particularly to that point; nor in any of the post-mortem examinations of children who died of dropsy after scarlatina during the epidemic of 1839, did I notice any indication of inflammation of the endocardium, though Von Ammon's observations prove the occasional connection of the two diseases. It is, perhaps, worthy of note that tubercle was present in some of the internal organs in all the three fatal cases, though extensive tubercular disorganization of the lungs existed only in one instance. The mother of M. Thomas was affected with phthisis at the time when she brought her child to me; phthisis was hereditary in the family of G. Cole, and the boy himself presented all the peculiarities of the strumous habit in a very marked degree.

The disease does not appear to be one which tends to an immediately fatal issue, though its sequelæ in the child as well as in the adult are often very distressing, and greatly shorten

life. Its early diagnosis is, therefore, a matter of considerable importance. It does not seem to be always announced by very striking symptoms, but a febrile attack of no great intensity, accompanied by increase of the heart's action, are often the only heralds of its onset. Since, then a disease so grave may commence with such comparatively trivial symptoms, it is a matter of great practical moment never to omit auscultating the heart, even in a case of what may seem to be merely a mild attack of simple fever.

I have nothing to add with reference to the treatment, since there does not appear to be any reason for deviating from that plan which would be proper in the adult. I regret, however, that in some of the cases above related I did not adopt more energetic measures than those to which I resorted.

AN INSTANCE
OF THE
LOSS OF IRRITABILITY IN THE
GLOTTIS FOLLOWING A WOUND
IN THE THROAT.

To the Editor of the Medical Gazette.

SIR,

If you should deem the accompanying communication worthy of your notice, please to insert it in the GAZETTE.

I am, sir,

Your obedient servant,
WILLIAM PRETTY,
Surgeon.

Camden Town, July 28th, 1843.

An old man, in a fit of despondency, attempted self-destruction by cutting his throat with a razor. The loss of blood was small; the wound was jagged, and of considerable size in front; respiration was carried on partly through it, and the voice was reduced to a mere whisper. Inflammation and suppuration of the wounded parts supervened, attended with fever and cerebral affection, and the patient died about the eighth or tenth day. During my attendance, I was much surprised to find that fluids introduced into the mouth passed freely out of the wound, sometimes attended with, and sometimes without, a moderate fit of coughing. This circumstance led me to suspect that the œsophagus was injured, though it did not appear so upon external examina-

tion. I believe that the passage of fluids from the mouth through a wound in the throat has usually been considered as a distinguishing sign of an opening having been effected in the œsophagus: upon examination after death the œsophagus here was found uninjured. I have not seen, in any former or subsequent case, the same fact, though it may have been observed by others. The sensibility of the glottis and the power of swallowing is remarkably continued in some cases of disease, when all other parts have seemed to have lost their irritability. I witnessed lately in a case of fever which proved fatal after forty-eight hours of insensibility, accompanied with perfect relaxation of the sphincter muscles of the bladder and rectum, a capability to swallow fluid jelly, and to cough when any small portion got into the glottis, till within one hour of dissolution taking place.

The few particulars of this case of cut-throat I have written from memory, my case-book not being at hand. I cannot give the precise situation and extent of the injury, but believe the wound was inflicted at the inferior margin of the thyroid cartilage, the glottis and epiglottis escaping injury; neither can I positively say that the facts of impaired deglutition, great loss of sensibility in the glottis, and the passage of fluids through it without producing great inconvenience, did immediately follow the receipt of the injury, but of this I am certain, that soon after, and till within a few hours of death occurring, air in respiration, and fluids attempted to be taken by the mouth, passed freely through the wound in the trachea. I allude here particularly to *time*, as being, perhaps, one way, as well as the nature of the particular parts injured, of accounting for the little opposition which this case offers to the conclusions fairly drawn by Mr. Erichsen in his experiments upon the trachea of the dog, and inserted in the *MEDICAL GAZETTE* of July 14th last, and which I have read with much satisfaction and interest. I have thought that this case might not be disadvantageously connected with these experiments.

THE LATE SIR C. NIGHTINGALE'S CASE.

To the Editor of the Medical Gazette.

SIR,

I BEG to send you a few additional observations upon the symptoms which attended the illness of the late Sir Charles Nightingale.—I am, sir,

Your obedient servant,

EDWIN LAMBERT.

Park Street, Bath, Aug. 13, 1843.

The mucous secretion, which was a prominent symptom in the late Sir C. Nightingale's case, appears to have arisen from irritation communicated to the solar plexus of nerves which ministers to the circulation and secretions of the stomach, whilst the constant vomiting and panting indicated a similar condition of that portion of the spinal cord from which the pneumogastric and phrenic nerves take their origin.

We cannot fail to be struck with the fact that not the slightest vestige of disease was discoverable in the pyloric orifice or mucous membrane of the stomach, which "was unusually pale," and this profuse secretion generated (not the acid of cardialgia, or alkaline secretion of pyrosis) without any evident cause existing in the organ itself. Can it, then, be attributed to any other cause than that of irritation propagated by nervous sympathy?

The icy coldness of the hands, which denoted that one portion of the spinal marrow had lost the power of transmitting heat, whilst it continued to exercise a very feeble influence over the circulating powers, and the consequent secretion, exhalation, and congestion, which the *post-mortem* examination so manifestly displayed, constitute a train of phenomena which can only be explained by the assumption of an irritant poison acting upon the nervous and circulating systems.

I will now mention another symptom of spinal irritation, omitted in my previous narrative, which presented itself a few hours before death, and although not observed by myself, was communicated to me by Mr. Thomas Nightingale, the son, who was with his father a short time before his dissolu-

tion; viz. the continual drawing up of the legs, which evidently proceeded from spasmodic contraction of the flexor muscles. It must be quite obvious to the pathological observer, that neither the partial disorganization of the liver (its nature is not described) or "Bright's disease" of the kidney were sufficient to destroy life, and as no other viscera are said to be organically diseased, we can only account for death by violence inflicted on the spinal marrow and circulation, through the agency of some deleterious ingredient. There were no appearances of the slightest tendency to hæmorrhage from the bowels during any stage of the disorder, but he complained of much irritation about the rectum. I saw one alvine evacuation on the Friday, of a perfectly healthy consistence, but of a dark colour; its discolouration, however, was not owing to the presence of blood; probably to extraneous matter.

I have now, in conclusion, to thank you, sir, for the space you have afforded me in your *GAZETTE* for the foregoing observations. The threats and annoyance which I have experienced, and the abuse with which I have been assailed, because I have come forward in the cause of truth and justice, have urged me on, upon this as it would upon any future occasion, with more resolute energy, to promote investigation, and to pursue that straightforward course, which, for the sake of my own character, as well as for the honour of the profession to which I belong, I am determined never to depart from.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

BATHING.

THERE is, perhaps, no subject bearing on public health which requires more unceasing efforts on the part of the journalist, than the personal habits of the working classes. Efforts for their

improvement, to be really efficacious, require not merely that the facts of the case be stated, but that the best means of applying the required remedies be accurately conceived and pointed out: the understanding may be convinced long before prejudice and apathy are removed. Prejudice and apathy are mentioned together, for they are apt to exist at the same time, though they are found in very different classes of persons, and the eager philanthropist too often finds that after he has succeeded in convincing the prejudiced, his benevolent schemes are still more provokingly thwarted by his converts gradually falling into the ranks of the indifferent; so that those on whom he counted as able coadjutors, if he could once remove their prejudices, afterwards disappoint him by their indifference, and require the exertion of all his energies to give them a fresh impetus in the right direction.

It is surely not too much to assert that a prejudice has existed in England against bathing. This assertion may surprise those who are thoroughly acquainted with the many and powerful arguments which have lately been used by popular writers to prove its value; but it will not surprise those who remember the manner in which it was spoken of in their youth and boyhood, or, what may have made less impression, the silence maintained on the subject by those in authority. It was spoken of as a boyish pastime of more than usual danger, and on that account either almost prohibited altogether by the sterner sort; connived at, but not recognised, by the more indulgent; or invested with so many perils, and fenced round with so many cautions, as to form quite a memorable exception to the sports which were permitted or encouraged. The most expert swimmers in our younger days, we remember to have been also cunning in devices for con-

cealing all traces of their prowess ; and boys who, for "headers," and deep divings, had been the envy of their comrades, became equally notorious for fishing up plausible excuses to account for lank hair and a wet pocket - handkerchief. But this is changed ; professorships of swimming have been established at Eton, and prizes are annually swum for in the Serpentine river, by the members of a swimming society and their pupils, "apparent rari nantes in gurgite vasto;" and so far as cold bathing goes, matters are improving. For this progress we are much indebted to the Messrs. Chambers of Edinburgh, to the conductors of the Penny Magazine, and other directors of the public taste. The publications intended for the working classes, it will be observed, are in reality chiefly bought and read by those much above them ; a very small proportion indeed, of those to whom they were professedly addressed, being yet in a condition to purchase them for want of means, or to benefit by them for want of education. The removal of nearly all social prejudices is effected from above downwards, and that against cold bathing is no exception to the general rule. It must not be imagined that the downward progress of common sense on this subject, through the middling classes, has been an easy matter, or that it has taken place as yet to any great extent. Indeed, as an occasional plunge into cold water is one of the natural occurrences of field labour, and even one of the instincts of human nature, whatever prejudices may exist against it must have been artificially inculcated ; and we do find such, accordingly, stronger and more universal in the middle than in the lowest ranks of life—in cities than in the country—while amongst philosophers and savages it exists not at all. Between these two extremes, of human wisdom on the one

hand, and human ignorance on the other, all manner of half wisdoms and unwisdoms, of appetites, passions, and self-denials, of convictions and prejudices, jostle one another in contending for partial and temporary dominion over the mind and the habits of man.

It is true, in fact, that many dangers beset civilized man when he yields to his natural instinct for cold immersion ; and there is little doubt that from the gradual observation of these has been compiled a commination against cold bathing in general, which, however wise and well meaning in its origin, has been repeated in the ears of the vulgar till it has caused more evils than it averted. In composing this, the professors of physic have doubtless had their share ; and as they have borne their part at all times in pointing out what was good for mankind, and what was evil, to the best of their knowledge, so it has happened that, as this knowledge happened to be founded on more or less accurate bases, it must have varied in value with the justness of the prevailing theories. But in our day medical men are not generally alarmists on the subject of cold bathing ; their tendency is perhaps the other way ; and there is reason to fear that Priessnitz and Father Mathew have indirectly excited an indiscriminating fanaticism in favour of cold water amongst those who should not have been led, in any curative or hygienic doctrine, beyond eclectic sobriety.

The hot bath in this country is seldom meddled with by the lower orders, but, like parturition, has been surrounded with so many real and imaginary dangers as not to be undergone without the advice and assistance of the faculty ; and we should be sorry to say any thing which should lead our compatriots, in their present artificial state of life, to consider the doing without us in either case other than as

a piece of hazardous eccentricity, which, though occasionally indulged in with impunity, is not often to be attempted. Healthy people may of course do many things without immediate, or even distant, ill consequences, which would be fatal to invalids; but a knowledge of the powers of the hot bath for good and for evil is far from universal even amongst ourselves; and as for the laity, it is certain they often do mischief by its imprudent use. We are, perhaps, from the little knowledge we possess, too timid; those who are quite ignorant, if fond of the hot bath as a remedy or a luxury, too careless—"fools rush in where angels fear to tread." Of one thing we may be quite sure, that by inculcating systematically and repeatedly the habit of cold ablution as a rule, we shall do great good in the middling and lower classes of society—we shall gradually acquire a knowledge of those cases in which it is prejudicial, or where more than ordinary caution is required in its use; and we shall prepare the way for total immersion whenever such a practice shall have become desired by the "million," and rendered practicable and easy for their adoption. At present, it is neither the one nor the other, but is becoming more so, if we may judge from certain symptoms lately observed. These are a manifest increase in the number of baths in the metropolis, a lowering of the prices, so that a tepid "mechanic's bath," as it is called, may be procured in Holborn for fourpence; and lastly, the swimming schools alluded to above. It would be a good plan for those who think bathing important, to provide themselves with a few bath tickets, which may be procured at a reduction on the price of a single bath, and distribute them judiciously amongst the working classes, to whom they are an acceptable present. A bath might often be recommended as a prophylactic to

other members of a family when it would not be ventured on, or could not be taken by a patient. One caution is especially needful; experience has abundantly proved that a cold bath in a cold place is seldom followed by comfortable sensations. We should be careful, therefore, to warn inexperienced bathers on this head, as, even if health be not thereby injured, a disagreeable impression of the bath is acquired, and the habit of bathing rendered less likely to be acquired. One reason why the higher classes are so beneficially addicted to cold ablution, even throughout the winter, is that they are careful, in cold weather, to take their bath in a warm room, or to dry the body near a fire; the chill is therefore confined to the time of immersion, and the reaction is immediate and complete.

The judicious remarks on the subject of bathing by that veteran advocate of ablution, Dr. James Johnson, can never be read without pleasure by those who are impressed with the importance of this subject. The Doctor's enthusiasm, while in fancy sporting with the nymphs, is quite refreshing; and it need hardly be said that personal experience will form the strongest recommendation, one which no gentleman, and therefore, it may be hoped, no medical practitioner of this day can be without. We are not all prepared to admit the arguments of the teetotallers, and therefore may decline to practise the abstinence they insist on; but in the copious application of water externally, it would be well to practise what we preach, and to preach it earnestly because we practise it diligently.

The visiter to the Cartoons in Westminster Hall cannot fail to have been pleased with the intelligence and good conduct shown by some of the poorest of his fellow-critics. The hygeist will wish that some clear-headed, keen-

scented legislator, would discover that such men could also appreciate cheap, nay, gratuitous, bathing, if part of the noble river which flows through their capital could be warmed and purified for such a purpose. Would the expense be much greater than that of Dr. Reid's airing apparatus, and would the public benefit be much less? "A question to be asked."

FELLOWES' CLINICAL PRIZE REPORTS.

BY ALFRED J. TAPSON.

University College Hospital, 1842.

[Continued from p. 687.]

CASE XV.—*Hemiplegia et Tubercula Pulmonum.*—*The former treated by cupping, purging, cantharides, &c. with considerable benefit.*

GEORGE P—, æt. 54, admitted May 21, 1842, under Dr. Williams: a man of very moderate conformation and sanguine temperament; is a watchmaker. His habits have been tolerably regular, excepting a great addiction to venery, although he is married and has had 18 children by his wife. His father died of consumption. He has sustained several bodily injuries at different times, which we mention as they may throw some light on the cause of the present diseases: thus, when six years old, he had his skull fractured over the left temple by a blow against a tea-kettle; about fourteen years ago he had a severe blow on the upper and back part of the head, in which situation there is still a swelling, and ever since this he has been subject to headache and occasional giddiness: the pain, he says, was always worse in cold weather, and was increased by stooping: he had a third blow on the head about two years ago by falling backwards. Again, he says that thirty-three years ago he strained his right side by lifting a heavy shutter, and has since frequently had pain in that side. Nine years ago he had an attack of pleurisy, caught by sleeping in damp clothes, and after he recovered his legs and feet used to swell constantly for a short time. Lastly, he says, that some time afterwards, when he awoke one morning, he brought up more than a pint of coagulated blood, of rather a dark colour. The following morning he vomited about half a pint of fluid blood, much brighter in colour, and for several days he continued to spit up small quantities of blood, without having any cough; he had not had any symptoms of gastric or pulmo-

nary disease previously, at least he does not remember any; he was bled, given iced water to drink, and a quantity of medicine, and he soon recovered, but he has ever since been subject to cough in the winter, and in damp weather; slight expectoration, and sometimes pain in the chest and tightness of breathing.

The *present attack* may be said to have commenced about eight weeks since, when he was seized with sudden giddiness, and partial loss of consciousness, also his speech was impeded, and his left arm and leg were very weak; he drank some brandy and water, and recovered in half an hour, and remained well till three weeks ago, when he had another attack whilst he was engaged at his work stooping forwards. He was now insensible for a minute or two, and on this, as well as on the former occasion, his mouth was drawn considerably to the right side. Since this attack he has kept his bed; has been very drowsy, and his sight and memory have suffered much; he has not been sick.

Present symptoms.—He has no pain in the head, but feels rather giddy; the face is drawn to the right side; the left side is flattened; the tongue when protruded deviates to the left; speech is very imperfect and thick (perhaps part of this is due to the habit of taking large quantities of snuff.) He can move the shoulder and arm of the left side down to the elbow, but not below, and cannot move the fingers at all; the arm hangs lifeless, as it were, from the elbows, and if allowed to hang down gets swelled and dark coloured; he can bend the thigh on the trunk, and the leg on the thigh, but cannot move the toes; sensation is not impaired in either limb, but the whole of the left side feels colder than the right; pulse 60, soft, and the patient feels weak; the tongue is rather white; appetite moderate; bowels costive; urine pale and rather scanty.

Physical signs.—The left side of the chest moves less in inspiration; the right side is flattened under the clavicle, and in this situation the sound on percussion is decidedly duller than on the left side, and there is a corresponding dulness on the supra-scapular fossa. The breath sound is bronchial under the right clavicle, and is loud under the left, and there is slight bronchophony under both.

Applicetur Cucurb. cruent. nuchæ ad f3viiij.

℞ Ol. Crotonis, ℥j.; Micæ Panis, q. s. ft. pilula omni nocte sumend.

24th.—The bowels have been well opened; urine scanty and turbid, but readily cleared by heat or by nitric acid—reaction acid; specific gravity 1024.

Sumat pil. om. alternâ mane.

℞ Tinct. Cantharid. ℥xv.; Tinct. Hyos-

cyami, ℥xx.; Potassæ Liq. ℥xx.;
Mist. Camph. fʒj. Ft. haust. ter die
sumendus. Nuchæ admov. emplast.
Canth.

25th.—The blister rose well; to-day he can raise the arm a little higher; he feels a pain running along the arm from the elbow to the fingers; cannot move these at all; the temperature in the left axilla is nearly a degree of Fahrenheit lower than in the right axilla; pulse 54, weak.

28th.—Still very drowsy; he sleeps at least fourteen out of the twenty-four hours; he has a little pain over the left temple to-day, and the left eye is suffused; the memory is worse, he says, than it was yesterday, and he feels confused; pulse 64, still weak; the pills gripe him a good deal, but do not purge him.

Auge Ol. Crotonis ad ℥ij.

30th.—The bowels were freely purged yesterday by the pill. The voluntary movements are scarcely at all improved, and the head feels rather confused. He states that when he awakes in the morning he frequently finds the fingers of the left hand contracted; and it was noticed that if the foot was tickled the toes were moved readily, and when he yawns the fingers are stretched out, and sometimes firmly closed involuntarily. In passing his urine he feels some little difficulty at first, but when it once begins to flow there is no further difficulty.

31st.—He complains of headache still, and feels more confused over the left temple, and is very drowsy; the left eye is a good deal injected; the pulse is only 48, but full and prolonged; the tongue rather more furred, and he has no appetite; the bowels are open.

Applicetur C. C. temporis sinistro ad fʒvj.;
Auge Tinct. Canth. ad ℥xx.

June 1st.—Feels much relieved since the cupping; has no headache, no confusion of ideas, no suffusion of the eye, and looks better altogether; tongue cleaner; pulse 48; was able to bend his toes a little this morning for a short time, and moves the leg rather better.

4th.—Much better in health; head quite clear; pulse 52; is able to walk about more easily, but cannot move the arm any better.

7th.—Feels stronger; appetite good; pulse 50, weak.

Full diet.

9th.—Improving; he can raise the arm better, and can partly flex some of the fingers, but cannot extend them again; has more power over the toes.

11th.—Health pretty good; pulse 56, rather small and weak; the left side of the chest still moves less than the right when a

deep inspiration is taken; he can move the arm more freely, and also can flex the fingers better, but cannot extend them; and when the arm is held out with the palm of the hand downwards the hand falls; he can also move the leg and flex the toes better, but cannot raise the toes, and when he walks the foot drags on the ground. He continues to take the croton oil pills every other morning, and the cantharides draughts as ordered: the urine is abundant and clear except when the pills are taken; then the urine is more scanty, and watery stools are produced.

Ordered to have a splint applied along the palmar surface of the fore-arm and hand.

17th.—Gaining strength and looks better in the face; he can walk a little without a stick; can bend the fore-arm better, and can flex all the fingers pretty well, but is not able to straighten them again; complains of pain extending along the fore-arm.

21st.—Feels stronger and looks more cheerful; has been allowed to go out for a short walk; can raise the arm up to the head, and flexes the fore-arm and fingers more strongly, but cannot extend the fingers yet; he has more strength in the leg, and can extend the foot better.

Auge Tinct. Canth. ad ℥xxv.

24th.—The tongue does not deviate much now when protruded; speech still rather indistinct; this arises, he says, from his mouth filling with water when he speaks; pulse 54; he still has a little difficulty at first when he attempts to pass his water; cannot extend the fingers yet; he can bend the foot upwards on the leg, but cannot extend the toes by themselves.

28th.—Much the same.

Omittatur haustus.

R. Tinct. Canth. ℥xxx.; Aquæ Menth.
Pip. fʒiiss. f. haustus ter die sumendus.

30th.—The left arm ordered to be electrified daily.

July 2d.—Moves the hand better than he has done at all; was able to extend the fingers in the morning.

Omittantur Pilulæ.

R. Pil. Cambog. C. gr. vj. omni nocte sumend.

July 5th.—He complains that he has pain in the left shoulder, and that it feels very weak. He has not been able to extend the fingers since the 2d inst.

8th.—Feels quite well, except being weak; the general appearance much improved; pulse 68; still has pain in the left shoulder and arm; can move the toes much better; is able to raise them without raising the whole foot. The pill does not keep his bowels open.

Sumantur duo pilulæ omni nocte.

12th.—Walks better; still has pain in the left shoulder; it is much increased by raising the arm; bowels regular.

Humero sinistro applic. Empl. Canth. quatuor pollices longum, duo lat.

14th.—Pain much the same; the blister did not rise well.

Omitt. pil.

R. Ext. Col. C. gr. viij. Ft. pil. omni nocte sum.

19th.—Looks and feels quite well, but still has the pain in the arm; the bowels are a little purged by the pill. Physical signs noticed again to-day: the sound on percussion dull under the right clavicle, and the respiratory murmur has a tubular character, almost cavernous, and attended with a sub-mucous rhonchus; loud vocal resonance also in the same situation: under the left clavicle the breath sound is tubular, but less so than on the right; the voice also too resonant; percussion is dull in the right supra-scapular fossa.

Rep. Empl. Canth. humero.

Sumat Pil. Col. C. gr. v. tantum omni nocte.

21st.—The blister rose well, and has relieved the pain in the shoulder; but he still feels pain in the forearm; pulse 70; bowels open; urine plentiful, clear, and he very seldom experiences any difficulty in passing it.

23d.—Moves both the leg and the arm very much better; the hand feels warmer; still has pain in the forearm, and occasionally in the shoulder.

28th.—General health good; sleeps well, and not so heavily as he did; walks more firmly on the left leg; cannot move the arm well, from the pain in the shoulder and elbow.

R. Liq. Ammon. f3ij. ; Olei Olivæ, Olei Terebinth. aa. f3ss. M. ft. linim. quo fricetur humerus nocte maneque.

He was discharged a few days after this, greatly relieved: he could walk pretty well, and move the arm much better; and we have since met him in the streets, looking quite well, but walking rather lame, and the arm was still very weak.

REMARKS.—Adopting the same plan in this as in other cases where there has been more than one disease, we shall notice, first, the paralysis, and secondly, the tubercles in the lungs; and combine with each so much of the previous history and subsequent results as belong to it.

The symptoms on the patient's admission were those of partial paralysis of all the

voluntary muscles on the left side of the body: thus, the face was drawn to the right side, indicating paralysis of the left; the speech was impaired, and the tongue, when protruded, deviated to the left side, shewing that the left side was paralysed. And supposing the paralysis not to be complete, we may illustrate the cause of the deviation to the left or paralysed side by comparing it with a Breguet's thermometer, in which the unequal expansion of two metals soldered together produces a similar deviation when heated. His sight and memory were also impaired considerably; the left side of the chest moved less than the right, and the arm and leg were paralysed, especially the lower half of each limb. Sensation was perfect in all these parts, but the temperature was diminished, and the circulation was imperfectly carried on, as evidenced by the dark colour and the swelling when dependent.

It did not appear that the involuntary muscles had suffered, unless the slight difficulty at first in attempting to evacuate the bladder be attributed to this cause. And the involuntary movements of the voluntary muscles were still easily produced, as by tickling the foot, and as in yawning.

We may now ask, what was the pathological state of the cerebro-spinal axis on which these symptoms depended? We see at once, from the paralysis of the face, and the affection of the memory and sight, and temporary loss of consciousness, in addition to the paralysis of the limbs, that they depended on some lesion within the cranium. In order to ascertain what this was, we refer to the history of the attack, and we there find that he had had four distinct fits, as they might be called. The first of these was apparently relieved by his drinking a glass of brandy and water, and the second and third passed off spontaneously. It was thus obvious that these could only have depended on some temporary condition of the brain; and the only condition, as far as we know, that would cause these symptoms, and which would itself be likely to be relieved by a stimulant, is congestion of the vessels of the brain, depending, probably, either on some trifling obstruction to the circulation, or on a loss of tone in the coats of the vessels; but on either of these suppositions it is difficult to explain the suddenness of the congestion. If we believe that the brandy and water had a good effect here, it may be asked, should we be warranted in ordering it in a case presenting similar symptoms? We can hardly think that we should, on account of the difficulty, if not impossibility, of knowing at the time that there is only congestion, and not hæmorrhage. It appears that the last fit came on similarly

to the others, but was more severe; and its effects were permanent, shewing that now there was something besides congestion of the brain. This fit, like the preceding ones, might have depended on congestion, in the first instance; but now, instead of passing off as before, it in all probability terminated in hæmorrhage into the brain, and thus caused the permanent paralysis of one side of the body. Had he in this attack taken brandy and water, it would have been almost sure to increase the effusion of blood, and might thereby have caused fatal effects; and yet there was no additional symptom at the time to prove the existence of anything beyond congestion.

We have been speaking of congestion as the cause of the attacks; but this itself must have a cause, like every thing else. Was there, then, any apparent cause here? To answer this we go still further back in his history; and we find that he had sustained several injuries of the head at various times; and one of these, viz. the severe blow on the upper part of the back of the head, was stated by Dr. Williams to have been very probably connected with it: he said it was just the kind of injury to produce disordered circulation in the head: he had seen many similar cases; and the occasional giddiness and frequent headache since he received this blow confirm this view. The injury was probably slight; but a slight injury of this kind, persisting, may lead to much more serious consequences. There were other causes which might have aided in producing congestion: thus the habit of taking enormous quantities of snuff may have assisted; also the excessive indulgence in venery, of which he said he had been guilty, is another cause, it is said, of many diseases of the nervous system, and may have operated here: and we must not forget that in his employment he would be constantly stooping, and two of the fits came on when he was engaged at his work. Thus we believe that there was a disposition to derangement of the cerebral circulation, produced by his habits and the injury he sustained, and that from some cause (perhaps similar to that which often determines an epileptic fit where there is a constitutional tendency to this) there had been distinct congestion produced three times, which again subsided without any further injury, but that on the fourth time it ended in extravasation of blood in the brain. As the patient lived, we could have no proof that there was hæmorrhage; but from the absence of any marks of inflammation or softening, we conclude that the symptoms must have depended on hæmorrhage. If this had occurred, it was no doubt somewhere in the right hemisphere of the brain, and very probably in its more

common situation, viz. in the corpus striatum or thalamus opticus.

In considering the treatment for such a case, it should have reference to the cause, whenever this can be ascertained. Now here it was believed to be congestion, and the symptoms seemed to indicate that, although hæmorrhage might have occurred, there still was some congestion; blood-letting, therefore, was indicated; and as he was weak, local blood-letting by cupping was deemed most advisable, and only to a small amount. The bowels being costive, the next thing was to purge these freely, which was done by croton oil. These remedies soon relieved the more important of the symptoms from the head for a time, but, as is often the case, a slight reaction occurred after a few days, which was immediately relieved after a few days by cupping over the left temple, where the pain now was. The remedy that was ordered more immediately to act on the nervous system was cantharides: the tincture was given, in doses of $\mathfrak{m}\mathfrak{x}\mathfrak{v}$. gradually increased to $\mathfrak{f}\mathfrak{z}\mathfrak{s}\mathfrak{s}$. three times a day, in combination with an alkali and henbane. The latter was omitted after some time, as it seemed to cause headache; at all events the headache ceased when this was left off. Counter-irritation was also used after the cupping. After a few days weakness was the most prominent general symptom; he was accordingly ordered full diet. After this there was no very important change made in the treatment; the purgative was changed, and local means were used to remove pains, apparently rheumatic, in the shoulder and arm. A splint was applied to prevent the hand from becoming permanently contracted, as it tends to do; and electricity was passed through the arm to assist in restoring strength to the paralysed muscles.

Under the use of the above means the patient recovered the use of the limbs in a great measure, sufficiently to be able to walk pretty well, and to use his arm a little; and at his age and weakened state it is not very probable that he will ever recover the perfect use of the parts. The order in which the power of motion returned in this case was similar to what is usual in such cases, viz. first in the leg and then in the arm, and in the flexors before the extensors. Thus it will be seen by the reports that the power of flexing the leg and toes returned on June 1st, that of flexing the arm and fingers on the 9th, that of extending the foot and toes on the 20th, and that of extending the fingers to a slight extent on the 2d July; but this last he lost again for a time.

Secondly, previous to his admission there had been various symptoms, and at the time of his admission there were various signs

referrible to the lungs which require a brief notice. In the history it is stated that as long ago as thirty-three years he had a severe strain on the right side, and had been subject to pain there ever since; that nine years ago he had severe pleurisy of the same side, and some time after this he vomited blood for two mornings, and then spit up a little for several days, and had had some tightness of breathing, and a winter cough with slight expectoration. The physical signs (*vide report*) were such as indicated some condensation of the upper lobes of both lungs, but chiefly that of the right lung. Was there any connection—and if any, what was it—between the previous history and these physical signs? The pleurisy which he had suffered from might have caused many of the signs, but it could not have caused the submucons rhonchus; and it is rare for pleurisy to affect the apex of the lung; besides, both lungs were affected. Again, it is stated that he had vomited blood; but this probably proceeded from the lungs, because there was hæmoptysis afterwards, and there were other symptoms of incipient phthisis already detailed, and hæmatemesis and hæmoptysis are always confounded by the vulgar; and, further, we know that he was hereditarily predisposed to phthisis. We have no hesitation, therefore, in concluding that there was consolidation of the lungs depending on tuberculous deposition, and that this had probably caused the hæmoptysis and the symptoms referrible to the lungs.

No treatment was adopted for the disease of the lungs, as there were no symptoms then to demand any, and the physical signs indicated that the disease was tolerably quiescent.

Lastly, it may be asked, is there any connection between the symptoms referrible to the lungs and those referrible to the nervous system? It is impossible to give any decided answer to this question, either in the negative or affirmative. Dr. Williams remarked on this point, that, "assuming that there were tubercles in the lungs, there might also be tubercles in the brain. The existence of these, however, would not alone cause the paralysis; but," we understood him to say that "the irregular circulation attending the progress of these cases might account for the paralysis." And he compared it to the production of hydrocephalus by any sudden excitement of the circulation when there was a tendency to the disease; and also to the excitement of the paroxysms of epilepsy when there was a permanent cause in the brain.

ON THE
SENSIBILITY OF THE GLOTTIS,
&c. &c.

To the Editor of the Medical Gazette.

SIR,

IN your journal of to-day an anonymous correspondent directs my attention to the fact of Magendie having, six years ago, pointed out the different degrees of sensibility possessed by the glottis, larynx, and trachea, which observation, he says, is to be found in the *Lancet* for 1836-7. Of this, sir, I was, until I saw your correspondent's letter, entirely ignorant; and I think, sir, you will agree with me that there is nothing very singular in my ignorance, as it would require a remarkably retentive memory to be able to bear in mind all the subjects treated of in the many valuable papers and lectures that are published in the medical journals. In the only two works of Magendie's that I consulted on the matter in question, viz. his *Treatise on Physiology*, translated by Dr. Milligan, and his "*Leçons sur les Phénomènes Physiques de la Vie*," published in 1838, I found no mention made of the sensibility of the air-tubes, with the exception of the following passage. "The air-tube does not possess the same degree of sensibility in different parts: whilst that of the glottis is the most exquisite, that of the larynx and trachea scarcely exists." (*Leçons, &c.* vol. ii. p. 216.)

I may further remark, that as the paper which you did me the honour to publish in your journal was not intended to be an essay upon the relative sensibility of different parts of the air-passage, but was merely a letter written in answer to the question, *as to whether the performance of tracheotomy tended to lessen the sensibility of the glottis*—on which subject, as your correspondent may see, if he will take the trouble to read the published accounts of the discussion that took place at the Royal Medical and Chirurgical Society, much difference of opinion existed—I did not think it necessary to ransack the journals in order to ascertain what had previously been done upon the subject. I merely contented myself with stating the results of my own experiments, although, had I been acquainted with those of Magendie, which, as far as they go, completely tally with mine, I should not have failed to have mentioned them; as well as some which I have since been told by Dr. C. J. B. Williams he instituted two or three years ago on the same subject.

Your correspondent seems to think it wonderful that I should have operated on the same animal—the dog, and used the

same instrument—the probe, as Magendie did. Perhaps he will allow me to inform him that the dog is, for various reasons, the animal that is *most generally* selected for all experiments, whether surgical, physiological, or therapeutical; and that there is no instrument, with which I am acquainted, except a probe, that would pass through a puncture of a line in length, which was the extent of the opening in the trachea in my first experiment. It appears wonderful to me that your correspondent did not, with his sapient “*mirabile dictu*,” discover a further resemblance between Magendie’s experiments and mine, viz. that we both used a scalpel and forceps.—I am, sir,

Your obedient servant,
JOHN E. ERICHSEN.

48, Welbeck Street.

INSANITY IN FRANCE.

THE *Gazette Médicale* of the 29th ult. contains the following announcement:—

The investigation on the subject of insanity, which formed part of the General Statistics of France, and the results of which were communicated to the Academy by M. Moreau de Jonnès, comprehends not one year only, as was inadvertently reported in our last number, but seven complete and consecutive years. The following is the number of insane persons in the eighty-six departments, ascertained by the medical and ministerial authorities, on the 1st of January in each year:—

	No. of insane.	Proportion of insane to 1000 inhabitants.
1835 . .	14486 . . .	·043
1836 . .	15314 . . .	·046
1837 . .	15870 . . .	·047
1838 . .	16892 . . .	·050
1839 . .	18113 . . .	·054
1840 . .	18716 . . .	·056
1841 . .	19738 . . .	·058

UNLUCKY BIRTHS.

HUMAN beings are occasionally offered in sacrifice at Ibu. Twins are in all cases put to death; and it is said that children who cut their upper-jaw teeth first were instantly destroyed.—*Medical History of the Expedition to the Niger during the Years 1841-2, by Dr. J. O. Macwilliam.*

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XL.

*On the Causes and Nature of Inflammation
of the Uterus and its Appendages in
Puerperal Women.*

THE causes of inflammation in the uterine organs after delivery are often involved in the deepest obscurity. By examining the accompanying tables, you will see that in a very large proportion of cases the disease occurs after natural labours, and cannot be referred to injuries inflicted upon the uterus by violence of any kind during parturition, or to exposure to cold and moisture, and irregularities of diet committed soon after delivery. The disease has been observed by me to prevail during the last fifteen years, and to assume the different forms described in the two last lectures, during spring, summer, autumn, and winter, though most frequently in the latter season, not only in the British Lying-in Hospital, the Lying-in Wards of the Saint Marylebone, St. James', and other parochial Infirmaries, but in every district of London, and the surrounding country; and in all the different ranks of life. The disease has generally arisen, like inflammation of the bowels and lungs, and other viscera, without any assignable cause—where the process of parturition had been completed in the most natural manner, where nothing could be discovered peculiar in the constitution of the atmos-

phere, and when typhus fever, scarlet fever, erysipelas, and other contagious and epidemic disorders, were not prevailing to an unusual extent. But it is an opinion which has long prevailed, that the uterine inflammation of puerperal women is of an erysipelatous nature, and that it is excited in some cases by contagion, or depends on a vitiated state of the atmosphere, like hospital gangrene, and may be communicated from one patient to another, by the nurse and medical practitioner. It is stated by Peau, that, in 1664, a prodigious number of puerperal women perished in the Hôtel Dieu at Paris, and that the cause of this mortality was attributed by M. Vesou, physician to the hospital, to the circumstance of the lying-in wards being situated immediately over those set apart for the reception of wounded persons. The bodies of the women were found after death to be full of abscesses. Uterine phlebitis was probably the cause of this great mortality, as I have found it to be most frequently where inflammation of the uterus has appeared to be excited by the contaminated air of an hospital, contagion, and erysipelas. Ponteau regarded the disease which appeared in the Hôtel Dieu at Lyons, in the spring of the year 1750, and produced great havoc among puerperal women, to be an epidemic erysipelatous inflammation of the peritoneum. The same opinion of the nature of the affection was maintained by Dr. Lowder, and Professors Young and Home of Edinburgh, who saw the disease in the Lying-in Wards of the Royal Infirmary. Dr. Gordon, of Aberdeen, states that he had unquestionable proof that the cause of the disease was a specific contagion, and not owing to any noxious constitution of the atmosphere. The constitution of the year, as it was termed by Sydenham, had little or nothing to do with its production. The disease seized such women only as were visited or delivered by a physician, or taken care of by a nurse, who had previously attended patients affected with the

disease. "I had abundant proofs," he observes, "that every person who had been with a patient in the puerperal fever became charged with an atmosphere of infection which was communicated to every pregnant woman who happened to come within its sphere." He acknowledges that he was himself the means of conveying the infection to a great number of women. "If the puerperal fever of Leeds was infectious, which by many it was thought to be," says Mr. Hey, "it was so in a very inferior degree to that at Aberdeen; for I have known instances of free communication, by the intervention of others, between women in labour or child-bed, and those affected with the disease, without any bad consequences. And, on the contrary, in many cases of puerperal fever no channel whatever was discoverable whereby the disease could have been conveyed. It was not from being convinced of its necessity, but for the satisfaction of his own mind and the safety of his patients, that he adopted the usual precautions to prevent the propagation of an infectious disorder. Dr. Armstrong observed that most of the cases at Sunderland, forty out of fifty-three, occurred in the practice of one surgeon and his assistant. He believed, at first, that the disease, as an epidemic, was invariably contagious; but afterwards had reasons for doubting whether it was so in the ordinary sporadic form. "It is hardly possible to prove," says Dr. J. Clarke, "that it is not infectious, but it has also arisen, as far as we can judge, as an original disease, where there had been no communication with infected persons."

Dr. Hulme maintained that uterine inflammation in puerperal women was not more contagious than pleuritis, nephritis, or any other inflammatory disease. Dr. Hull, of Manchester, was also of opinion that it is not contagious. M. Tonellé, who has recorded the history of the most fatal epidemic which has ever occurred in Paris, asserts that the idea of contagion was clearly out of the question in the Maternité there, for the women who were newly delivered had each a separate apartment, and yet were attacked with the disease; whilst in the sick ward of the hospital no instance of the propagation of the disease ever occurred. The evidence of M. Dugès against the doctrine of contagion is not less strong; for he states that in numerous instances pregnant women have been placed in the infirmary, where they were surrounded by cases of peritonitis, without being infected; and that still more frequently he has seen women newly delivered brought into the infirmaries on account of some other complaint, and who did not contract the disease. In no instance did he

observe a midwife entrusted with the care of two patients at the same time communicate peritonitis from a sick to a healthy individual, as is reported to have happened in London; and never has this inflammation been propagated from patient to patient in the wards set apart for the reception of healthy women. In the epidemic at Edinburgh described by Dr. Mackintosh and Dr. Campbell, I believe they saw no case which could be ascribed to contagion.

It is difficult to reconcile this conflicting evidence; and the facts I have observed, though they have led me to adopt the opinion that the disease is sometimes communicable by contagion, and sometimes has a connection with erysipelas, have not perhaps been sufficiently numerous, and of so decisive a character, as to dispel every doubt on the subject of its contagious or non-contagious nature, and to prove that it is a specific inflammation. It is but right to state that, in a vast majority of cases, the disease has occurred, and in the most destructive form, where contagion could not possibly be supposed to have operated as the cause. It has suddenly appeared in the practice of those who had never before seen the disease, or had any thing to do at the time with cases of typhus fever, erysipelas, and other contagious disorders.

In the last two weeks of September 1827, five fatal cases of uterine inflammation came under my observation. All the individuals so attacked had been attended in labour by the same midwife, and no example of a febrile or inflammatory disease of a serious nature occurred during that period among the other patients, who had been attended by the other midwives belonging to the institution. On the 16th March, 1831, a practitioner who resides in a populous parish in the vicinity of London, examined the body of a woman who died a few days after delivery, from peritonitis. On the morning of the 17th he was called to attend a private patient in labour, who was safely delivered on the same day. On the 19th she was attacked with the symptoms of uterine phlebitis, severe rigors, great disturbance of the cerebral functions, rapid feeble pulse, with acute pain of the hypogastrium, and peculiar sallow colour of the whole surface of the body. She died on the fourth day after the attack, the 22d March; and between this period and the 6th of April this practitioner attended two other patients, both of whom were attacked with the same disease in a malignant form, and fell victims to it. On the 30th March it happened that the same gentleman attended a patient, a robust young woman, seventeen years of age, affected with pleuritis, for which venesection was resorted to with immediate relief. On the 5th of April there

was no appearance of inflammation around the puncture which had been made in the median basilic vein, but there had been pain in the wound during the two preceding days. The inner surface of the arm, from the elbow nearly to the axilla, was now affected with erysipelalous inflammation; alarming constitutional symptoms manifested themselves; the pulse was 160; the tongue dry; delirium had been observed during the night. On the evening of this day the inflammation spread into the axilla. The arm was exquisitely painful; but in the vicinity of the wound, which had a healthy appearance, the colour of the skin was natural; and no hardness or pain felt in the vein above the puncture. On the 6th, patches of erysipelalous inflammation appeared in various parts of the body, on the upper and inner surface of the left arm, and on the sole of the left foot, all of which were acutely painful on pressure. The inflammation of the right arm had somewhat subsided; the pulse was 160; the tongue brown, dry, and furred; restlessness, constant dozing, and incoherence. When roused she was conscious; the face cold; heat of the surface irregular. On the 7th, pulse rapid; countenance anxious; teeth and lips covered with sordes; somnolence and delirium. The left arm, above the elbow, was acutely painful, and the erysipelas had made no further progress. The patches of erysipelas on the forehead and sole of the foot had disappeared; but there was a slight blush of inflammation on the inner side of the calf of the left leg. The symptoms became aggravated, and she died on the 9th of April. I examined the body with Dr. John Prout on the 11th, and the following morbid appearances were observed. The wound in the median basilic vein was open, and its cavity filled with purulent fluid. The coats of this vessel, and of the basilic vein, as you can still perceive in the preparation of the parts [exhibiting it], were thickened so as to resemble the coats of an artery. The inner surface of the vein was redder than natural, and at the upper part had lost its usual smoothness, but there was no lymph deposited upon it. The mouths of the veins entering the basilic were all closed up with firm coagula of blood or lymph. The cellular membrane along the inner surface of the vein was unusually vascular, and infiltrated with serum. This infiltration was to a much greater extent along the situation of the erysipelalous inflammation of the left arm, but the veins of this arm were perfectly healthy. It is highly probable there was something more than a mere coincidence in these events.

In the autumn of 1829 I was present at the examination of the body of a woman who died soon after delivery from inflammation of the peritoneal and muscular

tissues of the uterus. I dissected out the uterine organs, and after inspecting them carefully assisted in sewing up the body. I had scarcely reached home when I was hastily summoned to attend a young lady in her first labour, who was soon safely delivered; but in sixteen hours she was attacked with violent pain in the region of the uterus. Unequivocal symptoms of uterine phlebitis soon after showed themselves: she recovered, but with great difficulty. In December 1830, two patients in the British Lying-in Hospital, who had both been attended by the same midwife, were attacked with the disease on the same day; and both died from inflammation of the absorbents and deep-seated structures of the uterus. Another patient was admitted into the hospital two days after the death of the last of these women, and was examined by the same midwife to ascertain if labour had commenced. The pains were false pains; but she remained from Saturday till Monday in the hospital, expecting that labour would come on. The pains having left her, she returned home; and the following day was suddenly taken in labour, and safely delivered before she could be sent to the hospital. She went on favourably for two days, and was then attacked with the most violent symptoms of inflammation of the veins of the uterus, and died in thirty-six hours.

In 1835, a surgeon residing at the west end of London, while attending a gentleman who had phlegmonous erysipelas of the leg and extensive sloughing of the cellular membrane, was called to a case of labour, which was speedily followed by inflammation of the uterus, and proved fatal. The body was not examined; but, from the symptoms, there could be little doubt that both the peritoneal and vascular structures were affected. A second case occurred in his practice within a few days, which also terminated fatally. Soon after a third case occurred to him, the unfavourable result of which he attributed to the copious venesection employed immediately after the invasion of the disease. He was very unhappy at the thought of having destroyed the patient by bleeding her so profusely, and could not feel satisfied that her death was owing to any other cause than excessive depletion, although the quantity of blood removed barely exceeded 3xx., till I inspected the body, and showed him a great portion of the veins in the walls of the uterus, where the placenta had adhered, loaded with pus. The affair here ended with Mr. —, but not so with me; for the same evening, after examining the body of this patient, I was requested to see a lady in consultation, whose labour was protracted, and an opinion required respecting the propriety of interfering, and completing the

delivery by artificial means. I examined the patient, and recommended delay; and in a few hours she was safely delivered of a living child by the natural efforts. In 24 hours, this lady was attacked with peritonitis in the most violent possible form, and died in less than 48 hours with incessant vomiting, and great tympanites. The infant was cut off in no long time with erysipelas. A few days after this, having changed my clothes completely, and adopted every means that I could think of to prevent any further mischief, I attended a private patient residing near Oxford Street, whose labour was natural, and whose recovery after her two former deliveries was favourable: but in less than 30 hours she was attacked with acute inflammation of the uterus, which no remedies could subdue. The following facts are, if possible, still more striking, and leave no doubt whatever upon my mind that it is our duty to act in all cases as if the contagious nature of the disease had been completely demonstrated.

On the morning of the 4th of August, 1836, a practitioner who resides in a large healthy village about seven miles from London, with a populous country around, attended Mrs. O——, in labour, which was natural. The same evening he was called to a case of arm presentation, where, from the rigidity of the os uteri, and violence of the contractions, he found it impossible to deliver by turning, and he sent to request my assistance for Mrs. B——. The child was premature, and had been dead some time, so that I had no difficulty in drawing down the extremity, which presented deep into the pelvis, passing the fingers along the thorax and abdomen to the nates, and extracting the lower extremities, and then the trunk and head of the child. No violence was necessary in effecting the delivery, and it seemed probable the patient would recover in a favourable manner. On the following morning, Thursday, the 5th of August, Mrs. O——, who had not been visited in the interval from her delivery, was attacked with all the usual symptoms of severe uterine inflammation, and ultimately died. As Dr. — had not seen this patient from the time she was delivered, on the morning of the 4th, to the period of the attack, it is obvious that he could have communicated no contagion from Mrs. B——, whose labour occurred the same evening, and whose child had died within the uterus, and presented preternaturally. No case of severe uterine inflammation had ever come under the observation of Dr. —, though he had resided eight or ten years in the same village, and had attended numerous cases of labour. At this time there was no case of erysipelas under his care, and for a long period he had not examined any dead bodies.

Mrs. B——, who was delivered on the 4th of August, was attacked on the 6th with all the symptoms of uterine phlebitis, and died on the 9th. I examined the body with Dr. —, and his assistant, on the 10th, and found extensive peritonitis, and all the veins and absorbents on the left side of the upper part of the uterus, where the placenta had adhered, filled with pus. As the coats of the absorbents were not thickened, I suspected that the pus they contained had been absorbed by them from the veins. The left ovary was large and soft, and the left fallopian tube inflamed. The os and cervix uteri were sound. On the evening of the 10th of August, after examining the body of this patient, on returning home, I adopted every means I could devise to prevent the communication of any poison to others, but without effect, for early the following morning I was called to a private patient near Lincoln's-Inn Fields, who was soon safely delivered, but was seized in less than 24 hours with a violent fit of cold shivering, acute pain in the region of the uterus, especially on the right side and sacrum, headache, ringing in the ears, and intense thirst. The countenance was pallid and depressed when I first saw her: the pulse was 120, with nausea, sense of chilliness over the whole surface of the body, though it was intensely hot, and covered with perspiration. Blood-letting, general and local, was employed, but sparingly, and calomel, opium, cathartics, turpentine, prussic acid, and creosote, freely, but without the slightest effect, and she died with incessant vomiting of dark-coloured matter like coffee-grounds. Some time before death the pain of the abdomen subsided, and the left leg became exquisitely painful; it soon became livid and swollen around the ankle, the discoloration extended rapidly up the limb, the cuticle separated, and dark-coloured vesications were formed. The disease extended no further in my public or private practice, but another patient, attended by Dr. —, soon after was destroyed by it. The assistant of Dr. — was attacked a few days after the post-mortem examination of Mrs. B—— on the 10th August, at which he was present, with strong febrile symptoms, sickness at stomach, headache, sore-throat, and great prostration of strength. The tonsils became covered with foul superficial ulcers, the lower lip swollen, and covered with a pustular eruption; the tongue was intensely red at the point and on the edges, and covered in the middle with a thick white fur. These symptoms lasted for a week, and then went off, leaving him in a state of great debility. The cook in the family became affected a few days after with similar, but much milder, symptoms. I was informed that the carpenter, a young healthy

man, who placed the body of Mrs. B— in her coffin, had afterwards a most violent attack of fever and sore-throat, and recovered but with difficulty. The train of misfortunes did not end here, for an aged relative of Mrs. B—, who was in the apartment when I examined the body, was seized soon after with severe symptoms, like those of continued fever, and died after a few days' illness.

In 1839 in London, and in 1841 at Woolwich, several similar occurrences, but of a less striking character, took place, which also came under my observation, and they all point out the necessity of taking every precaution to prevent the extension of the disease from one puerperal woman to another, not only by careful and repeated ablution, and changing the clothes after attending patients who are affected with it, but what is far more efficacious—indeed the only thing to be trusted to—by discontinuing obstetrical practice altogether for a time when several cases occur in rapid succession. The great mortality in lying-in hospitals arises chiefly from the occurrence of uterine inflammation, and its spreading from patient to patient, or becoming epidemic in the wards. This circumstance induced me to make the following observation ten years ago, the truth of which is amply illustrated by the accompanying tables:—“From the registers of the British Lying-in Hospital, the Maternité at Paris, the Dublin Lying-in Hospital, and the tables of M. De Chateau-neuf, it is proved that the average rate of mortality greatly exceeds, in these institutions, that of those in which individuals are attended at their own habitations; and if it should ultimately appear that all precautions are unavailing in diminishing the numbers attacked by the disease, it becomes a subject deserving of the most serious consideration, on the ground of humanity, whether lying-in hospitals should not be altogether abolished, as injurious rather than beneficial to society. From what has fallen under my observation in the British Lying-in Hospital, and other similar institutions in this metropolis, where the utmost attention is paid to ventilation and cleanliness, and where the wards are not overcrowded with patients, I cannot hesitate to express my decided conviction that by no means hitherto discovered can the frequent and fatal recurrence of the disease be prevented in lying-in hospitals, and that the loss of human life thereby occasioned completely defeats the objects of their benevolent founders.”

TABULAR VIEW (No. 1) OF 100 CASES OF SEVERE INFLAMMATION OF THE UTERUS AND ITS APPENDAGES,

Which occurred to me in London, from March 1827 to the end of December 1830.

[Continued from p. 731.]

No.	Name, Residence, and Delivery.	Date of Attack and Symptoms.	Treatment.	Result and Morbid Appearances.
76	Phoebe Robins; æt. 28; Holborn. Tedious labour. 10th January, 1830.	Third day.—Severe after-pains; lochia suppressed; exquisite tenderness of uterus; skin hot; pulse strong and rapid; headache; symptoms very obstinate.	V.S. ʒxxvj., calomel, opium, leeches xxiv.	Recovered.
77	Marchant; British Lying-in Hospital. Natural labour. 11th January, 1830.	Third day.—Pain not very severe in the region of the uterus; rigors; pulse 100; headache.	Leeches xij., calomel, castor-oil.	Recovered.

78	Leaney; æt. 26; British Lying-in Hospital. Natural labour. 11th January, 1830.	Third day.—Headache; pyrexia; uterine pain; pulse 120; lochia suppressed; vomiting.	V.S. ʒxiv., leeches lx., calomel, opium, cathartics.	Recovered.
79	Measlin; æt. 22; British Lying-in Hospital. Natural labour. 13th January, 1830.	Second day.—Uterus large, hard, and painful; rigors; headache; lochia nearly suppressed; pulse 100; dyspnoea; cough; skin hot; pulmonary attack; abdomen distended; uterus hard and painful on pressure; vomiting; exhaustion.	V.S. ʒxvi., V.S. ʒxiv., calomel, Dover's powder, &c.	Died. Caput coli and transverse arch of colon covered with patches of lymph; uterus uncontracted, its anterior surface of a uniform dusky red colour; the muscular tissue under this reduced to a soft reddish pulp; the veins of the fundus uteri on both sides inflamed, and filled with a quantity of pus; both ovaria enlarged, their structure destroyed; fallopian tubes soft and vascular; lungs gorged with blood, but not inflamed.
80	Meaden; æt. 20; British Lying-in Hospital. 15th January, 1830.	Second day.—Headache; rigors; uterus painful, large, and hard; anxiety; countenance pale; breathing hurried; pulse 110; lochia scanty. Convalescent in 24 hours.	V.S. ʒxx., leeches xxiv., pulv. ipecac. comp. gr. v. ʒtia q. q. hora.	Recovered.
81	Case after natural labour; British Lying-in Hospital. 28th January, 1830.	Third day.—Pyrexia; severe pain of the uterus, increased by pressure. Depletion followed by immediate convalescence.	V.S. ʒxx., calomel, opium, fomentations and poultices to hypogastrium.	Recovered.
82	Williams; æt. 26; a patient of Dr. Hugh Ley's, Middlesex Hospital. Natural labour. 13th January, 1830.	Eighth day.—Vomiting; rigors; severe uterine pain; foul tongue; offensive lochia; pulse 120, soft.	V.S. ʒxvj., leeches xij., calomel, antimony, and opium.	Recovered. During this month several severe cases occurred among the out-patients of the Middlesex Hospital. In all there was more or less pain in the region of the uterus, increased by pressure, pyrexia, and diminished lochial discharge.

83	Case in a Mews near Portman Square. Natural labour. January, 1830.	Sixth day.—Continued well for six days after delivery, when fever of a typhoid character came on, with slight abdominal pain; puffy swelling over the left wrist, and on one of the thighs; slight tympanites.	Sulphate of quinine and stimulants.	Died. Uterus large; the left spermatic vein through its whole course lined with false membranes, its coats thickened, the lower part filled with pus and lymph; the upper part distended with coagula of blood; the veins at left superior angle of uterus lined with lymph, and filled with a bloody, purulent fluid; the veins on the right side of uterus gorged with pus; the right spermatic vein was healthy, also both hypogastrics. Recovered.
84	Sophia Humphries. 30th January, 1830.	Third day.—Acute pain of uterus, increased by pressure; headache; tongue white; pulse 100; lochia scanty; bowels confined; blood cupped and buffed.	V.S. ℥xij., calomel, cathartics.	Recovered
85	Jones; 48, Marshall Street. Natural labour. 11th February, 1830.	Third day.—Pyrexia; acute uterine pain; lochia suppressed; rigors; pain and swelling of left iliac region; cough; suppuration at the brim of the pelvis; the pus escaped under Poupart's ligament. Recovered after five months.	Leeches often repeated, cataplasms, bark, wine, stimulants; abscess opened artificially.	Recovered
86	Honeyman; Angel Street, City. Natural labour. 12th February, 1830.	Fourth day.—Acute uterine pain; violent rigor; headache; lochia suppressed; pulse 115, strong; respiration hurried.	V.S. ℥xxx., leeches xxiv., calomel, antimony, cathartics, diaphoretics.	Recovered.
87	Case in the Edgeware Road. 20th February, 1830.	Second day.—Pain in the region of the uterus; rigors; lochia and milk diminished; slight delirium; pulse 115; tongue white; great tenderness in the situation of right uterine appendages.	V.S. ℥xj., leeches, calomel, antimony.	— In the month of April, 1830, three cases occurred, which all yielded speedily to venesection, leeches, calomel, antim., Dover's powders, &c. The details of these cases are not preserved.

78	Leaney; æt. 26; British Lying-in Hospital. Natural labour. 11th January, 1830.	Third day.—Headache; pyrexia; uterine pain; pulse 120; lochia suppressed; vomiting.	V.S. ʒiiv., leeches lx., calomel, opium, cathartics.	Recovered.
79	Mesalin; æt. 22; British Lying-in Hospital. Natural labour. 13th January, 1830.	Second day.—Uterus large, hard, and painful; rigors; headache; lochia nearly suppressed; pulse 100; dyspnoea; cough; skin hot; pulmonic attack; abdomen distended; uterus hard and painful on pressure; vomiting; exhaustion.	V.S. ʒxvi., V.S. ʒxiv., calomel, Dover's powder, &c.	Died. Caput coli and transverse arch of colon covered with patches of lymph; uterus uncontracted, its anterior surface of a uniform dusky red colour; the muscular tissue under this reduced to a soft reddish pulp; the veins of the fundus uteri on both sides inflamed, and filled with a quantity of pus; both ovaria enlarged, their structure destroyed; fallopian tubes soft and vascular; lungs gorged with blood, but not inflamed. Recovered.
80	Meaden; æt. 20; British Lying-in Hospital. 15th January, 1830.	Second day.—Headache; rigors; uterus painful, large, and hard; anxiety; countenance pale; breathing hurried; pulse 110; lochia scanty. Convalescent in 24 hours.	V.S. ʒxx., leeches xxiv., pulv. ipecac. comp. gr. v. 3tia q. q. hora.	Recovered.
81	Case after natural labour; British Lying-in Hospital. 28th January, 1830.	Third day.—Pyrexia; severe pain of the uterus, increased by pressure. Depletion followed by immediate convalescence.	V.S. ʒxx., calomel, opium, fomentations and poultices to hypogastrium.	Recovered.
82	Williams; æt. 26; a patient of Dr. Hugh Ley's, Middlesex Hospital. Natural labour. 13th January, 1830.	Eighth day.—Vomiting; rigors; severe uterine pain; foul tongue; offensive lochia; pulse 120, soft.	V.S. ʒxvj., leeches xij., calomel, antimony, and opium.	Recovered. During this month several severe cases occurred among the out-patients of the Middlesex Hospital. In all there was more or less pain in the region of the uterus, increased by pressure, pyrexia, and diminished lochial discharge.

83	Case in a Mews near Portman Square. Natural labour. January, 1830.	Sixth day.—Continued well for six days after delivery, when fever of a typhoid character came on, with slight abdominal pain; puffy swelling over the left wrist, and on one of the thighs; slight tympanites.	Sulphate of quinine and stimulants.	Died. Uterus large; the left spermatic vein through its whole course lined with false membranes, its coats thickened, the lower part filled with pus and lymph; the upper part distended with coagula of blood; the veins at left superior angle of uterus lined with lymph, and filled with a bloody, purulent fluid; the veins on the right side of uterus gorged with pus; the right spermatic vein was healthy, also both hypogastrics. Recovered.
84	Sophia Humphries. 30th January, 1830.	Third day.—Acute pain of uterus, increased by pressure; headache; tongue white; pulse 100; lochia scanty; bowels confined; blood cupped and buffed.	V.S. ℥xij., calomel, cathartics.	Recovered.
85	Jones; 48, Marshall Street. Natural labour. 11th February, 1830.	Third day.—Pyrexia; acute uterine pain; lochia suppressed; rigors; pain and swelling of left iliac region; cough; suppuration at the brim of the pelvis; the pus escaped under Poupart's ligament. Recovered after five months.	Leeches often repeated, cataplasms, bark, wine, stimulants; abscess opened artificially.	Recovered
86	Honeyman; Angel Street, City. Natural labour. 12th February, 1830.	Fourth day.—Acute uterine pain; violent rigor; headache; lochia suppressed; pulse 115, strong; respiration hurried.	V.S. ℥xxx., leeches xxiv., calomel, antimony, cathartics, diaphoretics.	Recovered.
87	Case in the Edgeware Road. 20th February, 1830.	Second day.—Pain in the region of the uterus; rigors; lochia and milk diminished; slight delirium; pulse 115; tongue white; great tenderness in the situation of right uterine appendages.	V.S. ℥xj., leeches, calomel, antimony.	— In the month of April, 1830, three cases occurred, which all yielded speedily to venesection, leeches, calomel, antim., Dover's powders, &c. The details of these cases are not preserved.

88	Mrs. Hadden; æt. 30; 3, Castle Street, Bloomsbury. Arm presentation.	Fourth day.—Uterine pain; lochia suppressed; rigors; pain in right groin; pulse 100; tongue white. The pain was not effectually relieved till cathartics were freely administered.	V.S. ʒxij., leeches xvj., calomel, antimony, cathartics.	Recovered.
89	Mrs. Sears; æt. 26; 23, Church Lane. Natural labour. 20th June, 1830.	Fourth day.—Great uterine pain; pulse 100, full; lochia suppressed; rigors; blood cupped and buffed.	V.S. ʒxvj., leeches xxiv., calomel, antimony.	Recovered.
90	Mrs. Allen; æt. 26; 12, Phoenix Street, St. Giles's. Natural labour. 10th June, 1830.	Fourth day.—Uterine pain; pulse frequent and full; lochia suppressed; tongue brown; vomiting; pain in right groin; pulse 130; respiration hurried.	V.S. ʒxxvj., calomel, antimony, opium, cathartics, salineeffervescing draughts.	Recovered.
91	Sankey; 35, Wardour Street. Protracted labour. June, 1830.	Soon after delivery, a sudden attack of fever, with severe pain in the right iliac region and left groin and thigh; rigors; tongue loaded. July 12: the left iliac region is hard, swollen, and painful on pressure,—the hardness extends half way down the thigh, in the course of the femoral vessels; great constitutional disturbance. Aug. 6: a great quantity of pus discharged above Poupart's ligament. A slow but complete recovery.	Leeches, poultices, anodynes.	Recovered.
92	Mrs. Gyde; æt. 22; Brewer Street, Golden Square. Natural labour. 26th June, 1830.	Second day.—Rigors, and pain of the lower part of the abdomen, with pyrexia and suppression of the lochia. 29th: pain but slightly relieved; fever continues. July 4th: intense pain of the whole abdomen, and distension; pulse rapid and feeble; constant sickness and vomiting; tongue brown. 6th: symptoms aggravated. Died on the tenth day from attack.	V.S. ʒxij., leeches xij., opium, leeches, a blister, cathartics.	Died. lb. ij. of dark-coloured sero-purulent fluid in peritoneal sac; the whole abdominal viscera inflamed; small intestines, omentum, and uterus, all glued together with lymph; an abscess under the peritoneum of the uterus, near its fundus, on the left side; a small abscess in the body of the uterus on the left side; uterine appendages on both sides vascular, and coated with lymph.

93	Phillips; æt. 32; 2, Sussex Street. 30th July, 1830.	Fifth day.—Great uterine pain; pulse 130; violent headache; exquisite tenderness, increased by pressure, in the left side of the uterus, which gradually diminished, and the pulse became less frequent. A slow recovery.	V.S. ʒx., leeches xij., calomel, antimony, opium, cathartics.	Recovered.
94	Mrs. Chapman; æt. 36; 9, Belton Street, Long Acre. Natural labour. 19th August, 1830.	Fifth day.—After drinking cold beer, seized with sudden uterine pain; rigors; headache; delirium; pulse 120, weak; tongue dry and brown; constant vomiting and diarrhoea; delirium; great debility; coma; hurried respiration. Duration of disease nine days.	Leeches xii. to the temples, calomel, opium, pulv. cretæ comp. c. opio, fermentations, &c.	Died. Ovaria red, soft, and enlarged; left tube filled with pus; muscular coat of the uterus at the fundus where the placenta had adhered so soft, that the fingers passed through it in removing the parts; no inflammation of peritoneum or effusion into the abdominal cavity. Recovered.
95	Keene; æt. 34; 2, Little Earl Street. Tedious labour. 2d September, 1830.	Third day.—Uterus large, hard, and painful, especially on the left side; headache; slight rigor; pulse 132; lochia continue.	V.S. ʒxvj., leeches xij., calomel, antimony, opium, cathartics, pulv. ipecac. co.	Recovered.
96	—; æt. 30; Stewart's Rents, Long Acre. 5th October, 1830.	Third day.—Great uterine pain, increased by pressure; dyspnoea, and pain in right side of thorax; distension of abdomen. Duration of disease, five days. Dying when first seen.	V.S. copious leeches, fermentations, &c.	Died. Pleura and substance of lungs on right side inflamed; the left inferior lobe coated with lymph; two quarts of serum in the peritoneal sac; small intestines covered with lymph; uterus imbedded in lymph; uterine appendages inflamed; veins of uterus healthy.
97	Mrs. Wall; æt. 32. Protracted labour from distortion of pelvis. 1st November, 1830.	Attacked the day after delivery.—Acute uterine pain; uterus large and hard; lochia suppressed; pulse 100, soft; pain in left groin; pulse rapid; countenance dejected; great debility.	V.S. lb. ss., leeches xx., calomel, antimony, opium, cathartics.	Died. Two pints of a dark-coloured serum in the peritoneal sac; uterine peritoneum inflamed; both ovaria soft, red, and large, and when cut into seemed filled with a purulent gelatinous fluid; the absorbents of the uterus on the left side filled with pus; veins and muscular coat healthy.

98	Sexton; æt. 30; British Lying-in Hospital. Hæmorrhage. 19th December, 1830.	Third day.—Great uterine pain; lochia suppressed; headache; rigor; countenance dusky; pulse rapid and feeble; distressing flatulence; tympanites. Second day.—Intense pain of uterus and both groins; lochia suppressed; rigors; headache; vomiting; features collapsed; abdomen swollen; hurried respiration; pulse 120. Duration of disease, three days.	V.S. ʒiix., leeches xxxvj., calomel, antimony, opium, cathartics, &c. V.S. ʒxij., leeches xxxvi., calomel, &c.	Died.
99	Jones; æt. 24; British Lying-in Hospital. Natural labour. 20th December, 1830.			Died. The placenta had been attached to the left side of the fundus uteri; the veins here were lined with lymph and gorged with pus; the absorbents on the left side distended with pus; both ovaria large, and so soft that they were broken down by a small stream of water falling upon them; tubes inflamed; ʒiv. of serum in peritoneal sac, and patches of lymph over the small intestines.
100	Cecilia Boyd; æt. 31; 32, Peter Street. Natural labour. 28th December, 1830.	Fourth day.—A rigor; great pain in the region of the uterus; slight delirium; pulse 120, from the time of delivery; countenance pale; abdomen tumid; hypogastrium and iliac fossæ painful on pressure; constant dozing; tongue dry and brown; vomiting; flatulence; distension of abdomen; pulse rapid and feeble, and irregular.	V.S. ʒxij. (followed by syncope), leeches xxvj., calomel, opium, antimony, poultices, mercurial friction.	Died. Abdomen distended with gas; ʒvi. of red serous fluid in its cavity; peritoneum healthy throughout, except that portion covering the posterior surface of the uterus and its appendages; pus in cellular membrane under peritoneum of uterus behind; both spermatic veins contained pus in considerable quantities, as did also the venous branches at the angles and inferior portion of the uterus; the fallopian tubes vascular; the muscular coat of uterus healthy; no appearance of pus in the orifices of the veins at that part to which the placenta had been attached.

ON THE PROPER METHOD OF STUDYING CHEMISTRY

AS A BRANCH OF PROFESSIONAL AND
GENERAL EDUCATION,

Forming part of a Lecture, concluding the Chemical
Course in the University of Glasgow,
April 25, 1843,

DELIVERED BY DR. ROBERT D. THOMSON.

BEFORE bringing the chemical winter session to a close, I trust I may be excused if I direct your attention very briefly to the importance of the study of chemistry, and to the proper mode of acquiring a knowledge of the science. And in order to place this in a practical point of view before you, I think I cannot avail myself of a better method than to detail to you shortly the results of some of the investigations which have been undertaken during the past winter in the laboratory. Chemistry being a truly practical science, it is only by *working* that one can become familiar with its details. Lectures on chemistry can only assist you in practically working out a knowledge of the science. They are powerful, nay necessary auxiliaries; but by attending lectures alone, no man ever became a chemist, while by working, even without lectures, many chemists have been produced. In these observations I refer to lectures in which the lecturer alone performs the experimental illustrations. But there is another kind of lectures which have been introduced latterly into many schools, erroneously known under the title of Practical Chemistry, in which a number of students are formed into a class, headed by their lecturer, and are made to perform, by dictation, as many experiments as they conveniently can execute during one hour per day, or in some cases three times per week. The second kind of lectures, when arranged so as to make each student personally perform the experiments, is a decidedly important addition to the first kind of lectures; but if they are allowed to degenerate into a mere *short course of lectures* of the first description, and dispense with practice in the laboratory, which is very liable to happen, it may with some truth be apprehended, that the shadow is substituted for the substance, and thus students are led to believe that they are practically acquainted with chemistry, while, in fact, they have not been taught to handle a crucible. Those who have passed through the ordeal of their studies, and have engaged in their practical application to the business of life, reflecting upon the disadvantages under which they have laboured in their subsequent career, from a misdirection of their minds in their own practical education, must ever sympathise with their juniors who may be liable to suffer from similar influences. It is there-

fore usual with lecturers to bewail their own inattention to study in their youth, and to ascribe their deficiency to idleness. There may be some truth in this conclusion, but much depends on the proper direction of the mind to study.

Having had peculiarly extensive opportunities of comparing the methods of teaching chemistry in various parts of this country, and likewise on the continent of Europe, I have no hesitation in affirming, that the only method of studying practical chemistry is that introduced first by Dr. Thomson into Edinburgh, in the beginning of the century, and afterwards by him, in 1817, into Glasgow, viz., by the students personally working in the laboratory.

By combining analytic operations in the laboratory with the practical lectures alluded to, I believe that much good may be effected, and during the winter the laboratory pupils have accordingly been formed into a class during one hour, in which they have been exercised in the preparation of substances, and in manipulations, arranged in a systematic order.

The student, on commencing practical chemistry, should occupy himself with a simple analysis. To take to pieces a body consisting of two or three ingredients will probably be enough for him to manage in the first instance. With a medical student, some medicinal salt,—with the manufacturer, some ingredient employed in the arts,—and with the farmer, some simple constituent of the soil, may properly form their respective introductions to the practice of chemistry. He may then proceed to the analysis of minerals, and to more complicated substances. I shall only, however, allude to two of these, as they are not destitute of interest. Dr. Black examined the water of hot springs from Iceland, and found it to contain, in solution with soda, silica, or sand, a substance which, under ordinary circumstances, is well known to be insoluble in water. This was a most important observation, because it afforded a key to the explanation of the various appearances which silica assumes, whether as chalcedony, opal, or agate, and indicated the existence, at some period, of hot springs in those localities where such minerals are met with. Deposits in the neighbourhood of hot springs, it might be presumed, would contain much silica, and this is proved to be the case by the following analysis of a deposit from a hot spring in New Zealand:—

Silica	77.35
Alumina	9.70
Peroxide of Iron	3.72
Lime	1.55
Water	7.66

99.98

Another mineral analysed, from New Zealand, was the native Prussian Blue, or phosphate of the protoxide of iron. Its constituents were found to be—

Water	28.4
Organic Matter	2.8
Silica	5.2
Phosphate of Iron	62.8
	<hr/>
	99.2

Both of these analyses were made by Mr. Robert Pattison.

I notice this substance more readily because it was in directing the analysis of it that my attention was again recalled to a

proper mode of separating phosphate of iron from other phosphates, or iron from earthy oxides; and I think that by the use of cyanide of potassium, as prepared by Professor Liebig's easy process, or also by the use of tartaric acid, this separation can be easily effected. The study of this mineral was therefore a good introduction to the numerous analyses of soils which have been conducted in the laboratory during the session, principally by agricultural students.

In the following Table the results of four analyses of the same soil, from Erskine, are given, as executed by Messrs. Michelmores and Watson :—

COMPOSITION OF THE SOIL	When fresh.		After being some days in the laboratory.	
	Watson.	Michelmores.	Watson.	Michelmores.
1. Silica	249.86	214.5	247.1	213.87
2. Water of decomposed Soil . . .	111.17	110.60	90.5	53.95
3. Stony Matter	70.80	74.50	49.0	93.20
4. { Organic Matter, containing of . }	20.82	Carbon	20.50	8.15
		Azote		1.8
		Hydrogen, Oxygen
		Water of undecom. Soil
5. { Perox. Iron and Phosphates }	...	Perox. Iron	41.29	53.93
		Phos. Iron		1.9
		Phos. Lime and Magnesia		2.9
		Phos. Alum		1.2
6. Carbonate of Lime	5.97	9.1	18.24	24.79
7. Alumina	15.40	16.40	6.23	6.19
8. Magnesia	2.27	2.20
9. Sulphate of Lime	0.60	1.00
10. Chloride of Potassium	0.06	0.06
11. Chloride of Sodium	0.14

In this table I may call your attention to what must be viewed as an improvement in the analysis of soils. I found that the results by the old plan, of determining the organic matter of soils, were erroneous, and I have accordingly been in the habit of late of ascertaining the quantity of carbon and azote (the important elements for the nutrition of plants) by organic analysis. The

1.	10 grains of soil gave 5.4 per cent carbon, with red oxide of iron.
2.	10 grains " 6.8 "
3.	10 grains " 7.05 "
4.	10 grains " 1.85 "
5.	10 grains " 1.63 "

expensive nature of oxide of copper induced me to try black oxide of manganese and red oxide of iron as a substitute for the combustion of the organic matter, and in every instance the resulting carbon was so much in excess that I was obliged to abandon these bodies. Mr. Michelmores obtained the following results with the above soil :—

with black oxide of manganese.
with black oxide of copper.

The soils were in each experiment from the same parcel, and all at the same temperature,

But the analysis of a soil is of little value without the analysis of the grain which grows upon it; because it is by a comparison of the two results that we are enabled to determine whether a soil is calculated to produce a crop of a particular grain; for as the

grain derives its inorganic constituents from the soil, it is obvious that this affirmation must hold with truth in all cases. Analyses of grain grown with different manures have, therefore, engaged our attention, and some analyses of this kind I present to you, executed by Messrs. Michelmores and Watson, of oats, including the husks, grown at Erskine with—

	Foreign Guano.	Sulph. Soda.	Brit. Guano.
Organic Matter	967.25	970.58	972.24
Silica	11.37	15.28	13.37
Alkaline Phosphates	1.87	2.00	3.75
Phosphates of Lime and Magnesia	8.76	11.63	10.64
Phosphate of Alumina	0.60	0.50	trace
Phosphate of Iron	trace	trace	trace

For the quantity of inorganic matter in other specimens of oats, I refer you to the "Proceedings of the Philosophical Society of Glasgow," No. 6, just published.

There is still a kind of inquiry relative to agriculture, which forms the connecting link between that art and the science of health, and is, therefore, of equal value to the student of medicine and agriculture—I refer to the determination of the amount of the nutritive part of grain. Bread, we found in a preceding part of the course, contains the elements of the blood, and in proportion as the amount of these principles calculated to produce this fluid are greater or less in the aliment consumed, so is the latter possessed of superior or inferior nutritive power. The table annexed gives the result of a series of experiments upon the bread and flour of different countries.

The foreign bread was brought by myself from the towns mentioned; the flour was supplied by Mr. Wilson, Baker, of Gordon Street. The analyses were made by myself, and some of them were repeated by Mr. Watson and Mr. Michelmores. The numbers in the table were obtained by determining the quantity of ammonia which can be formed

from the azote contained in the flour. The process is exceedingly simple, and can soon be acquired. The second column is read thus: 100 parts of Naumburg bread are equal in nourishing power to 150 of States flour, &c.

	Nutritious Principles.	
	Per Cent.	Equiv.
Naumburg Bread (Prussia)	16.49	100.
Dresden Bread	14.30	115.31
Berlin Bread	14.21	116.04
Canada Flour	13.81	117.23
Essex Flour	13.59	121.33
Glasgow unfermented Bread	13.39	123.15
Lothian Flour	12.30	134.06
United States' Flour	11.37	145.03
Ditto Ditto	10.99	150.00

The process, exhibited to you in a former lecture, for the mechanical analysis of flour, is equally interesting to the farmer and surgeon, and should be mastered by both. The following was conducted by Mr. Michelmores, and was the specimen from the United States noticed in the table. The coincidence in respect to the nutritive principles between the results of the two analyses conducted in different ways, is highly striking:—

		Per Cent.
Starch	902.	68.73
Gluten {	Fibrin 116.8	130.4 9.93
	Casein 5.27	
	Glutin and Oil 3.04	
	Loss—Water 5.29	
Albumen	14.0	1.06
Gum	60.4	4.60
Sugar	16.3	1.24
Water	189.3	14.44
3 oz. = 1312.5 grs.		100.00

Your time will not permit me to enlarge further upon the subject of practical chemistry, that is, the dedication of as much time as possible in the laboratory to operations which require, on the part of the pupil, the exercise of the mind and hands; but before concluding, I cannot too much insist upon the indispensable nature of this study to the manufacturer, farmer, and medical man; for it is the essence of the arts of calico printing, dyeing, bleaching, &c. and we can in vain look for any permanent advance in agriculture until farmers are educated practically in the elements of chemistry, just as they learn

to plough, sow, and reap, or to sum up accounts. Without such a knowledge they will either be compelled to be sceptical or apathetic, as the chemical language addressed to them must be that of an unknown tongue, or they must ever be subject to be misled by the popular fallacies of the chemical empiric. To the surgeon and physician, practical chemistry, such as I have defined it, is as requisite as practical anatomy, and soon we may expect to find a session in the laboratory a part of the medical curriculum. The school which shall first take this position will show itself most alive to the progress of science.

The expense has been much overrated; and I believe the arrangements now adopted in the Glasgow College Laboratory will bring practical chemistry within the reach of most young men who desire to improve their minds by the study of one of the most valuable and interesting sciences with which man can occupy himself. But, as a branch of general education, I know of no study equally calculated to develop the mind. To make an analysis, that is, to divide a body composed of many parts united together into its ultimate constituents, a student must remember and reason, if he is properly taught; and if he enters upon a research, that is, a combination of analyses, one experiment arising out of another, until the united results enable a conclusion to be drawn, he becomes a disciple of Lord Bacon—an inductive philosopher, the safest condition for all study and for every profession. Irrespective, then, of the important knowledge to be acquired in the laboratory, the training which the mind undergoes is of the highest value, and I may appeal with confidence to all those who have passed through the studies of the laboratory, whether, whatever their future occupation in life has been, they have not had their powers of observation sharpened, and their appreciation of evidence improved, by their chemical education.

OBSERVATIONS
ON THE
CLIMATE OF THE BRITISH COLONIES OF NEW ZEALAND, NEW SOUTH WALES, AND VAN DIEMAN'S LAND,

AS COMPARED WITH THAT OF THE BRAZILS, MADEIRA, AND THE CONTINENT OF EUROPE:

From personal remarks, and the most recent authentic statistical data.

WITH A
FEW REMARKS ON THE DISEASES OF THE
"ABORIGINES," AND THOSE INTRODUCED BY EUROPEAN COLONIZATION.

BY JAMES B. THOMPSON, M.D.

(For the London Medical Gazette.)

HAVING, during my recent sojourn in the colonies, made some reports on the vegetable and mineral productions of New Zealand in particular, and which are published in the first number of the New South Wales Magazine for 1843, it may not be deemed uninteresting to offer a few remarks on the subjects with which this paper is headed.

I have selected the statistical facts from the most correct and authentic sources that were available during my brief sojourn in antipodean regions.

From the most recent and approved medical standard works on pulmonary complaints, (Sir James Clark, Williams, Stokes, and Louis), it would appear that the people of this country are subject, in a more than ordinary degree, to diseases of the chest and lungs; and that greater mortality arises from this than from any other class of disease. Now whatever difference of opinion may be entertained as to the extent to which this peculiar liability is attributable to the unequable character of the English climate, the influence of climate on pulmonary disease is universally admitted to be by no means inconsiderable. I arrived in Auckland, in New Zealand, on the 8th of October, 1842, and sailed for Sydney on the 3d of December, and during this stay of nearly two months I had an opportunity of visiting several of the native and European settlements, and had also an opportunity afforded me of observing the diseases prevalent amongst the natives—these being a form of scurvy called "fe fe," rheumatism, dysentery, diarrhoea, and ophthalmia. The venereal disease is now very prevalent at the Bay of Islands, which is the great whaling station, principally North American and French, and it is most painful to witness the awful and destructive ravages which this disease produces on the natives, male and female. They are naturally, from their mode of life and little regard to cleanliness or clothing, and exposure to night air, often lying in their damp coverlets after their fishing excursions during a hot day, predisposed to glandular affections: indeed, scrofulous affections seem to have been entailed on the present generation by this neglect, probably, on the part of their progenitors, and I would adduce this fact as a proof of the great fatality amongst the Aborigines generally when become diseased with venereal or any of our exanthematous complaints.

It is incredible in what a short time any of this latter class of diseases will run a destructive and fatal course—once the constitution of the native becomes tainted, nothing will effectually remove the germs of the virus:

they invariably become affected with pulmonary complaints, and no medical treatment seems capable of affording them permanent relief. If a case is seen at the very incipient stage, you may calculate upon being of some utility; but once beyond this, it is a hopeless case. Venereal, particularly, seems to run a quick and fatal course, producing the most extensive sloughing ulcers, and affecting the bones and cartilages in a more marked form than I have ever witnessed in any of our large British hospitals. The natives have a great objection to bleeding and vaccination, and in order to induce them to take any medicine, they will expect you to give them some present for so doing, as they imagine they are doing you a favour by acceding to your request on this point.

In the vicinity of the European settlements they are now beginning to appreciate the use of medicine, and the other many advantages likely to result from the attendance of a medical man, and have, in many instances, gone for advice and medicine to the colonial surgeon. The medical man must have recourse to more active and rigorous measures in all cases of fevers, inflammations, &c. than in England; he must, to make use of a homely phrase, be beforehand with the disease, and, as some of the old school would call it, be thereby enabled to "knock the disease under." This is the mode of practice requisite in all tropical climates, making it, of course, suitable to the previous history of the patient, and to meet the urgency of the individual case.

Having made a short visit to the Brazils on my return from the colonies, I had an opportunity of witnessing some diseases amongst the African slaves, both in the hospitals and amongst the out-door patients; and it would appear to me that they are predisposed to similar diseases with the Aborigines above alluded to, with the additional prevalence, probably, of dysentery, ophthalmia, and rheumatism. Those slaves who have been resident in Brazil for some years appear comparatively healthy, and whenever operated upon for any disease, the late much lamented Dr. Lowdon, surgeon for sixteen years to the British hospital at Pernambuco, informed me that they bore the operation

well, and became convalescent in a much shorter period than some of the Europeans operated upon at the same time and for a similar affection.

The wounds heal and cicatrize very quickly, unless there be some previous delicacy: They also seem to be equally exposed to the fatal consequences of venereal and the exanthemata. As an instance in confirmation of this latter point, I will here mention a circumstance which occurred just previous to my arrival at Pernambuco in May last. A slave-ship had arrived, having sailed from the opposite coast of Africa, Angola, with 1000 slaves on board; during the voyage, which is, on an average, about five weeks, and, from the want of ventilation and other necessary requisites for the comforts of these poor creatures, they lost 100 before they landed at the coast of Brazil; and in about ten days after there were only 600 souls left, 300 having died of small-pox. This was told me by Mr. Cooper, the British Consul. In corroboration of the fact of these slaves soon getting well after being operated upon, I think it may be well to mention that I saw one man in hospital who had been operated upon for a malignant disease, it was stated, in which it was necessary to remove a portion of the lower jaw. The man was nearly well when I saw him, and he bore this painful operation with great patience and fortitude.

Though the month of May is about the commencement of their rainy season in the Brazils, still I found it rather disagreeably warm and oppressive. They have had very little rain for the last year. The country is generally very low and marshy, and would lead one to expect such a place as would be rife for those diseases arising from miasmata and the direct rays of a tropical sun: still, it is remarkable how free from all such complaints this country generally is; in fact, it would induce one to doubt the existence of malaria or contagion, at least from atmospheric influence, and still more lead one to question the mischief so much talked of as arising from swamps and vegetable decomposition. The summer comprises three-fourths of the year here, and is somewhat hotter generally throughout than in England. The spring and autumn have the temperature, and clear settled weather, of

78	Leaney; æt. 26; British Lying-in Hospital. Natural labour. 11th January, 1830.	Thlrd day.—Headache; pyrexia; uterine pain; pulse 120; lochia suppressed; vomiting.	V.S. ℥iiv., leeches lx., calomel, opium, cathartics.	Recovered.
79	Messlin; æt. 22; British Lying-in Hospital. Natural labour. 13th January, 1830.	Second day.—Uterus large, hard, and painful; rigors; headache; lochia nearly suppressed; pulse 100; dyspnoea; cough; skin hot; pulmonic attack; abdomen distended; uterus hard and painful on pressure; vomiting; exhaustion.	V.S. ℥xvi., V.S. ℥xiv., calomel, Dover's powder, &c.	Died. Caput coli and transverse arch of colon covered with patches of lymph; uterus uncontracted, its anterior surface of a uniform dusky red colour; the muscular tissue under this reduced to a soft reddish pulp; the veins of the fundus uteri on both sides inflamed, and filled with a quantity of pus; both ovaria enlarged, their structure destroyed; fallopian tubes soft and vascular; lungs gorged with blood, but not inflamed.
80	Meaden; æt. 20; British Lying-in Hospital. 15th January, 1830.	Second day.—Headache; rigors; uterus painful, large, and hard; anxiety; countenance pale; breathing hurried; pulse 110; lochia scanty. Convalescent in 24 hours.	V.S. ℥xx., leeches xxiv., pulv. ipecac. comp. gr. v. 3tia q. q. hora.	Recovered.
81	Case after natural labour; British Lying-in Hospital. 28th January, 1830.	Third day.—Pyrexia; severe pain of the uterus, increased by pressure. Depletion followed by immediate convalescence.	V.S. ℥xx., calomel, opium, fomentations and poultices to hypogastrium.	Recovered.
82	Williams; æt. 26; a patient of Dr. Hugh Ley's, Middlesex Hospital. Natural labour. 13th January, 1830.	Eighth day.—Vomiting; rigors; severe uterine pain; foul tongue; offensive lochia; pulse 120, soft.	V.S. ℥xvj., leeches xij., calomel, antimony, and opium.	Recovered. During this month several severe cases occurred among the out-patients of the Middlesex Hospital. In all there was more or less pain in the region of the uterus, increased by pressure, pyrexia, and diminished lochial discharge.

83	Case in a Mews near Portman Square. Natural labour. January, 1830.	Sixth day.—Continued well for six days after delivery, when fever of a typhoid character came on, with slight abdominal pain; puffy swelling over the left wrist, and on one of the thighs; slight tympanites.	Sulphate of quinine and stimulants.	Died. Uterus large; the left spermatic vein through its whole course lined with false membranes, its coats thickened, the lower part filled with pus and lymph; the upper part distended with coagula of blood; the veins at left superior angle of uterus lined with lymph, and filled with a bloody, purulent fluid; the veins on the right side of uterus gorged with pus; the right spermatic vein was healthy, also both hypogastrics. Recovered.
84	Sophia Humphries. 30th January, 1830.	Third day.—Acute pain of uterus, increased by pressure; headache; tongue white; pulse 100; lochia scanty; bowels confined; blood cupped and buffed.	V.S. ℥xij., calomel, cathartics.	Recovered
85	Jones; 48, Marshall Street. Natural labour. 11th February, 1830.	Third day.—Pyrexia; acute uterine pain; lochia suppressed; rigors; pain and swelling of left iliac region; cough; suppuration at the brim of the pelvis; the pus escaped under Poupart's ligament. Recovered after five months.	Leeches often repeated, cataplasms, bark, wine, stimulants; abscess opened artificially.	Recovered
86	Honeyman; Angel Street, City. Natural labour. 12th February, 1830.	Fourth day.—Acute uterine pain; violent rigor; headache; lochia suppressed; pulse 115, strong; respiration hurried.	V.S. ℥xxx., leeches xxiv., calomel, antimony, cathartics, diaphoretics.	Recovered.
87	Case in the Edgeware Road. 20th February, 1830.	Second day.—Pain in the region of the uterus; rigors; lochia and milk diminished; slight delirium; pulse 115; tongue white; great tenderness in the situation of right uterine appendages.	V.S. ℥xj., leeches, calomel, antimony.	— In the month of April, 1830, three cases occurred, which all yielded speedily to venesection, leeches, calomel, antim., Dover's powders, &c. The details of these cases are not preserved.

88	Mrs. Hadden; æt. 30; 3, Castle Street, Bloomsbury. Arm presentation.	Fourth day.—Uterine pain; lochia suppressed; rigors; pain in right groin; pulse 100; tongue white. The pain was not effectually relieved till cathartics were freely administered.	V.S. ℥xij., leeches xvj., calomel, antimony, cathartics.	Recovered.
89	Mrs. Sears; æt. 26; 23, Church Lane. Natural labour. 20th June, 1830.	Fourth day.—Great uterine pain; pulse 100, full; lochia suppressed; rigors; blood cupped and buffed.	V.S. ℥xvj., leeches xxiv., calomel, antimony.	Recovered.
90	Mrs. Allen; æt. 26; 12, Phoenix Street, St. Giles's. Natural labour. 10th June, 1830.	Fourth day.—Uterine pain; pulse frequent and full; lochia suppressed; tongue brown; vomiting; pain in right groin; pulse 130; respiration hurried.	V.S. ℥xxvj., calomel, antimony, opium, cathartics, salineeffervescing draughts.	Recovered.
91	Sankey; 35, Wardour Street. Protracted labour. June, 1830.	Soon after delivery, a sudden attack of fever, with severe pain in the right iliac region and left groin and thigh; rigors; tongue loaded. July 12: the left iliac region is hard, swollen, and painful on pressure,—the hardness extends half way down the thigh, in the course of the femoral vessels; great constitutional disturbance. Aug. 6: a great quantity of pus discharged above Poupart's ligament. A slow but complete recovery.	Leeches, poultices, anodynes.	Recovered.
92	Mrs. Gyde; æt. 22; Brewer Street, Golden Square. Natural labour. 26th June, 1830.	Second day.—Rigors, and pain of the lower part of the abdomen, with pyrexia and suppression of the lochia. 29th: pain but slightly relieved; fever continues. July 4th: intense pain of the whole abdomen, and distension; pulse rapid and feeble; constant sickness and vomiting; tongue brown. 6th: symptoms aggravated. Died on the tenth day from attack.	V.S. ℥xij., leeches xij., opium, leeches, a blister, cathartics.	Died. lb. ij. of dark-coloured sero-purulent fluid in peritoneal sac; the whole abdominal viscera inflamed; small intestines, omentum, and uterus, all glued together with lymph; an abscess under the peritoneum of the uterus, near its fundus, on the left side; a small abscess in the body of the uterus on the left side; uterine appendages on both sides vascular, and coated with lymph.

93	Phillips; æt. 32; 2, Sussex Street. 30th July, 1830.	Fifth day.—Great uterine pain; pulse 130; violent headache; exquisite tenderness, increased by pressure, in the left side of the uterus, which gradually diminished, and the pulse became less frequent. A slow recovery.	V.S. ʒi., leeches xij., calomel, antimony, opium, cathartics.	Recovered.
94	Mrs. Chapman; æt. 36; 9, Belton Street, Long Acre. Natural labour. 19th August, 1830.	Fifth day.—After drinking cold beer, seized with sudden uterine pain; rigors; headache; delirium; pulse 120, weak; tongue dry and brown; constant vomiting and diarrhoea; delirium; great debility; coma; hurried respiration. Duration of disease nine days.	Leeches xii. to the temples, calomel, opium, pulv. cretæ comp. c. opio, fermentations, &c.	Died. Ovaria red, soft, and enlarged; left tube filled with pus; muscular coat of the uterus at the fundus where the placenta had adhered so soft, that the fingers passed through it in removing the parts; no inflammation of peritoneum or effusion into the abdominal cavity. Recovered.
95	Keene; æt. 34; 2, Little Earl Street. Tedious labour. 2d September, 1830.	Third day.—Uterus large, hard, and painful, especially on the left side; headache; slight rigor; pulse 132; lochia continuæ.	V.S. ʒxvj., leeches xij., calomel, antimony, opium, cathartics, pulv. ipecac. co.	Recovered.
96	—; æt. 30; Stewart's Rents, Long Acre. 5th October, 1830.	Third day.—Great uterine pain, increased by pressure; dyspnoea, and pain in right side of thorax; distension of abdomen. Duration of disease, five days. Dying when first seen.	V.S. copious leeches, fermentations, &c.	Died. Pleura and substance of lungs on right side inflamed; the left inferior lobe coated with lymph; two quarts of serum in the peritoneal sac; small intestines covered with lymph; uterus imbedded in lymph; uterine appendages inflamed; veins of uterus healthy.
97	Mrs. Wall; æt. 32. Protracted labour from distortion of pelvis. 1st November, 1830.	Attacked the day after delivery.—Acute uterine pain; uterus large and hard; lochia suppressed; pulse 100, soft; pain in left groin; pulse rapid; countenance dejected; great debility.	V.S. lb. ss., leeches xx., calomel, antimony, opium, cathartics.	Died. Two pints of a dark-coloured serum in the peritoneal sac; uterine peritoneum inflamed; both ovaria soft, red, and large, and when cut into seemed filled with a purulent gelatinous fluid; the absorbents of the uterus on the left side filled with pus; veins and muscular coat healthy.

if attention be paid to the facts I have mentioned, there will be no need to part with a tried and established remedy for one whose mode of action is no doubt essentially similar.

I might also remark, that the nitrate of silver seems to possess an almost equally beneficial action when applied to the skin in the immediate vicinity of other inflamed or irritable mucous membranes. My opinion was requested by a medical gentleman some months back, on a patient of his who had been under his care for about four months. It was a case of gonorrhœa, which had been about eight months under treatment before it came under the care of the gentleman alluded to. The patient was a young man of full habit, and a wine merchant, who was tolerably fond of good living. Almost every plan of treatment that could be thought of had been carefully tried, and had failed, over and over again; and at the time of my seeing him there was still a considerable discharge of thick yellow matter from the urethra, much pain in making water, and occasional attacks of chordee. By my direction the nitrate was applied along the under surface of the penis, as far as the scrotum, and also slightly behind it. I again saw this gentleman about three days afterwards, when he informed me that he was better than he had been for months, that the discharge was nearly gone, and serous, and that he had no pain in making water.

Since that period I have not seen either the patient or his medical attendant, and am therefore unacquainted with the termination of the case; but I left him with an understanding that he was to paint over the course of the urethra with the tincture of iodine about twice a week, until all the symptoms were removed.

13, Bloomsbury Square.

PECULIAR SOUND OF THE HEART, INDEPENDENT OF VALVULAR DISEASE.

To the Editor of the Medical Gazette.

SIR,

THE following case has been thought so interesting, that I have been requested to publish it. It proves the possibility of the existence of certain sounds of the

heart, *frémissement cataire*, and of a peculiar jerking pulse, supposed to be sure signs of valvular disease, when none existed.

Henry Hughes, æt. 31, admitted into the Brighton Hospital, March 15, 1843, died June 3, 1843; a tinman, of a full, bloated habit. He was in the hospital about a year before, and had a hard superficial tumor, the size of an egg, taken from the loins. His present symptoms are, pain in the back; acute pain in the loins, as if they were broken; urine scanty, turbid; violent cough; mucous expectoration, not copious; bronchial sibilant râle all over the chest; pulse from 120 to 160, small, jerking; sounds of the heart strong, as if the left ventricle were hypertrophied; *frémissement cataire*, as if from mitral regurgitation; biliary secretions healthy.

For these symptoms he was bled, cupped, took ipecacuan, colchicum, digitalis, diuretics.

Post-mortem Examination. — Hard encephaloid tumors all over the parietes of the chest, from the size of a pin's head to that of an egg, embedded more or less in the muscular substance; lungs full of the same; mesenteric glands all hard and enlarged; large mass of similar tumors beneath and about the base of the heart, pressing upon and binding the aorta and heart; similar tumors beneath the stomach. The gall-bladder unusually distended with healthy bile. Lumbar vertebræ carious, the interior absorbed, leaving only a shell, through which the knife passed with slight pressure. Bronchial glands enlarged and hardened. The heart and valves perfectly sound; the ventricles rather small; and the parietes rather thin.

The peculiar pulse and the sounds of the heart seem to have been caused by the number of hard tumors which pressed upon the aorta and heart, and in a degree strangulated and modified its action.—I am, sir,

Your obedient servant,

W. KING,

Physician to the Brighton Hospital, Fellow
of the Royal College of Physicians.

Brighton, August 1843.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Lectures on the Comparative Anatomy and Physiology of the Invertebrate Animals, delivered at the Royal College of Surgeons in 1843. By RICHARD OWEN, F.R.S. Hunterian Professor to the College. From Notes taken by W. W. COOPER, M.R.C.S., and revised by Professor OWEN. Illustrated by numerous woodcuts. London, 1843. 8vo. pp. 392

It is unnecessary to recommend a work on comparative anatomy by Mr. Owen; it is sufficient to announce its appearance.

The book consists of twenty-four lectures; and the Professor has added to Mr. Cooper's notes the details which, for want of time, Mr. Owen omitted in the theatre.

Spiders, it seems, generally have eight eyes, and never less than six:—
“The spiders which inhabit short tubes, terminated by a large web exposed to the open air, have the eyes separated, and more spread upon the front of the cephalothorax.

“Those spiders which rest in the centre of a free web, and along which they frequently traverse, have the eyes supported on slight prominences, which permit a greater divergence of their axes; this structure is well marked in the genus *Thomisa*, the species of which lie in ambush in flowers. Lastly, the spiders called *Errantes*, or wanderers, have their eyes still more scattered, the lateral ones being placed at the margins of the cephalothorax. The structure of these simple eyes resembles that which has been so well described by Müller in the scorpion; Lyonnet had recognised the crystalline lens. The iris, or process of pigment which advances in front of the lens, is green, red, or brown, in the diurnal spiders, and black at the back part of the eye. The nocturnal species, as *Mygale* and *Tarantula*, have a brilliant tapetum, but no dark pigment.” (Page 256.)

Professor Owen's lectures will be eagerly perused by those who have leisure for the delightful science of which they treat.

Next year he will lecture on Vertebrated Animals.

On Feigned and Factitious Diseases, chiefly of Soldiers and Seamen, &c. By HECTOR GAVIN, M.D. &c. London, 1843. 12mo. pp. 436.

DR. GAVIN'S Essay gained the prize proposed by the Professor of Military Surgery at Edinburgh, in 1835. It has been since altered and enlarged, and is a very creditable performance. We extract the following excellent observations with great pleasure. The author says that Scott, Forbes, and Marshall, “do not plead for the notorious malingerer; but when instances of deception become *frequent*, in any country, in any garrison or station, in any regiment, or in any ship of war, they presume that the question may be very reasonably asked—is there not something wrong in the arrangement of the place, in the government or administration of the particular portion of the community in which such frequent deceptions abound? something which, acting injuriously on the bodies or minds of the men, is therefore not beneath the consideration of the medical officers of the establishment, who alone can appreciate the mischief, and by whose mediation alone it is likely to be remedied? The privilege conferred by their profession, of being the *friend of mankind*, is one which ought not to be willingly resigned. A striking exemplification of the truth of the foregoing remarks was shown in Trinidad, on the completion of the emancipation of the slaves. *The hospitals were emptied*; the sick were cured, the lame healed, the blind were restored to sight, and the insane to their senses. The boy of the Monday before, belonging to the second or lower gang, was suddenly endowed with the strength and muscle of a man, and wanted a full task; whilst the feeble man, whose strength before would not allow him to go through the work of the first gang, found it instantly renovated to the necessary pitch: the whole being the miraculous result of the sanatory effects of freedom.” (p. 45-6.)

If Dr. Gavin's book reaches a second edition, which it richly deserves, he

should revise his Latin quotations, some of which are in a very perplexing state.

On the Curative Influence of the Climate of Pau, and the Mineral Waters of the Pyrenees, on Disease. With descriptive notices of the Geology, Botany, Natural History, Mountain Sports, Local Antiquities, and Topography of the Pyrenees, and their principal Watering-Places. By A. TAYLOR, M.D. London, 1842. 12mo. pp. 342.

THE work before us is divided into nineteen chapters discussing the various points relating to the Pyrenean watering-places which are likely to interest either the physician or the invalid. The places described are Pau, Bagnères de Bigorre, Capbern, Barèges, St. Sauveur, Cauterets, Eaux-Bonnes, and Eaux-Chaudes. If we might hint a fault, we would suggest that the author should completely translate a number of French sentences in the geological part, which have been left in a transition, or Anglo-Gallic state. For example: "The secondary formation is composed of grès rouge, grès blanc, grès schisteux, and poudingue. With the exception of some beds of limestone, these rocks do not contain any foreign strata. The minerals accidentally met with, disseminated in the grès rouge, are fer sulphuré, fer hydraté, and cuivre pyriteux. The baryte sulfatée laminaire, rarely accompanied with a small portion of cuivre carbonaté and ocre de fer, frequently forms veins in the red sandstone." (p. 129.) Dr. Taylor's book contains solid information, and will be consulted with advantage.

MEDICAL GAZETTE.

Friday, August 25, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE PLEA OF MONOMANIA IN CRIMINAL CASES.

ONLY two kinds of madness are recognized in popular language—the furious

and the melancholy. When these forms are strongly developed (as in the figures by Cibber, which adorned the front of the old Bethlem, in Moorfields,) the patients are unfit for any of the offices of life. Such patients can neither fill the higher stations of society, nor perform the humble duties of hewers of wood and drawers of water. But there is a third kind of insanity, which, though it must always have existed, has but lately obtained a fixed place in nosology. We mean *monomania*—a name first given by Esquirol some thirty years since.

If we were asked by a medical student where he could learn the nature of this mental disease, we should refer him to the wards of a lunatic asylum, where he would find plenty of examples; but if the question were proposed by a man of letters, disinclined to study insanity practically, we should say, "Read Don Quixote once more."

In the romance of Cervantes we find a gentleman of fine feelings and cultivated understanding, who has hung over the tomes of chivalry till the day-dreams which they suggest have swallowed up the dull realities of life. Yet, although actual existence must have appeared to him flat and unprofitable, he seems to have carried on his affairs, not well perhaps, but tolerably, until his monomania passed into the second stage, and he sallied forth in quest of adventures. And now Cervantes brings us to that delicate point, where monomania touches upon crime, and hallucinations lead to acts incompatible with the peace of society. The knight of La Mancha, taking Amadis of Gaul, or him of the Burning Sword, for his guide, resolves with his own right arm to redress the wrongs of the world:—

Parcere subjectis, et debellare superbos!

His delusions, meantime, are on the increase; his eyes, misguided by his brain, become very faithless inter-

preters of the external world, and turn a flock of sheep into an army, and a barber's basin into Mambrino's helmet. In short, his hallucinations lead him so widely astray, that without being a criminal in the vulgar sense of the word, Don Quixote is constantly on the verge of committing murder. To most readers his adventures seem ludicrous to the highest degree, and palpably impossible; yet we might say to the modern monomaniac,—

mutato nomine, de te
Fabula narratur!

Thus, some addle-headed mechanic imagines that the difficulties which perplex society can be solved by the simple expedient of destroying the head of the state, or the leading politician of the day; the knot of human affairs, too great for his capacity to unravel, can be severed, he thinks, by the knife or the bullet. What is to be done with the assassin? The old, and perhaps the best plan, was to hang him. Oh! no! cry many modern writers, you must not hang him; for the man is a lunatic, and lunatics, says the law, are not chargeable for their acts.

Here, then, is a forensic difficulty of no ordinary magnitude. On the one hand, no one would send a stark, staring madman to the gibbet.

On the other, while it is clear that these political or religious enthusiasts are not of perfectly sound mind, the same is true of all criminals whatsoever; and if we acquit every assassin whose crime appears to lack an adequate motive, and all who have appeared at any time whimsical or crotchety, additional Bethlems may entirely replace Australia and the gallows.

No human being can draw an unerring line between the madness which makes a man irresponsible for his crimes, and that which still leaves him

answerable to the law. It is the effect of discussion, however, and the office of legislation, to clear up some of the extreme points; and it is plain that to treat the assassin as an innocent man, merely because he has added murder as a kind of climax to his previous deviations from right, is of the most dangerous consequence to society. If he had killed a hare, his eccentricity would not save him from jail: he has sacrificed a man, and his life should expiate the deed. "A rogue," said Coleridge, "is a round-about fool—a fool in circumbendibus;" but the knave cannot therefore claim the privileges of the untainted simpleton. Nor is it true that capital punishment would be useless as an example to other monomaniacs. The half-mad, who perfectly understand the meaning of the gallows, abound, and on them the execution of a murderer is by no means lost.

Hence the Frenchman who thought that homicidal insanity was best cured on the *Place de Grève*, was not far from the mark.

On a former occasion* we ventured to assert, that the jury did right to acquit Macnaughten, if they believed him to be destitute of the glimmering of reason which would enable him to see the link between murder and the gallows; but though most persons who have seen him agree that he is mad, it may be doubted if he could have been acquitted by our test.

Among the writers who have lately endeavoured to throw light on this intricate subject, is Dr. Stark, of Edinburgh, who has lately put forth a pamphlet on the responsibility of monomaniacs for murder.

Dr. Stark is not always consistent with himself. Thus, immediately after insisting on the capital punishment of murder, because it is enjoined in the Pentateuch, he asserts that murder is

* MEDICAL GAZETTE, March 24th, 1843.

the only crime for which life ought to be forfeited, forgetting how numerous were the offences punished capitally by the Mosaic law.

But passing over this, let us proceed to three important questions which he asks and endeavours to answer.

The first is, "*Are all monomaniacs necessarily led to acts of destruction?*"

"By no means," we should reply, and all the world with us. There are, however, two classes of destructive monomaniacs; those, namely, who have always been homicidal, and those who have become so, as a subsequent and accidental symptom in monomania of another form. Dr. Stark, however, will only allow of the latter kind, where the thirst for blood is engrafted upon the monomania of love, ambition, or fanaticism; and will not hear of it as a separate disease. Nevertheless, it exists; yet, we should be loath to make its existence a shield for the murderer. Ought a Thug to escape the gibbet which he has earned so richly and so repeatedly, because he has been a murderer from his youth up, and wrong is to him right?

The next question is, "*Does the existence of mental alienation on one point so confuse a man's intellects as to deprive him of the power of judging between right and wrong?*"

Some will reply "Yes!" Dr. Stark answers "No!"

Instead of entering into all the intricacies of this difficult problem, we would again refer to the test we gave above, or to Lord Brougham's speech on the 14th of March last, as quoted by Dr. Stark. "Then what was the true distinction which the law drew between right and wrong? Why lawyers told us that that which was according to law was right, and what was contrary to law was wrong. Then why not say so in so many words? This was the test he suggested."

The third and last question is, "*Are monomaniacs impelled to commit murder or suicide by a power which they cannot resist, so that they do not act as free agents?*"

Dr. Stark answers this question broadly in the negative. Whether this answer is universally true is of little importance. Let the legal test be applied to the assassin, and if he has enough reason to know that he is committing a capital crime, he has no cause to complain that the sentence of the law is executed in his person. It is quite certain, too, that the execution of a monomaniac checks the propensity to crime among other persons suffering under partial insanity. Dr. Stark observes, that the monomaniacs who committed murder in imitation of Henrietta Cornier amounted to a dozen at least, but not one of the imitative murders occurred till the result of the trial was known, that the prisoner, namely, had been acquitted on the plea of insanity.

Dr. Stark is astonished that judge and jury should be so much guided by the medical witnesses in trials where insanity is pleaded on behalf of the prisoner. "I say, I cannot understand how they allow this—how they allow themselves to be led by the *opinion* of a man who, however eminent his standing in his own profession may be, is far from being nearly so capable as the judge (aye, or even, perhaps, the jury-men themselves), of forming a sound opinion on the facts which he may have heard from the ordinary witnesses, or from his having seen the prisoner once or twice."

We suppose that judge and jury are guided by the old maxim, *cuique in sua arte credendum est*; and that they believe an old mad-doctor who has treated ten thousand lunatics to have more tact in discerning insanity than the most experienced draper in the

jury-box. As to the quantum of insanity which makes a man irresponsible for his crimes, that is a different matter. It is a point of law rather than of physic, and can hardly be better explained than in Lord Brougham's speech.

In conclusion, we think that monomania can seldom be a valid defence to a charge of murder. The law has not lost its terrors for monomaniacs; a fact which might easily be deduced from their being amenable to discipline in a lunatic asylum.

REGULATIONS OF THE COLLEGE OF SURGEONS.

THE Regulations of the College of Surgeons have just been altered in the following points :—

1. Students were formerly required to bring proof "of having studied anatomy and physiology, by attendance on lectures and demonstrations, and by dissections, *during three anatomical seasons or sessions, extending from October to April inclusive.*"

The latter part of the rule now runs thus : "*during three winter sessions, of not less than six months each.*"

2. Each course of the practice of surgery, physic, chemistry, materia medica, and midwifery, was formerly of the obligatory length of seventy lectures: this is now left undefined.

Moreover, the following circular has been sent round to medical teachers :—

Royal College of Surgeons in London,
August 15, 1843.

Sir,—I am directed by the President of this College to transmit to you the inclosed copy of their Amended Regulations respecting the professional education of candidates for their diploma; and, at the same time, to express the opinion of the Council that it is highly inexpedient that the pursuits of the Students should be interrupted by a vacation at Christmas, or at any other period of the winter, and to state that they strongly recom-

mend that the vacation hitherto allowed should be discontinued.

I am, sir,

Your most obedient servant,

EDM. BELFOUR, Sec.

These alterations are of different degrees of merit. The London College of Surgeons was the only educational body which required an anatomical session to continue seven long months, from October to April inclusive.] A change much desired by many teachers has now taken place. But the College might perhaps have done better had it required the anatomical session to continue from November to April, both inclusive; thus insuring its commencement on the 1st of November, and its continuance for six months only. It was scarcely advisable to abolish the present minimum of seventy lectures for a course, and substitute no other in its stead; and whatever may be thought of some subjects, seventy lectures are certainly not too many for a course on the practice of physic, surgery, or midwifery.

There is an obvious danger, that among so many schools under no observation or control, a very insufficient number of lectures may be given, even on the most important subjects.

We believe that the College thought the pupils over-lectured; while the Society of Apothecaries could not see this; and hence probably this imperfect attempt at legislation.

We do not like the scheme of abolishing all holidays at one fell swoop. Hard unvarying toil, unsweetened by the gaieties of festive seasons, and the charities of domestic intercourse, will not make better men, or better surgeons. The student should be allowed to leave his murky lodging for a while, and fly on railway wings to Devonshire or Cumberland. Give him extra examinations, if you please, but do not cut off his intervals of repose.

UNIVERSITY OF LONDON.

B.M.—EXAMINATION FOR HONOURS, 1843.

Thursday, Aug. 17.—Morning, 10 to 1.

Anatomy and Physiology.

Examiners, Mr. KIERNAN & Prof. SHARPEY.

State the dissection required to expose the glosso-pharyngeal nerve and its branches after its exit from the cranium; commencing at the integuments, and describing the several parts brought into view in the dissection. The tympanic branch of the nerve not to be traced.

Afternoon, 3 to 6.

1. A line being drawn round the arm two inches above, and another two inches below the bend of the elbow, describe the soft parts seen in dissecting the included portion of the limb, both before and behind, in the order in which they appear. The joint not to be described.

2. Give an account of the structure and mode of distribution of the capillary vessels in general, with the differences they present in respect of size, number, and arrangement, in different textures, and in the same texture at different periods of life. What evidence can be produced for, and what against, the existence of colourless capillaries?

Friday, Aug. 18.—Morning, 10 to 1.

Chemistry.

Examiner, Professor DANIELL.

1. What are the analogies which subsist between light and heat? Why, in a bright winter's day, is the snow melted around a leafless shrub or a post, whilst it is little affected by the direct rays of the sun?

2. What do you mean by *specific electric induction*?

3. State Professor Ohm's theory of voltaic force and resistances; and apply his formulæ

$$\frac{E}{R+r} = A \text{ and } \frac{nE}{nR+r} = A \text{ to the explanation of quantity and intensity in the voltaic current.}$$

4. To what is the (so-called) *polarization* of the plates and electrodes of a voltaic circuit to be ascribed; and how may it be prevented?

5. Describe the principal phenomena of magneto-electric induction.

6. Describe and exemplify the characters of *monobasic*, *bibasic*, and *tribasic* acids.

7. What is Professor Graham's view of the constitution of *double salts*?

8. Draw a parallel between the principal compounds of ethule and methule.

9. What would be the products, carefully collected, of ten grains of tartrate of silver

($\bar{T} + 2 \text{ AgO}$) burned with oxide of copper; the silver to be determined by a separate experiment.

Afternoon, 3 to 6.

Materia Medica and Pharmaceutical Chemistry.

Examiner, DR. PERRIRA.

1. How is the presence or absence of copper in oil of cajuputi to be ascertained? If powdered rhubarb were adulterated with powdered turmeric, by what chemical test would you detect the fraud? By what chemical means would you determine the absence of poppy oil in a given sample of castor oil?

2. Describe the microscopic appearances of starch-grains, and point out by what characters you would detect the presence of potato starch in West India arrow root, illustrating your answer by a sketch of the shapes, &c. of these two kinds of amylaceous grains.

3. Describe the mode of preparing the *Antimonii Oxysulphuretum*, Ph. Lond.; explain the chemical changes which attend the process; and state the composition of this medicine.

4. Describe the effects and uses of arsenious acid; and especially point out those symptoms which are apt to follow the long-continued medicinal employment of this substance. State what remedies you would resort to in a case of acute arsenical poisoning.

5. Enumerate the principal purposes for which cold is employed as a therapeutical agent.

6. Describe the botanical characters and medicinal qualities of *Ranunculaceæ*.

7. Name the substances respectively numbered 1, 2, 3, 4, 5, and 6.

FIRST EXAMINATION.

The names are arranged in the order of proficiency.

LUNATIC ASYLUM REPORTS.

BELFAST ASYLUM,

Health of inmates.—The general health which pervaded the whole establishment, throughout the past year, was extraordinarily good; even during the severest weather scarcely a cough was to be heard; and from the beginning of the month of November to the middle of the February following, a period of upwards of three months, not a death had to be recorded—a length of time unprecedentedly long, in the annals of the establishment, without a casualty of this kind. The total amount of deaths which occurred during the year was eighteen (an average of about $7\frac{1}{2}$ per cent.), being nine less than last year.

Restraint of lunatics.—The average daily number of patients, during the year, amounted to 249.44—last year's was 244.67. Amongst so large a number, the cases requiring recourse being had to temporary physical restraint did not amount to more than two per cent. throughout the whole year.

There was no greater day of excitement in the establishment, during the year, than on the 12th of July last, or one more loudly calling for the application of restraint; inasmuch as, on this remarkable anniversary, a regular pitched battle had well nigh taken place amongst some of the females, in support of their respective political opinions and predilections; and, to prevent which, the nurses had to use the utmost vigilance during the day, which, however, happily passed over without any thing very serious occurring.—*Thirteenth Annual Report, by Dr. Stewart.*

DUNDEE ROYAL ASYLUM.

THE treatment, medical and moral, is of course much the same as before—the former, varied according to the different kinds of disease; and the latter, though it may have presented new modes of enjoyment, or of relaxation, or exercise, has still been the same in principle as before.

It would be uninteresting both to the meeting and the public to detail the numerous opportunities of innocent enjoyment afforded to the inmates of the Institution, as they have been so often noticed in former reports. One occurrence of sufficient importance to have occupied your time, the visit to the Asylum of the celebrated Mr. Mainzer, has been already so fully described in the different newspapers, and by the Rev. Mr. Roxburgh in the Directors' Report, that it is unnecessary here to do more than allude to it. We may just remark, that the conduct

of the patients on that occasion was becoming; several showing very striking proofs of self-control.

We have got an Accordion for the use of the patients, and hope soon to have an Organ. Rocking-horses are being made similar to those in other institutions.

On several occasions, George Duncan, Esq. Member of Parliament, the Sheriff, the Chairman, and other Directors and Office-bearers, dined at the Asylum with a select number of the patients.

Religious Services.—The benefits arising from the performance of Divine Service are still very apparent. The opportunity of attending the chapel is highly prized by very many of the patients. One of them, an epileptic, says, "Let me go, and should the fit come on I can just be carried out." The experiment of allowing some of them to take the Sacrament in Dundee, was again tried both in October and April last, and with the most beneficial results.

Restraint.—During the whole of last year there was not a single patient under personal restraint of any kind.

Many of the patients estimate highly the kindness and attention with which they have been treated. Two proofs of this, which occurred last year, may not be unworthy of notice. One of the pauper patients who was discharged cured, came on foot a distance of fifty miles to see his old acquaintances in the Asylum. Two persons who had formerly been patients, being seized with premonitory symptoms, presented themselves at the Asylum, and insisted on being admitted.

To the Directors we beg again to tender our respectful thanks, for the uniform kindness and attention which they have shown to us individually, and to the interest of the Institution generally.

To Mrs. Kilgour, the Matron, we beg also to express our thanks for the great zeal with which she has seconded all our efforts, and for many valuable suggestions.

PATRICK NIMMO, Physician.
A. MACKINTOSH, Surgeon,
Superintendent.

MONTROSE LUNATIC ASYLUM.

A TABLE which is given shows the admissions to have been 12 males and 18 females—making 30—equal to those of the preceding year. But, among the former, one individual is marked twice; as, though not having relapsed, he required treatment in the Infirmary for some weeks, after which he again occupied his old position.

In respect to age, the admitted may be ranked thus:—

Up to 20, two; thence to 30, six; to 40,

three; to 50, eleven; to 60, three; to 70, two; and to 80, three. The average age is a fraction above 44.

In most of the cases, there was obviously bad health, or bodily disease in some form, at the time of entry—as paralysis, epilepsy, delirium tremens, among the males—hysteria, dyspepsia, scorbutic or rather scrofulous affections, with dropsy, in the other sex. On the whole, they required a greater amount and variety of purely medical treatment than any corresponding series during my charge. As, to a certain extent, confirming this remark, it may be mentioned that three, out of the six deaths occurring within the year, were of individuals received into the House since last Report. One of them was from dropsy—in a female; the second occurred in a male, who, besides the direct consequence of intemperance, early assumed symptoms of typhus, which I have encountered only once before in the Asylum during five years; and the third, which took place suddenly, seemed to have arisen from epilepsy—the malady for which, a few months previously, he had been a patient in the Infirmary. To complete the list—though not exactly in due order—the remaining deaths, three, were all of persons advanced in life, and one of whom had been an inmate for more than 40 years—in fact the oldest and longest residenter in the House. His occupation in early life, I may add, connected him incidentally with a well-known disaster—the loss of the Royal George—on which he had worked as a carpenter. One of the three—a female—was admitted in 1831. She laboured long under epilepsy, but otherwise enjoyed tolerable health, though perpetually in bed; and, in regard to moral qualities, was one of the most amiable and engaging creatures ever under my care. A man—deaf and blind—particularly noticed in a former Report, completed this trio. He sank gradually, without lucid intervals.

Sundry interesting features were presented in a few of the admitted; but, saving one, I shall not advert to them on this occasion. It afforded an exemplification of derangement in the propensities, emotions, or sentiments, without discoverable lesion of intellect; and was the more remarkable, as well as more certainly receptive of sympathy, because unaccompanied by any spirit or disposition tending towards the injury of others. It might be characterized, in a single sentence, as a case in which terror predominated, totally in opposition both to reason and daily experience. For some time after admission, every new event, no matter how trivial, excited that demon, whom it was impossible to cast out, subdue, or even assuage. Under his dominion, the poor patient, an inoffensive and seemingly

well-principled female, proved at once a sore grievance and a laughing stock to her astonished sisters. On the one hand, her outcries and violent perturbation broke their usual quietude. On the other, such extraordinary disproportion—in fact, such entire contrariety—between her paroxysms of agitation, and the circumstances on which they depended, became, at times, the cause of merriment, if not a provocative to sarcasm. I found it practicable at times to work on her own sense of the ludicrous, to which some of her apprehensions, rightly interpreted, gave ample exercise. They latterly varied in kind or object, became gradually weaker, wore off, and then could be recollected as some thing like dreams. Now, strange as to some it may seem, this woman's perceptions of all objects, so far as I could judge, were quite correct; while her judgment—I speak of the reasoning power—was perfectly adequate to her safe guidance under the usual occurrences of life. How, then, shall we explain her constant unmitigated wretchedness—for she really was altogether miserable—where every circumstance was regulated so as to secure her safety and promote her comfort? I answer—simply by asking another question. How shall we explain the intense horror, or agonising distress—not to be escaped from—which there are few persons who have not experienced during some minutes—passing as long, long heavy hours—of sleep? For theory and speculation on the topic, I have neither time nor liberty in discharging immediate duty. I cannot even advert to its intimate connection with a matter greatly debated of late, and, in sundry quarters, as I cannot help believing, most erroneously represented—that, namely, to which the doubly indefinite, and, consequently, very disputable, expression has been applied—the responsibility of monomaniacs. Somewhat prematurely, as I think, this patient was removed by her friends—greatly composed, but not entirely free from a tyranny that rendered her equally pitiable and troublesome.

Our state of health during last year continued generally good, and had only a few—and these trivial—interruptions. I think scarcely above six patients—and these at different periods—were bed-ridden, even throughout the rigour and storms of winter. There cannot be a doubt, that, under Divine goodness, exemption from serious or widespread disease was owing to the measures, in regard to diet, clothing, air, exercise, employment, and recreation, steadily pursued, and found to be efficacious. I can vouch also for the predominance in the House of order, peace, and contentment—for the reality as well as the display of which, Mrs Macfie (now, not a little unhappily, to

be styled the late matron,) must receive a full meed of commendation. Her excellent endowments—for a short time put forth on the narrow field of action which Montrose presents—will be amply tested, as I hope earnestly they may be sustained, in the vastly wider dominion of Middlesex County Asylum.

The proportion of recoveries—or, at least, of restoration to ordinary life, during the year—say about 14 out of the total discharged—though not large, is as fair as, in my opinion, the state and circumstances of our inmates generally might lead the experienced to expect. Incurable cases are, so to say, the rule in all old Asylums, and certainly abound; while the promising and curable form exceptions to it—more to be wished for than calculated on.—*Report for the year ending June 1, 1843, by R. Poole, M.D.*

RETREAT NEAR YORK.

DURING the past year, extending from Midsummer 1842 to Midsummer 1843, there have been 21 patients admitted into the Retreat; being three more than during the preceding year. This is a rather greater number than has been admitted during any single year, for the last fifteen years; and at the present time there are 94 patients remaining in the house, or more than have been under care at one time, for three years. The average number, however, resident during the year has not exceeded the average for the three years now expired.

Of those admitted during the year, four were neither members of the Society of Friends, nor connected with it; and, at the date of this report, there remain twelve not so connected, under care.

There have been 10 patients discharged recovered during the year. This is a very satisfactory number; and, as was anticipated in last year's report, such as fully compensates for the smaller number reported for that year.

The general health of the inmates of the Institution has been good; and the deaths, which were 4 in number, have been rather below the average; giving 4.46 per cent. as the mean rate of mortality of the year. The mean annual mortality of the Institution, for the previous three years, 1839-42, was stated in last year's report at 4.53 per cent. and that for the entire period of its operation, of 47 years, from 1796 to 1843, is 4.77 per cent. Though, however, the mortality of the past year is somewhat below the average, it is obvious that, where the numbers under care are comparatively so small, little value can attach to the varying results of single years. The annual review

of these results may, however, become both interesting and useful, by suggesting the probable causes of the fluctuations which are observed in them; provided due caution be observed as to the inferences which are thus formed.

The diseases which proved fatal, during the year, were general paralysis with gangrene, in the male; and pulmonary consumption in one female, atrophy in a second, and disease of the heart in a third. The last of these patients was seventy-six years of age, and had been for forty years under the care of the Institution. The average age of those who died was sixty-three years and a quarter. * * *

The importance, however, of placing the patient under proper care at an early period of the disorder is not only apparent from a comparison of the results of treatment, but is equally inculcated by that aggravation of the disorder and increased difficulty of management, which are the nearly uniform results, when persons attacked by insanity are detained at home. The friends of the patient are not always aware of these facts; but when they are, are too often repugnant to stamp the case with the character, or, as some think, the stigma, of confirmed insanity. It is believed, however, that more correct views with respect to mental disorders, and such as cannot but prove more advantageous to the patient, are gradually diffusing themselves in the public mind. "Whoever," as Sir James Mackintosh wrote to the celebrated Robert Hall, "has brought himself to consider a disease of the brain as differing only in degree from a disease of the lungs, has robbed it of that mysterious horror, which forms its chief malignity." By these remarks, however, it is far from being intended to recommend the premature removal to hospitals for the insane, of persons attacked by mental derangement, or by delirious excitement. Such a course, in many cases, is altogether unnecessary, and, in some, would be positively injurious; and it should rarely, if ever, be resorted to except under the advice of a judicious medical practitioner.

Nothing material has to be reported this year with respect to the internal economy and management of the Institution. Were it indeed an object in these reports to record every modification of practice or addition to the plans of treatment, or to report the respective results of established means, such might in several respects be stated. As, however, it has become the annual practice to present a statement of the numbers more or less employed, as well as the modes of employment during the year, a Table has been prepared to exhibit these. From a comparison of this table with those of previous years, it will be seen that as large a

proportion have been in different ways occupied during the past as during any former year. It is satisfactory to state that our conviction of the importance of agricultural pursuits, in the treatment of a large proportion of patients of the male sex, is confirmed by the experience of succeeding years.

It seems here due to the Committee and Directors of the Institution to mention the great addition to the cheerfulness and comfort of the establishment, during the winter months, which has resulted from the introduction of lighting by gas, as well as from the warming of the corridors by a hot-water apparatus.

In concluding this report, I can hardly avoid taking the opportunity of stating, as it is highly gratifying to me to be able to do, that during the past year the important duties of the attendants have been performed to general satisfaction; and that, to many of those filling the office, I feel much indebted for the efficient manner in which they have carried out my views and wishes, as well as those of the other officers of the establishment.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

*Historical account of uterine inflammation
in puerperal women.*

WE know from the ancient writers that puerperal women have been liable in all ages to attacks of inflammation of the uterine system. In the works, however, of the earlier authors, its history is short and imperfect; and it is probable that the disease did not attract the particular attention of physicians before the middle of the 17th century, when it occurred at Paris as a malignant epidemic in the lying-in wards of the Hôtel-Dieu, and the bodies of those who died of it were found to be full of abscesses. Since that period it has often been observed in the principal cities and lying-in hospitals of Europe, both in a sporadic and epidemic form, and has been denominated by medical authors puerperal fever, child-bed fever, puerperal peritonitis, peritoneal fever, puerperal typhus, the epidemic disease of lying-in women. Upwards of 200 cases of this disease have come under my observation since the spring of 1827, the histories of more than 160 of which have been reduced into a tabular form. I have watched the symptoms and progress of these cases with the closest attention; observed the effects of the different remedies employed, and where death took place I carefully examined the alterations of structure in the uterine and other organs. The bodies of a great number of women have been inspected by myself personally: this task was not delegated to others ignorant of the pathology of the uterine system; and in all, without one single exception, there was some morbid change, decidedly the effect of inflammation, either in the peritoneal coat of the uterus or of its appendages, in the muscular tissue, the

lining membrane, or in the veins or absorbents of the organ, which accounted in a most complete and satisfactory manner for all the constitutional disturbance which had taken place during life. The ganglia and nerves of the uterus were the only structures which were not examined. These observations entirely subvert the opinion that there is a specific, essential, or idiopathic fever, which attacks puerperal women, and which occurs independently of any local affection in the uterine organs, and may even prove fatal without leaving any perceptible change in the organization of any of their different textures. As the constitutional symptoms thus appear invariably to derive their origin from a local cause, as the local affection is always uniform, and nothing else is so in the history of the disease, I have thought that it would be more philosophical, and more consistent with the correct principles of nosological arrangement, to banish entirely from medical nomenclature the terms puerperal and child-bed fever, and to substitute in their place that of uterine inflammation, or inflammation of the uterus and its appendages in puerperal women. The confusion and error which have hitherto prevailed on this subject have recently been aggravated by a futile attempt to include under the term "puerperal fevers," not merely the disease usually known by the name puerperal fever, but puerperal intestinal irritation, which is a totally distinct affection; hystericalgia, or what has incorrectly been called false peritonitis, and milk fever. "If, under the head of *puerperal fevers*," says the author of this new and unscientific arrangement, "we are to include all the fevers to which lying-in women are liable, and that are peculiar to the puerperal state, we must not pass over what is commonly called *milk fever*."

Until a recent period, the pathological anatomy of the uterine organs in puerperal women had not received that attention which its importance demanded. In the histories of the different epidemic fevers which have prevailed amongst lying-in women since the middle of the 17th century,

the symptoms and the morbid appearances, though imperfectly described, nevertheless strongly confirm the conclusion that the whole phenomena, local and general, of these fevers, are to be referred to inflammation of the uterine organs, and that the symptoms vary according as the superficial or the deeper-seated structures are affected. The winter of 1746 at Paris was most destructive to puerperal women, and they died between the fifth and the seventeenth day after their confinement. The epidemic attacked the indigent, but much less frequently and severely those women who were delivered at their own habitations than in the Hôtel-Dieu. Of twenty women in child-bed affected with the disease in February of that year, in the Hôtel-Dieu, scarcely one recovered.

M. Malouin has giving this history of the epidemic:—"The disease usually commenced with a diarrhoea, the uterus became dry, hard, and painful; it was swollen, and the lochia had not their ordinary course; then the women experienced pain in the bowels, particularly in the situation of the broad ligaments; the abdomen was tense; and to all these symptoms were sometimes joined pain of the head, and sometimes cough. On the third and fourth day after delivery the mammæ became flaccid. On opening the bodies curdled milk was found on the surface of the intestines; a milky serous fluid in the hypogastrium; similar fluid was found in the thorax of certain women, and when the lungs were divided they discharged a milky or putrid lymph. The stomach, the intestines, the uterus, when carefully examined, appeared to have been inflamed. According to the report of the physicians, there escaped clots on opening the vessels of this organ." "This terrible disease," says M. Tenon, in the *Mémoires sur les Hôpitaux de Paris*, p. 243, "has shewn itself at different epochs, and its returns have been more frequent than ever; it re-appeared every winter from 1774; it commenced usually about the middle of November, and continued till the end of January. It is met with also at the other seasons of the year, even during spring, for it has come to prevail more and more, and to be as it were naturalized. Those who were attacked in the years 1774 and 1775 died between the fourth and seventh days after delivery, and seven out of every twelve women who were delivered were seized with the disease. Two distinct forms of it were successively observed, one a simple form, which was cured by ipecacuan; the other a complicated form, for which there was no remedy; so that there perished in 1816, one of every seven of those who were attacked with puerperal fever, and death took place from the sixth to the eighth day after delivery, and often much earlier. The first symptoms manifest themselves twenty-four, or forty-eight hours after de-

livery, and sometimes, but rarely, in the space of twelve hours. The symptoms of the simple puerperal fever are developed in the following order: rigor, slight pain in the region of the kidneys, intestinal colic, which in two hours affects the whole hypogastrium, and gradually becomes more acute. Pulse concentrated, fever moderate, lochia not suppressed; mammæ flaccid, tongue dry in the middle, covered with a yellow mucus on the edges; hiccup and vomiting of green-coloured matters. There was sometimes combined with these constant and characteristic symptoms of the disease which took place in the years 1774 and 1775, a diarrhoea of a bilious glairy matter, a considerable swelling of the hypogastrium, thirst, and remarkable retention of urine. In the complicated puerperal fever the pyrexia is stronger, with exacerbations, the tongue is black and dry, the belly is tense, distended, and tympanitic, and slightly painful. In some women the lochia have been either wholly suppressed or only diminished; others have experienced attacks of ophthalmia; in some the respiration was difficult; in general the blood shewed the buffy coat. On opening the abdomen, the stomach, the intestines, particularly the small intestines, were inflamed, adhering to one another, distended, filled with air and a yellow fluid matter. The uterus was contracted to its ordinary dimensions, and was seldom found inflamed. I had occasion to dissect two: in one the uterus contained a coagulum of blood; an infiltration of a milky appearance, or whey-like fluid existed in certain women in the cellular membrane which surrounds the kidneys. Sometimes, also, a thick white cheesy matter was met with when the lungs were gorged with blood, or inflamed, or emphysematous, an effusion of serum was found in each side of the chest. We did not observe the hæmorrhages which occurred in the epidemic of 1664, and the uterus was not found dry, hard, and tumefied, as in that of 1746. In the epidemic of 1774, the lochia flowed, but they did not flow in 1746. "Sauvages, chiefly on the authority of Sennert and Mauriceau," observes Dr. Craigie, in his *Elements of the Practice of Physic*, "referred the disease to the head of inflammation of the womb, of which he distinguished three forms; the puerperal, the typhoid, or that complicated with malignant fever, and the milky, or that from suppression of the mammary secretion; the first and third, however, equally inflammatory in nature and tendency. In 1770, there appeared in the Hospital of St. Mark, at Vienna, a puerperal epidemic, which Storck regarded as inflammatory; and the disease continued to prevail in the same city for the two ensuing years with great fatality; with considerable abdominal swelling and pain in the hypogastric region: on inspection after death the intestines were found covered by false

membrane, and several viscera, and among others the womb, bore marks of inflammation and gangrene. About the same time, the disease, which had originally been noticed by Strother (1718), and Burton (1751), in England, began to attract particular attention. Dr. Denman, the first English author who gave an express account of it, does not appear to have formed any very decided opinion of its nature. He speaks, indeed, of the inflammation of the womb, of the tenderness and pain of the os internum, and of the signs of inflammation preceding those of putridity. But he admits that he never had an opportunity of examining the body of any one who died of this disease, and adopting the appearances mentioned by Lieutaud as accordant with the result of later dissections, is satisfied with saying that the milky matter (*materia lactea*), with which the intestines were said to be covered, is probably an inflammatory exudation (p. 39). Dr. Manning, who wrote shortly after (1771), like most authors of the day, confounded the pathological or proximate cause with the remote causes, and ascribes all its phenomena to the putrid tendency of the humors." Drs. Hulme and Leake considered inflammation of the omentum to be the proximate cause of the disease, and the latter suspected that the whole mass of circulating blood becomes contaminated by absorption of the fluids effused into the peritoneal sac. "Considering," observes Dr. Leake, "the suppuration of the omentum, and large quantity of purulent fluid found in the abdomen after death, it is easy to see how a secondary fever, which was truly inflammatory at the beginning, may soon become putrid, by absorption of that fluid, which like old leaven, will taint the blood, by exciting a putrid ferment in the whole mass, and change its whole qualities into that of its own morbid nature. Some of those who survived recovered very slowly, and were affected with wandering pains and paralytic numbness of the limbs, like that of chronic rheumatism. Some had critical abscesses in the muscular parts of the body, which were a long time in coming to suppuration, and when broke discharged a sanious ichor." Dr. William Hunter, on examining the bodies of those who died from puerperal fever, found the viscera and every other part of the abdomen inflamed. There was a quantity of purulent matter in the cavity of the abdomen, and the intestines were all glued together. Pain of the head and abdomen, with fever, were the symptoms which Dr. Lowder considered to be pathognomonic of the disease; and redness of the peritoneum, adhesion of the intestines, effusion of serum mingled with pus and lymph, the most frequent morbid appearances. The history of the symptoms and morbid changes of structure, by Drs. Joseph Clark, Gordon, Campbell, Mackintosh, and other writers, is nearly the same;

and the late Dr. Hamilton, who believed that puerperal fever was a fever *sui generis*, nevertheless admitted that the appearances on dissection were exactly similar to the descriptions generally given by these authors, and that acute pain of the abdomen was a primary and not a secondary symptom of the disease. In the epidemic puerperal fever, which prevailed at Aberdeen between the years 1789 and 1792, Dr. Gordon examined the bodies of three patients who died of the disease, and in each the peritoneum and uterine appendages were inflamed. "The omentum," he observes, "does not appear to be more especially affected than the other productions of the peritoneum; which are all equally and indiscriminately affected. The dissections which I have made prove that the puerperal fever is a disease which principally affects the peritoneum and its productions, and the ovaria. The peritoneum was inflamed, and the omentum, mesentery, and peritoneal coat of the intestines, were all promiscuously affected." He found blood-letting and cathartics to be the most important remedies. Dr. John Clarke admitted that in most cases of the true puerperal fever which he examined, there was some degree of inflammation in the cavity of the abdomen, and that the uterus and the ovaria sometimes partook of the inflammation. In the greater number there was a large quantity of fluid in the peritoneal sac, and all the surfaces of the viscera and of the peritoneum were covered with a crust formed of the solid part of this matter, resembling coagulable lymph. The parts, however, lying under this coat or crust, were not always inflamed. The attempt made by Dr. J. Clarke to distinguish uterine inflammation from the low child-bed fever sometimes epidemic, is now universally admitted to have been unsuccessful; there is no distinct limit which bounds them in nature; and all pathologists now admit that these copious effusions into the peritoneal sac are invariably the result of acute inflammation, and not of any peculiar disposition of the vessels of the part, as he supposed. The works of Dr. Armstrong and Mr. Hey contain the histories of two epidemics, in which the leading symptoms were those which are present in cases of abdominal inflammation, and the employment of copious blood-letting, cathartics, and other antiphlogistic remedies, was attended with decided benefit. The actual condition of the uterine and other organs, was not, however, ascertained by either of these writers, as they were not permitted to examine the bodies of any of those who were cut off with the disease. Pinel, Bichat, Laroche, and Gardien, found the peritoneum inflamed in so many fatal cases, that they have considered this disease, as Mr. John Hunter did, essentially to depend on inflammation of the peritoneum. A foreign author, who has subsequently ob-

served the disease, and who entertains the same opinion of its nature, asserts that nothing can be more absurd, more chimerical, or more contrary to the spirit of analysis and observation, than the idea that there is a fever essential or peculiar to women recently delivered. The bodies of 56 women were examined who had died of puerperal fever in the General Hospital at Vienna, in the autumn of 1819, and in all of these, with the exception of two, where delivery had taken place a considerable time previous to death, effusions of sero-purulent fluid were found in the abdominal cavity, and traces of inflammation in one or more of the abdominal viscera. The ovaria and fallopian tubes were always more or less swollen, red, and tender, and the body of the uterus was in consequence of inflammation flabby, tender, and easily broken down with the finger. It is also stated in the report of this epidemic, that the accession of fever is always preceded by marked changes in the whole system, particularly in the uterus, clearly indicating an inflammatory state. The symptoms, indeed, were such that the inflammation combined with high fever could not be mistaken.

Still more recent, and far more extended and accurate researches, have been made on the morbid anatomy of the uterine system in those who have died of puerperal fever. Of 222 cases examined by M. Tonellé in 1829, at Paris, there were traces of peritoneal inflammation observed in 193. There was more or less redness, and increased vascularity, of the peritoneal coat of the intestines, or of the mesentery, omentum, or peritoneum covering the uterus, with more or less effusion of serum, pus, and lymph. Changes resulting from inflammation were observed in the uterus and its appendages in 197 cases; which proves that the uterine system was more frequently affected than the general peritoneal sac. Inflammation of the ovaria was observed in 58 cases, and suppuration of them in four, and it appears from another statement that inflammatory lesions of the ovaria were observed in 99 cases. Traces of inflammation of the peritoneum, and in the uterus or its appendages, were found variously associated in 165 cases, and they were found separated in 57. In the substance of the uterus and ovaria there was simple inflammation in 79; superficial softening in 29; deep-seated softening in 20; inflammation of the ovaria in 58; suppuration in 4. In 90 there was purulent matter in the veins; in 32 in the absorbents; in 3 in the thoracic duct; and 9 along with inflammation and suppuration in the lumbar, inguinal, and other glands: the total changes in the uterus thus amounting to 324. Suppuration within the veins was accompanied with suppuration of the uterus in 32 cases; with softening in 11; with inflammation and softening combined in 5; with peritonitis without any other change, in 34; or without any other

lesion in 8. Suppuration within the lymphatics was associated with phlebitis in 20 cases; with metritis in 13; with softening without suppuration of the uterus in 6; with simple peritonitis in 3; without other lesion in 2. Inflammation of the ovaries was distributed in the following manner: associated with simple peritonitis in 29 cases; various changes in the uterus in 27; simple inflammation in 8; softening in 7; suppuration of the vessels in 12; all the previous alterations united in 16.

From all these facts discovered by morbid anatomy, you can now be at no loss to comprehend why inflammation of the uterus in puerperal women is so frequently fatal, so little under the control of remedies, and why it has been so difficult to give a clear and correct delineation of its constitutional symptoms. The facts disclosed by morbid anatomy, observes the learned pathologist already quoted, show that all the original descriptions of puerperal fever, however elaborate, from Strother and Denman, to the present times, are more or less inaccurate, in so far as they confound together the symptoms belonging to lesions of different parts and tissues. "Much confusion, disorder, and discordance, indeed, have prevailed among practical writers on the number and nature of the distinctions which they admit of the several forms and varieties of puerperal fever. Nor in the recent descriptions by different obstetrical authors does it appear to have been made practicable to avoid ambiguity in distinguishing the symptoms into different forms. Most authors agree that there are varieties in the disorder; but on the number and characters of these great discordance prevails. The great difficulty consists in the circumstance that though very generally the disease begins with inflammatory symptoms more or less distinctly marked, yet in almost all cases these are quickly succeeded, and as it were masked or disguised, by symptoms, in which feebleness, languor, listlessness, and mortal oppression occupy a prominent part, and consequently present that general character to which many physicians have applied the name of putrid, typhoid, ataxic, and adynamic. We have seen that J. Clarke considered it as an epidemic low fever of specific character, yet was obliged to admit that it is attended with inflammation of various abdominal and pelvic organs. Peu, Tissot, White, Alphonse Le Roy, looked on it as a putrid, typhoid, or adynamic fever; Antony Petit and Selle thought it a nervous fever; Doulat ascribed it to a gastric disorder; and lastly Walter, Johnston, Forster, and Cruikshank, Baillie, Hull, and Hey, deemed it a local inflammation of the peritoneum. The systematic writers have not diminished this discordance, and by the multiplicity of division and refinement in distinction they have rather obscured than elucidated the subject. Boer, the most accurate observer of the nature, character,

and tendency of this disorder, distinguished it in 1806 into four forms: the first, the benign puerperal fever not inflammatory; the second, inflammatory puerperal fever; the third, anomalous puerperal fever; and the fourth, the malignant puerperal fever not inflammatory. M. Vigarous distinguishes five species of puerperal fever—first, the gastro-bilious, marked by intense hypogastric pain; 2d, the putrid-bilious, distinguished by great debility, small intermitting pulse, hypogastric swelling, with frequent pain, and putrid symptoms; 3d, the pituitous or mucous; 4th, the phlogistic or uterine inflammation, denoted by sense of great weight in the pelvis, hypogastric swelling, pain and hardness, with acute fever; and 5th, sporadic puerperal fever, proceeding from mental emotion, distress, &c. Gardien recognises six varieties of the disorder—1st, the angiotenic or inflammatory; 2d, the adeno-meningeal or mucous; 3d, the gastric or bilious; 4th, the adynamic or putrid; 5th, the ataxic or nervous; and 6th, that complicated with affection of other organs. These varieties, M. Martin, of the Hôpital de la Charité, at Lyons, augments to seven in the following manner:—1st, the gastric, the most frequent, often complicated with worms, with epigastric pain, headache, and full pulse; 2d, the intestinal, also complicated with worms, with meteorismus, borborygmi, and diarrhoea; 3d, the epidemic puerperal, assuming the character of the prevailing epidemic constitution; 4th, puerperal fever from retention of the placenta, first inflammatory, then adynamic or typhoid, with hard painful hypogastrium, small pulse, and faintness; 5th, adynamic or putrid puerperal fever, succeeding the gastric variety; 6th, puerperal uterine inflammation, marked by fixed pain in the region of the womb, suppression of the lochia, hard pulse, redness of the margins of the tongue, dry skin, and porraceous vomiting; and 7th and lastly, puerperal fever consequent on mental emotions, profuse hæmorrhages, copious external suppurations, or purulent deposits in the substance of organs, always terminating in ataxic or nervous symptoms. Still more recently Dr. Samuel Cusack distinguished the disease into three forms—1st, the genuine inflammatory, marked by acute abdominal pain and tenderness, quick hard pulse, and other symptoms of synocha; 2d, the low or typhoid, generally epidemic, and allied to erysipelas and typhus fever, and similar low disorders, without tenderness, but with dull weight in the hypogastrium, weak languid pulse, and a sense of great faintness; and 3d, a mixed form, partaking of the characters of both, with abdominal tenderness, yet with the pulse neither so hard and incompressible as in the first, nor so weak as in the second variety. M. Tonellé refers all the varieties of the distemper which he observed under

M. Desormeaux to three principal forms: an inflammatory form, a typhoid, and an anomalous or ataxic form; which, he thinks, correspond to the different lesions of the solids, of the fluids, and of innervation. The inflammatory form he further subdivides into two varieties: one in which the inflammatory symptoms were open, distinct, and permanent; the other in which they were transitory, and were speedily followed by typhoid symptoms. The second variety and the typhoid form were by far the most prevalent, and were generally, if not invariably, associated with softening of the womb, and purulent matter within the veins and lymphatics, whether that were the effect of venous inflammation, or received within their interior by absorption. This division has been modified by Mme. Boivin and M. Dugès, who admit only two forms, one the simple inflammatory, or metro-peritonitis angiotenica, with strong full hard pulse; the other the typhoid, in which, though the symptoms are at first inflammatory, a secondary adynamic state speedily ensues, with small, contracted, oppressed pulse, burning heat, intense thirst, and great oppression of all the vital and animal motions; and they refer to the latter both the typhoid and the ataxic form of MM. Desormeaux and Tonellé. Lastly, Dr. Lee, discarding the name and nosological characters of puerperal fever and puerperal peritonitis, as hitherto maintained by authors, considers the several febrile disorders ensuing on parturition as essentially dependent on inflammation of the womb and its appendages; and the different forms which they assume as referable to the circumstance of affection of the serous, muscular, or venous tissue of the organ. Little doubt can be entertained that, so far as our knowledge of the relations between the external symptoms and the affection of the internal organs goes, this view is the most rational. If it be still imperfect, that is rather to be attributed to the circumstance, that in very few cases, perhaps, is one tissue exclusively affected, and consequently it is difficult, if not impracticable, to connect in any given case the external signs with any single lesion. The symptoms of mere peritoneal inflammation are modified, or it may be obscured, by those arising from ovarian or tubal inflammation, inflammation of the substance or inner surface of the womb, or the symptoms of uterine venous inflammation. This circumstance shews at once that the terms of typhoid, or adynamic, or ataxic puerperal fever, whether applied to forms or stages of puerperal fever, must convey a most erroneous notion of the pathological nature of the disease, and are in every respect inadmissible. Puerperal and typhus fever agree in no circumstance, unless in their concluding stages, namely, the production of the fatal event."

TABULAR VIEW (No. 2) OF 62 ADDITIONAL CASES OF INFLAMMATION OF THE UTERUS AND ITS APPENDAGES,

Observed by me from January 1831 to the end of April 1835.

No.	Name, Residence, and Delivery.	Date of Attack and Symptoms.	Treatment.	Result and Morbid Appearances.
101	Holding; 4, Marshall Street, Golden Square. Natural labour. January 18, 1831.	Third day.—Severe uterine pain; rigors and headache; lochia suppressed; pulse 130; features pallid; enlarged painful veins at the top of left thigh; great debility; vomiting; pain ceased.	V.S. ℥xvj., leeches xlviij. thrice, calomel, cathartics, stimulants, &c.	Died. Intestines distended with air, their peritoneum healthy; peritoneal coat of the posterior part of the uterus coated with lymph; both ovaria large and soft, the right covered with lymph; the muscular coat of the uterus, at the superior and anterior part where the placenta had adhered, of a yellow colour, and easily torn; the veins at the neck of the uterus on the left side filled with pus; the absorbents at the left superior angle of the uterus, and between the broad ligaments, filled with pus. Died.
102	—; æt. 22; Northumberland Street, New Road. Natural labour. February 7, 1831.	Third day.—Violent pain and enlargement of uterus; no rigor; pulse 140, feeble; incessant vomiting; tympanites; delirium; lochia not suppressed.	V.S. ℥xvj., leeches liv., blisters, mercurial friction, calomel, antimony, opiates.	Died.
103	—; Compton Place. Natural labour. February 22, 1831.	Fifth day.—Slight uterine pain; headache; pain and swelling of groin; lochia suppressed; delirium; tremors; pale and sunken countenance. March 2d: iliac fossæ painful and swollen; no pain in umbilical and epigastric regions; nervous tremors.	V.S. ℥xvj., leeches, cataplasms, stimulants. Dying when first seen.	Died.

104	Mrs. Crampton; 75, Gray's Inn Lane. Natural labour. May 16, 1831.	Fifth day.—Acute uterine pain; severe pyrexia. On the 12th day hectic fever; a large abscess pointing at the groin, from which a quantity of pus was discharged.	Leeches xxiv. three or four times, poultices, cathartics, opiates.	Recovered.
105	Mrs. Baird; æt. 30; Meard Street. Natural labour. May 1831.	Third day.—Pain in the region of the uterus, increased by pressure; suppression of lochia.	V.S. ʒviiij., calomel, Dover's powder, &c.	Recovered.
106	A Lady; æt. 26; Great Prescott Street. Placenta retained six hours. June 19, 1831.	In a few days great tenderness of the uterus and fever, with great prostration of strength. At the end of three weeks pain and tension along the brim of the pelvis, and a colourless swelling of the whole left inferior extremity. July 21st: pulse 150; nausea, vomiting, diarrhoea; tongue brown; dusky hue of skin; cough, dyspnoea, and expectoration. Died 24th July.	Leeches, fomentations.	Died. Uterus greatly reduced in size; recent adhesions between the uterus and rectum, and a quantity of pus; peritoneal and muscular coats of fundus and body soft, and of an inky-black colour; branches and trunk of left hypogastric vein full of pus, and lined with dark-coloured false membranes; the coats of common external, iliac, and femoral veins thickened and filled with lymph and pus; the vena cava in the same state.
107	Mr. Morley's case; Queen Street, Seven Dials. July 24, 1831.	Second day.—Rigors; tenderness of the hypogastrium; suppression of the lochia; rapid feeble pulse. July 31st: slight distension of abdomen; delirium; sickness; vomiting.	V.S. ʒij., leeches, calomel, antimony, cathartics.	Died. Double uterus; extensive peritonitis, with sero-purulent effusion; uterine appendages imbedded in thick masses of lymph; veins of cervix uteri on left side full of pus.
108	Williams; 1, Kennedy Court, Crown Street. Hæmorrhage and retained placenta. July 29, 1831.	Second day.—Pain in the hypogastrium; rapid feeble pulse; suppressed lochia; no relief after the first leeches; great uterine tenderness; ptyalism, followed by a remission of all the symptoms.	Leeches xvij. twice, calomel and opium, and cathartics.	Recovered.

109	Porter; 21, High Street, Long Acre. Instrumental labour. August 7, 1831.	First day.—Great tenderness of abdomen; pyrexia; lochia scanty; abdomen tympanitic. Continued conscious till death.	V.S. twice during labour and twice after delivery, leeches, &c.	Died. Extensive peritonitis; inflammation of the peritoneum, covering the uterus and intestines, and softening of posterior part of uterus; uterine appendages inflamed; great effusion into the abdominal cavity.
110	Case in St. Marylebone Infirmary. October 1831.	Acute pain in the region of the uterus; rapid feeble pulse; vomiting and tympanites.		Died. Inflammation of uterine peritoneum, ovaria and tubes; extensive effusion into the peritoneum.
111	Bentley; British Lying-in Hospital. Natural labour. December 1831.	Intense soreness in the region of the uterus, aggravated by pressure; lochia suppressed; pulse 120; rigors; severe headache; thirst; pain extending to umbilical region.	V.S. 3xx., leeches xxiv., calomel, opium, cathartics, Dover's powder.	Recovered.
112	Howard; Tichfield Street. December 1831.	Constant pain in uterus, increased by pressure; lochia suppressed; pulse natural; rigors; violent headache.	V.S. 3xviiij., calomel, and opium.	Recovered.
113	Wood; St. James's Infirmary. Natural labour. December 19, 1831.	Second day.—Pain in right side of hypogastrium; chills, not rigors; lochia scanty; tenderness increased; pulse 135; vomiting.	V.S. 3xviiij., leeches xij., calomel and opium, V.S. 3xij., leeches xij., V.S. xvij.	Recovered.
114	A lady; at. 26; Conduit Street. Natural labour. January 6, 1832.	Severe irritation of the bowels from a cathartic before labour; 16 hours after delivery diarrhoea, with severe pain, increased by pressure, over the whole of the hypogastrium; pulse 160; no rigor. This might have been considered a case of intestinal irritation, but the symptoms did not subside till leeches had been applied, and calomel and opium given.	Leeches, calomel, Dover's powder, a blister.	Recovered.
115	A lady; at. 25; South Street, Manchester Square. Protracted labour. January 9, 1832.	Twenty-four hours after delivery had a severe rigor, followed by tenderness of the uterus, increased by pressure; uterus large and hard; lochia scanty; tongue furred, dry, brown; delirium; hurried respiration; pulse 160, soft and feeble; vomiting. Jan. 12th: great pain in the left side of the hypogastrium; tympanites; vomiting; delirium; diarrhoea. 18th: pulse 145; tympanites and other bad symptoms subsided, but she had nearly died afterwards from paralysis.	V.S. 3xxiv., a great number of leeches, and large quantities of calomel and opium, clysters, blisters, sedative draughts.	Recovered.

116	Case; British Lying-in Hospital. January 9, 1832.	Second day.—Pain in the region of the uterus; pulse 130; seemed to recover after the bleeding, and subsequently died with symptoms of inflammation of the deep structures of the uterus.	V.S. ℥x. (blood not buffed), calomel, extr. of colocynth, mistura salina c. camph. et ammonia, emplastr.	Died.
117	Case; British Lying-in Hospital. January 9, 1832.	Thirty hours.—Rigors; slight tenderness in the region of the uterus, increased by pressure; with quick pulse, loaded tongue, and suppressed lochia and milk.	V.S. not employed. Anodynes, stimulants.	Recovered.
118	—; æt. 26; 12, Chapel Place, Crown Street. Distorted pelvis. January 19, 1832.	First day.—Rigor of great severity, followed by pain in the region of the uterus; suppression of lochia; pulse 130; great heat of surface; tongue white; urgent thirst; no nausea. Jan. 22d: a large swelling in the situation of the right parotid, with erysipelas of the face, and suppuration.	V.S. (blood not buffed), leeches, calomel, opium, cathartics, ol. ricini.	Recovered.
119	Case; British Lying-in Hospital. Natural labour. January 30, 1832.	Feb. 1st.—After a rigor, seized in the night with constant severe pain in the hypogastrium; lochia and milk suppressed; pulse 120; exquisite tenderness; tongue white; urgent thirst; nausea; pain across the forehead; no pain in abdomen, except in the uterus. 4th: convalescent. After leaving the hospital had another severe attack, which yielded immediately to blood-letting.	V.S. ℥xvj. (blood buffed), leeches xxiv., calomel, opium, saline draughts, cathartics. Took 50 grains of calomel. Poultices, &c.	Recovered.
120	Tellbury; British Lying-in Hospital. Natural labour. February 4, 1832.	Second day.—Acute pain in uterus; lochia suppressed; rigors; headache; tongue white on the edges, dry in the middle; pulse 140, feeble; face flushed; respiration hurried; occasional cough; great diarrhoea followed the calomel.	V.S. ℥xviiij. (followed by immediate relief), leeches twice, calomel, opium, saline effervescing draughts, cathartics.	Recovered.
121	Otley; æt. 32; British Lying-in Hospital. Natural labour. February 7, 1832.	Second day.—Rigor; pain in the hypogastrium; suppression of lochia; pulse 140; skin warm; headache. Feb. 10th: pain on pressure in the right side of uterus; pulse frequent; abdomen soft and puffy; tongue loaded.	V.S. ℥xiv. (blood buffed), leeches xxiv., calomel, opium, ol. ricini.	Recovered.

122	Wildman; æt. 30; British Lying-in Hospital. Natural labour. January 27, 1832.	Obscure febrile symptoms a few days after delivery; no pain in region of uterus. Tenth day after delivery incoherent; a severe rigor; pulse 130; tongue dark glossy red; countenance yellow; left lower extremity swollen. Feb. 13th: conjunctiva of both eyes intensely red and swollen; right knee-joint painful; gangrene over the sacrum. 14th: eyes enormously swollen; pain in right knee, elbow-joints, and wrists. Died on the 18th; sight lost before death.	Leeches, calomel, opium, stimulants and anodynes, fomentations, &c.	Died. Uterus contracted; abscess in muscular coat of uterus; coats of the left common external iliac and femoral veins deep and superficial, thickened, and their cavities filled with coagula; lower part of vena cava coated with lymph; the uterine, vaginal, gluteal, and other branches of the internal iliac, gorged with pus, and lined with false membranes; uterine branches of right internal iliac also affected. Recovered.
123	Norris; æt. 30; British Lying-in Hospital. Natural labour. February 18, 1832.	Second day.—Severe rigor; pain in the region of the uterus; pulse 120, full; skin hot; lochia suppressed; headache; tongue furred. 21st: tenderness in the region of the uterus; frequent cough. First day.—Rigor; pain of hypogastrium, increased by pressure; pulse 100; headache; tongue white. Twenty-fifth day: pain immediately relieved by the bleeding. Twenty-seventh day: slight return of pain.	V.S. ʒxxx. (blood neither cupped nor buffed), 40 grains of calomel taken with opium, leeches xij. V.S. ʒxxx. (blood buffed), leeches xvij., calomel, opium, leeches.	Recovered.
124	Little; æt. 28; British Lying-in Hospital. Natural labour. February 23, 1832.	Second or third day.—Rigors; uterine pain; accelerated pulse; and other symptoms; which immediately yielded to copious bleeding, &c. A case occurred the following day, and with the same result.	Copious V.S., calomel, opium, and oil of turpentine.	Recovered.
125	Case at Teddington. After natural labour. End of February, 1832.	Third day.—Slight rigors; diffused pain, increased by pressure, over the abdomen, and especially on the sides of the hypogastrium; headache; pulse 100; lochia and milk diminished. One of the mildest cases contained in this table.	Leeches xvij., calomel, and opium.	Recovered.
126	A lady; æt. 26; Charlotte Street, Bloomsbury. Natural labour. February 24, 1832.	First day.—Rigors; exquisite tenderness in the region of the uterus; headache; pulse 110, feeble; tongue white; nausea and thirst; March 1st: pulse 110; pain diminished. 2d: gone, and convalescent.	V.S. ʒviiij. (blood not buffed), calomel, antimony, opium, leeches xxiv.	Recovered.
127	Case; British Lying-in Hospital. After hæmorrhage and retained placenta. February 28, 1832.			

128	Walter; æt. 29; British Lying-in Hospital. Twins. February 20, 1832.	Second day.—Low and depressed ever since delivery; pulse 120; irregular shiverings; countenance haggard. Has not complained of much pain in the abdomen; no vomiting. The symptoms were apparently produced by mere debility, without any local affection. Died fourteen days after delivery. The symptoms were very obscure.	Neither blood-letting, general or local, or any other remedies, were employed.	Died. The whole of the peritoneal coat of the intestines, liver, and uterus, thickly covered with lymph, and a considerable effusion of sero-purulent fluid; the uterine appendages much inflamed; muscular coat and veins healthy.
129	Gates; æt. 22; British Lying-in Hospital. Natural labour. March 2, 1832.	First day.—Rigors; quick pulse; tenderness, increased by pressure, in the region of the uterus. March 4th; incoherence; great pain of uterus continues; tongue brown; urgent thirst; no sickness; pulse 120; countenance sallow.	Leeches xvij., calomel, opium, leeches, cathartics.	Recovered.
130	Case; British Lying-in Hospital. After natural labour. March 15, 1832.	Second day.—Rigors; pain in the region of the uterus; diminished lochia; quick pulse; loaded tongue. March 18th: relieved by the bleeding.	V.S. ʒij. (blood buffed), large doses of calomel and opium.	Recovered.
131	A lady; æt. 28. Uterine hæmorrhage. March 27, 1832.	On the second day, great quickness of pulse; and on the third, pain, increased by pressure, in the region of the uterus, especially on the left side; lochia diminished; no milk; slight incoherence. In a few days there was great febrile excitement; pulse 130; delirium. Tenderness of the left groin followed, and crural phlebitis on the left side. Pain in the right side of the hypogastrium, increased by pressure; rapid pulse; suppression of lochia and milk; great delirium. Duration of disease nine days.	Leeches, calomel, opium, sedatives, quinine, wine.	Recovered.
132	Case; Lying-in Ward of St. Marylebone Infirmary. April 1, 1832.	Pain in the right side of the hypogastrium, increased by pressure; rapid pulse; suppression of lochia and milk; great delirium. Duration of disease nine days.	Leeches, &c.	Died.
134	Sweatman; æt. 30; British Lying-in Hospital. Natural labour. April 14, 1832.	Third day.—Pain in the back. Fourth day: rigor; great tenderness in the uterine region; pulse 120; tongue red and dry in the centre, white and moist on the edge; thirst; cough; lochia scanty; uterus felt large and hard. Nineteenth day: pain relieved; pulse 110; mouth sore from mercury. Twenty-second day: vomiting; delirium; rapid pulse; great swelling in the situation of the puerperal rotids; no swelling, pain, or tension of abdomen; conscious till she sank.	V.S. ʒiv., calomel, opium, leeches xij.	Died. Omentum, liver, uterus, intestines, all matted together with lymph; a little serum in the peritoneal sac; right ovary and tube inflamed severely; all the veins passing into the right spermatic vein filled with pus; a great part of the veins in the walls of the uterus filled with purulent fluid.

OBSERVATIONS ON
SOME OF THE
MORE IMPORTANT DISEASES OF
CHILDHOOD.

By CHARLES WEST, M.D.

Member of the Royal College of Physicians;
Physician to the Royal Infirmary for Children;
and Physician-Accoucheur to the Finsbury
Dispensary.

[Continued from p. 742.]

II. *On a peculiar form of croup which
occurs as a complication of measles.*

DURING the autumn of 1842 diarrhoea prevailed to an unusual extent among the patients at the Infirmary for Children. The period of its greatest prevalence was the month of August, when 71 out of 168 patients admitted under my care, or 41 per cent., were suffering from it. In September the cases of diarrhoea sank to 24, in October to 14, and in November to 8 per cent. of the total monthly admissions. In proportion, however, as the diarrhoea declined, catarrhal affections of the air-passages became frequent. Bronchial catarrh, which, in the month of August, existed in only 11 per cent. of the cases, attacked 20 per cent. in September, and 28 per cent. in October; and, though it became less frequent in November and December, still 18 per cent. of all cases admitted in December were affected by it. In the month of July 1842, at which time diarrhoea first assumed an epidemic character, affecting 30 per cent. of the patients, cases of measles began to occur more frequently, and the disease soon became epidemic, though for many months it had occurred only as a sporadic affection. Measles continued to prevail epidemically during the whole of the autumn, but did not reach their maximum frequency until the end of November and commencement of December, in which latter month 20 per cent. of all patients who came under my care were affected with them. Measles became less frequent in the beginning of 1843, and their place, as an epidemic, was taken by hooping-cough, which has been the sole epidemic of the present year.

The epidemic constitution of the whole period from the autumn of 1842 until the following spring, which, moreover, shewed its character by an unusual prevalence of that form of ulcerative inflammation of the mucous membrane of the mouth known by the

name of stomatitis, appears to have imparted something of its peculiarities to the measles then epidemic, giving rise to a very insidious and dangerous complication, which consisted in an affection of the mucous membrane of mouth and air-passages more nearly resembling diphtheritis than ordinary croup.

In no English work have I found any account of this complication of measles, beyond the mention of the occasional occurrence of croup during the progress of the disease, or as one of its sequelæ. The slight notice taken of it by continental authors would likewise lead to the inference that it is not often a grave complication of measles in other parts of Europe. MM. Rilliet and Barthez, the most recent and most trustworthy writers on children's diseases, expressly state* that the inflammation of the pharynx and larynx which supervenes in the course of measles is generally of but slight importance, that its symptoms are seldom grave, and the lesions which it produces are seldom serious. To this general rule, however, there are some notable exceptions: thus, in the years 1837-38, an epidemic of measles prevailed in the district of Besigheim†, in the kingdom of Wurtemberg, in which the period of desquamation was often attended with an extremely perilous secondary croup, accompanied with very extensive formation of false membranes in the air-passages. During the prevalence of an epidemic of measles in the year 1835, in Sigmaringen‡ and the adjacent country, false membranes formed on the tonsils and palate, accompanied with other symptoms of croup; but this diphtheritic affection existed only in one parish, though a tendency to it shewed itself in other parts by the formation of aphthous ulcers about the tongue. A similar complication, too, existed in some cases during the very fatal epidemic of measles at Bonn, in the years 1829 and 1830§. An examination of the periodical literature of medicine would probably discover

* *Traité des Maladies des Enfants*, t. ii. p. 721.

† For an account of this epidemic, see Dr. G. C. F. Hauff, *Medicinische Abhandlungen*, 8vo. Stuttgart, 1839, S. 79.

‡ Described by Heyfelder, in his *Studien im Gebiete der Heilwissenschaft*, Stuttgart, 1839, 8vo. ii. Band, S. 9.

§ Described by Wolff, *De morbillorum epidemia annis 1829 et 1830*. Bonnæ, etc. grassante. Bonn, 1831.

many instances in which measles were complicated with croup or diphtheritis. My present object, however, is not to write a history of the epidemics of measles, but simply to describe what came under my own notice.

None of the six cases of which I have preserved a record presented, at the outset, any peculiarity. The preliminary catarrh was not more severe than usual, nor was the eruption of measles either more or less abundant than in cases where no such complication occurred. In one instance the throat affection came on on the second day of the eruption; but in the other cases not until its decline, or till the period of desquamation had commenced. In the first case that I met with, that of an infant at the breast, of the name of Newell, living at 19, Prince's Court, Commercial Road, Lambeth, the attack of measles had been comparatively mild; the child had reached the sixth day from the appearance of the eruption, and everything seemed to promise a favourable convalescence. On the seventh day there was slight drowsiness, with some increase of the morbillous catarrh, but there seemed to be so little to excite anxiety in the symptoms, that I did not visit the child till the ninth day. I found it then labouring for breath, with all the symptoms of croup in a far advanced stage, and with great prostration of strength. These symptoms had then existed for twenty-four hours, and in twelve hours more they terminated in death. The child had had considerable inflammation of the mucous membrane of the mouth, with small aphthous ulcers on it and on the tongue, from the third day of the eruption. I was not, however, at that time aware of their betokening the existence of more serious mischief.

Another case, in which the croupy symptoms were well marked, though not so rapidly fatal as in the preceding instance, was that of—

John Mayhew, æt. 4½ years; residing at 2, James Place, Union Street, Southwark. This child had good health until January 20, 1843, when he was taken ill; and on the 22d the eruption of measles appeared on him abundantly: he seemed going on well until the night of the 25th, when he began to cough, and on the 26th his breathing

became difficult, and from that time grew worse and worse.

His mother had applied four leeches to the throat, had given him medicine and fomented his chest without relief; and brought him to me on January 28.

The remains of the eruption of measles were still to be seen on his face and back, his countenance was heavy and oppressed, breathing difficult, rather hurried, loud wheezing attending the inspiration, occasional slight hoarse cough, without much clangor. Pulse full, bounding, but easily compressible. Tongue red and raw, with slight aphthous spots upon it, and one or two similar spots upon the tonsils, which, however, were not very red, nor covered with false membranes. He had had on that day, for the first time, some difficulty in swallowing, and also occasional attacks of dyspnoea, in which suffocation seemed impending.

No unnatural sound was detected in either lung, but the air entered very imperfectly.

The case did not appear to be one in which depletion was admissible. I therefore ordered a solution of half a grain of the sulphate of copper every ten minutes till free vomiting should be produced, and to be continued afterwards every hour, and a drachm of the strong mercurial ointment to be rubbed into the thighs every two hours.

At 7 P.M. I visited him again. He had taken nine doses of the medicine, after the second of which he vomited, but the vomiting had not recurred. There was rather less dyspnoea than in the morning, and the child was sleeping quietly when I came in, but was easily roused, and when awake his face presented much less of that expression of anxiety which it wore in the morning.

I now discontinued the sulphate of copper, but directed the mercurial ointment to be still rubbed in, and ordered gr. ij. of calomel with gr. ¼ of tartar emetic to be given every two hours.

January 29, 10 A.M.—Slept much through the night, but had had two or three accessions of very urgent dyspnoea, and his mother considered him worse. He had made one effort to vomit, but rejected only a little phlegm, and that without any relief; and his bowels had acted twice. He was sitting upright in the bed, with much anxiety

expressed in his face; jugular veins much distended; inspiration hissing; cough painful; and more suppressed than on the previous day. He swallowed tolerably, but distressing cough sometimes followed deglutition. He complained of his chest, and said his throat hurt him when touched.

The skin of the body was hot, but the extremities were cold; the pulse was about the same in frequency as on the day before, but it had lost power. His tongue was still red and raw, but there was no great redness of the fauces, nor were there any specks of false membrane upon them; there was considerable ulceration of the gums, and some foetor of the breath.

The calomel was now discontinued.

The mercurial inunction was still employed: gr. ij. of ammonia with ℥x. of tincture of squills and half an ounce of the decoction of senega were given every two hours.

In the evening the child was much the same, but the pulse was 140, and interrupted by occasional paroxysms of dyspnoea. I found him at 10½ A.M. on January 30, sitting up in his mother's arms, being unable to lie down; his face flushed and extremely anxious, the perspiration standing in big drops on his forehead, looking round with an expression of unutterable distress, as if in quest of relief. Respiration hissing, voice quite reduced to a whisper, cough hoarse, and without any clangor; and air entering the lungs but scantily. Gums very sore, fauces red, a little false membrane on the tonsils.

A blister was now applied to the upper part of the chest, the inunction was continued every three, and the ammonia given every two hours.

In the course of the evening he became able to lie down, but sank into a comatose condition, in which he continued with occasional intervals during the 31st of January, and until 6 A.M. on February 3d, when he died.

On the day before his death he appeared to breathe with far greater facility than he had done for some days. His face lost much of its anxious expression; the respiration became noiseless and unattended with effort; the cough less smothered; the voice, though still a hoarse whisper, was more distinct, and when aroused he answered rationally, and his mind no longer

wandered. At midnight, on February 2d, however, these treacherous appearances vanished, and in six hours he died.

On examining the body after death, the lower third of the lower lobe of the right lung was found in a state of red hepatization; the bronchial glands were red and swollen.

The soft palate was thickened and oedematous, and there was a small ulcer on the right side of the uvula.

The under surface of the epiglottis, and the mucous membrane of the larynx, were generally rough and granular, looking as if eroded by innumerable little ulcerations. Their surface presented a dirty ash grey colour, was not coated with false membrane, but only with a little dirty mucus.

The trachea was red in patches, intensely so for an inch above the division of the bronchi. The larger bronchi were intensely red, and those on the right side contained a frothy reddish fluid, but the smaller bronchi were not injected.

The brother of this child, a fine infant about a year old, was taken with measles at the same time. In him the measles were complicated, almost from the outset, with pneumonia, and the croupy symptoms which came on on the third day were less distinctly marked. His gums became sore; his tongue red, raw, and ulcerated; he lost his voice, had a croupy cough, though unattended with clangor: his dyspnoea was less urgent than in his brother's case, but, like him, he sank into a state of coma, and died on the seventh day. I was unable to obtain a *post-mortem* examination.

In all of the three above-mentioned cases the nature of the affection was sufficiently obvious, and in two the croupy symptoms were well marked. Sometimes, however, much greater obscurity attends the diagnosis. The child is evidently more ill than the mere existence of measles will account for, but it makes no definite complaint, and it cannot be ascertained that any organ in particular is suffering. There is considerable drowsiness, disinclination to swallow, and reluctance to speak, but cough may be absent; no croupy sound accompanies the respiration, and the child speaks in so low a tone that it is hardly possible to appre-

ciate any alteration in the tone of its voice. In such a case I overlooked the dangerous complication till too late. The patient was a little girl, five years of age, named Jenkins, living at 13, William Street, Waterloo Road. She was attacked with measles, and I watched her the more sedulously because she had had several attacks of croup. The eruption came out naturally, and there was nothing unusual in the case except a preternatural drowsiness, which existed almost from the outset of the disease. The respiration was rather hurried; the pulse frequent, and without power; but there was neither cough nor croupy sound in breathing, nor did auscultation detect any serious mischief in the lungs. Still the child grew more and more drowsy; she took hardly any drink, never spoke, her pulse grew more frequent, and she sank into a state approaching to coma. I now bethought me of what I had hitherto neglected, and examined the state of the mouth. The fauces were very red and much swollen, and shreds of false membrane covered the tonsils and palate. Twelve hours afterwards, on the fifth day of the disease, the child died.

Ellen Douglas, aged 21 months, living at 7, Prince's Court, Commercial Road, Lambeth, was taken with measles on Dec. 9, 1842. She had a cough from the first, and the measles were associated with double pneumonia, which was combated by local depletion, and the administration of calomel and antimony. For a few days the child seemed to improve, but on the 16th she became worse, dozing for a short time, then suddenly starting up in the bed, as if in alarm. She grew habitually restless, was much troubled by hacking cough, and often refused drink, though she did not appear to have any particular difficulty in swallowing. Her voice became hoarse, this hoarseness terminating, some days before her death, into almost total aphonia. Still there was at no time any stridor in the breathing, or marked croupy symptom; but the tongue was red and raw, and little aphthous ulcers appeared at its edges, and the gums were sore; a circumstance attributed, probably erroneously, to the mercury that had been administered. Her restlessness increased, her strength declined daily, but no new symptom showed itself

until the 24th, when, though her dyspnoea did not seem increased in urgency, she would not lie down in bed, but continued sitting upright in her mother's arms, or in bed; and if laid down for a moment, she would instantly start up into the sitting posture. She continued thus until 6 A.M. on Dec. 25th, when she died.

After death, lobular pneumonia in the first stage was found in the upper lobe of the left lung; vesicular pneumonia, and grey hepatization of the greater part of the lower lobe. There was general lobular pneumonia, in the first stage, in the right upper lobe, with one patch of red hepatization; grey hepatization of the middle and lower lobes, with some vesicular pneumonia, in the lower.

The root of the tongue, and posterior part of the pharynx, were covered with shreds of false membrane, and the surface of the epiglottis presented a similar appearance, little excavated ulcerations seeming to occupy the site of the epiglottidean glands. The whole of the œsophagus was much congested, and lined by a complete tube of false membranes, which reached to within about an inch of the cardiac orifice of the stomach, and terminated in an irregular edge.

The lower surface of the epiglottis was coated with false membrane, and presented ulcerated spots just like those on its upper surface.

The mucous membrane covering the arytenoid cartilages was puckered and swollen, and the aperture of the glottis was much narrowed, partly by swelling, partly by deposit of false membrane.

Dirty greyish false membrane lined the larynx, filled up the interval between the true and false chordæ vocales, and obliterated the entrance to the sacculus laryngis. On removing the false membrane, the surface of the larynx appeared uneven as though worm-eaten, but not at all red or congested.

The false membrane did not extend below the larynx; the trachea was not at all congested, and contained only a small quantity of mucus.

The last case that I have met with was that of Evelina Turner, aged eighteen months, living in Pearl Row, Blackfriars Road, who was suffering, when admitted under my care, from diarrhoea following measles. The eruption had disappeared four days; the

diarrhœa was severe, attended with tenesmus and bloody stools; and there were small aphthous ulcers in the inside of the mouth. For four days she appeared improving: she then was not brought to me for three days; and at the end of that time she returned with difficulty in deglutition, almost complete aphonia, slight croupy sound in breathing, and false membranes coating the intensely congested soft palate. In twenty-four hours more the child died.

The lungs were inflamed, and in some parts the pneumonia had reached the third stage.

The soft palate, fauces, epiglottis, and upper part of the pharynx, were intensely congested, and covered with false membrane, which was closely adherent, and extended for about an inch and a half into the œsophagus.

The larynx was lined with pus, and covered with a false membrane similar to that on the pharynx; its mucous membrane was intensely congested, but not ulcerated. This congestion terminated abruptly at the lower margin of the thyroid cartilage, and the trachea was quite pale, though containing some puriform fluid.

The foregoing details render any lengthened observations unnecessary. They show that an affection of the air-passages, dangerous in its character, often obscure in its symptoms, does occasionally occur as a complication of measles. They display a two-fold mode of attack, according to which the disease is either clearly marked, and attended from the first with obvious croupy symptoms, or its character is masked and its cause insidious. Its tendency is seen to be to produce a fatal result, while the violence of the symptoms during life affords no index from which to infer the amount of mischief which a post-mortem examination may reveal. Its hazard is further increased by the frequent coexistence with it of inflammation of the lungs, which, moreover, serves to throw the symptoms of croup into the shade. The existence of this affection, however, may be suspected wherever there are universal drowsiness, disinclination to swallow or difficulty in the act of deglutition, reluctance to speak, or alteration in the tone of the voice, even though there may be no croupy cough nor stridulous breathing. This suspicion would be raised almost to

certainly, if the gums have a spongy appearance or be actually ulcerated, if the tongue be preternaturally red and raw, and if small aphthous ulcers be visible on its edges and on the lining membrane of the mouth. In such a case, an examination of the fauces, which ought never to be omitted, will usually disclose redness and swelling of the soft palate, and usually, though not invariably, the presence of false membrane.

A depressed state of the system, such as wholly to contraindicate depletion, accompanies the local affection. The employment of calomel, and of those measures usually resorted to in the treatment of inflammatory croup, is wholly inefficient; while it seems probable that success would attend the early and efficient application of caustics, as in ordinary cases of diphtheritis. Still the case of J. Mayhew shows that the development of false membrane on the fauces is not an invariable occurrence, that fatal mischief in the larynx may exist without it, and consequently that a favourable issue could not be anticipated in every case, even from the most timely use of cauterization.

TREATMENT

OF

CALCULI IN THE BLADDER.

To the Editor of the Medical Gazette.

SIR,

I MAKE no apology for offering the following case to the notice of the profession: the risks and anxieties necessarily following upon the operation render every ray of light welcome to the lithotomist; on which account I wish to give force to a suggestion offered by Sir B. Brodie in his "Lectures on the Diseases of the Urinary Organs;" for to that suggestion I was indebted for the steps taken, which although differing a little in mode, were adopted on the same principle, and followed by the same successful result.—I am, sir,

Your obedient servant,
HENRY CHARLES SHERWIN.

Hull, August 23d, 1843.

—Hartley, æt. 9 years, was brought to me by his mother (a widow), on the 8th of June, 1842, to be sounded for stone in the bladder. I detected one, if

not two small ones. He had arrived the day before from near Ferrybridge, Yorkshire, a distance of 70 miles, and had suffered great pain during the journey. I was strongly importuned to cut him on the morrow, to which I imprudently consented: the operation was satisfactorily performed in the presence of my friends, Drs. Sandwith and Cooper, and two small calculi were removed in a few minutes; they were thinly coated with the triple phosphate of lime. An opiate was given, and the boy, without any apparent exhaustion of his vital system, was put to bed. As he had a rather deep perinæum, I made a very free incision through the intervening parts leading to the bladder, which induced me not to leave a canula in the wound, which I regretted afterwards. I will now quote from my notes.

Vespere.—Has slept; though calm, has a slight pain in the left groin; skin hot and perspiring; pulse 96, and full, apparently the effect of opium and reaction; the urine has flowed from the wound, which is smeared with lime.

10th, 9 A.M.—Has passed a painful and restless night; belly slightly tympanitic; there is acute pain beginning above the left groin, and extending upwards to the scrobiculus cordis; skin hot and dry; pulse 135, and small; tongue dry, and brown in the middle; countenance anxious; the upper lip retracted, with an expression of anguish. Some urine has passed by the penis as well as by the wound.

To apply half a dozen leeches to the left hypochondrium, followed by bran bag fomentations; to take *Ol. Ricini* ʒij. in mint water; to have a small warm-water enema.

4 P.M.—Has passed some loose stool and flatus with slight but temporary relief: symptoms much the same as in the morning; pulse 140, and weaker; belly more tympanitic; urine has come away as before.

To have 2 grs. of Dover's powder statim, and repeated after 4 hours; continue fomentations.

10 P.M.—No relief, except by occasional discharges of flatus; the wound is closing, and but little urine has passed that way.

To continue the fomentation, with an enema now and then to facilitate the discharge of flatus.

Pulse is 145, very feeble, soft, and intermitting.

I now felt convinced that I should lose him; as from the very onset of the attack, the vital powers seemed unable to sustain any depleting measures, and though having most of the characters of peritonitis, the symptoms precluded the antiphlogistic treatment. On referring the same evening to Sir B. Brodie's published "Lectures," I felt impressed with the fidelity of his description of the untoward symptoms following lithotomy. I caught at a suggestion he offers in a similar case, which he rescued by laying open the rectum with the wound, so as to give exit to a quantity of sanies: and I will take upon me here to remark, that the work alluded to, though offered to the profession in the simplest and most unostentatious style, is replete with the soundest principles of practice, and is a most excellent guide. But to return to my narrative.

11th, 7 A.M.—Found matters looking still worse; the boy had passed a wretched night, rolling from side to side in great pain; the belly hard and tympanitic; pulse feeble and fluttering, and hardly to be felt or counted, with more frequent intermissions; countenance of dusky leaden hue: occasional sighs and hiccoughs; tongue quite brown and dry. I now determined to open the wound, which was externally united: this was done with the handle of a scalpel, and having pushed up my finger to explore the parts, I gave exit to about 2 or 3 oz. of a pink-coloured sanies, having a foetid and ammoniacal odour. I was glad to find the opening in the bladder small and neatly contracted, with a well-defined margin, and scarcely admitting the tip of a finger. I broke up the entire wound in the perineum, and had the patient raised out of the hollow of his bed into a more depending position; gave a little brandy and water with a teaspoonful of castor oil.

11 A.M.—Much improved in every respect; countenance calm; had slept a little, and parted with a good deal of flatus; the pulse settled to 100.

9 P.M.—Has slept well; looks happy; pulse slower; tongue is moist; has asked for tea, and bread and butter. From this time the boy did well, and he returned to his home quite free from ailment in about three weeks after.

REMARKS.—The urine was alkaline, with considerable deposit of lime and mucus; this (which ought to have been done before) was afterwards corrected by mineral acids, with Decoct. Pareiræ Bravæ, and Quinine. If, instead of giving a free vent to the sanies, I had treated the case as one of pure peritonitis, there can be no doubt but that he would have sunk in a few hours. Yet I committed an error in the first instance by operating so soon after a long journey. I relied too confidently on the youthfulness of the patient: time ought to have been allowed for the bladder and constitution to become tranquil before he incurred the additional risk of a formidable operation. Again, his bed was an inconvenient one; it allowed his pelvis to sink into a hollow, which, with my neglecting to leave a canula in the wound, allowed some of the urine to lodge between the rectum and bladder; a circumstance that has proved, probably, a more frequent source of mischief after lithotomy than is generally suspected. As an additional proof of the comparative immunity from risk enjoyed by young subjects, I would observe, that out of upwards of a dozen operations, and all successful ones, nine of them have been under the age of twelve, and only one turned sixty years, and, what is perhaps more worthy of note, eight of the former are the children of sloop-men from the banks of the Trent, Ouse, and their tributary rivers from thirty to sixty miles inland. With the exception of one, Mulberry, all the calculi mainly consisted of the mixed phosphates upon uric acid nuclei. Three of the boys (children of different parents) came from a small village adjoining Ferrybridge, where a large quantity of lime is burnt.

The eastern coast of Yorkshire, though subject to the same severe vicissitudes of climate as that of Norfolk, and quite as populous, does not yield many cases of stone in the bladder, especially when compared with the latter district; so that I am apt to think it still remains a problem how one district should abound in calculi so much more than others of a similar temperature. I have never been able to fix upon any one circumstance as tending more than another to originate this disorder; and on this account the fact of so large a proportion of my cases occurring in one class of

the labouring poor (sloop-men) is worthy of note. In operating, I am careful to limit the opening in the bladder within the boundary of the prostate—a principle first publicly enjoined by Sir B. Brodie, and since very strongly confirmed by Messrs, Liston, Ferguson, &c.; and I quite agree with Mr. F. that when the stone is previously ascertained to be a small one, it is worse than needless to divide more of the deeper parts of the perinæum, preliminary to the section of the prostate, than will suffice for the easy introduction of the forceps. I use the knife and staff sold by Weiss, as Liston's the latter having a better defined groove than others, on account of its lower margin projecting beyond the upper one, and thereby rendering the groove more distinguishable when inserted, especially in the penis of a boy, whose parts are not so fully developed about the neck of the bladder as in man. The sound which has enabled me to detect a stone with the greatest facility is a straight one, having at its extremity a short turn, not exceeding an inch in length, which enables it to be freely turned in every direction.

ON
IRRIGATION AND WATER-
DRESSING IN THE TREATMENT
OF STUMPS AFTER
AMPUTATION.

To the Editor of the Medical Gazette.

SIR,

I HAVE ventured to submit to your notice the subjoined cases on the good effects of irrigation and water-dressings in the treatment of stumps after amputation, should they merit that importance, and, in doing so, venture to hope the subject may attract the attention of more competent persons, whose opportunities for its trial may better appreciate its efficacy than my limited practice can afford.

My attention was first directed to this course of treatment after seeing the use of water-dressings more serviceable in the treatment of ulcers than sticking-plaster, as prescribed by the late Dr. Macartney, and followed, with increased success, in the practice of our intelligent and practical contemporary, Professor Liston; the only difference

betwixt their practice and mine being in the use of irrigation by stream upon the amputated limb at the first succeeding dressing subsequent to that of the operation, which, in my opinion, possesses advantages in contracting the capacity of the vessels, promoting the effusion of coagulable lymph, and retarding profuse suppuration to a greater extent than is to be derived from the use of water-dressings alone. However, should I not be able to establish this to your satisfaction, every unprejudiced surgeon must acknowledge the use of irrigation ensures cleanliness of the stump, comfort to the feelings, and has a decided preference over what may be justly deemed the opprobrium of surgery, viz., loading the amputated limb with adhesive stimulating plasters, bandages, &c.; thus exciting undue temperature of the stump, profuse discharges, and severe fever.

The use of strips of adhesive plaster to approximate the edges of the incision has no preference to isinglass spread upon gold-beaters' leaf; the difficulty of obtaining the latter, and its expense, alone precludes its use in provincial practice.

The manner in which irrigation was used was by a stream more or less elevated above the limb, or locally by saturating folds of lint with water, and applying them over the incision, and retaining the same with a bandage kept wet with water: the temperature of the water should vary from 60° to 80° Fah., according to the effect wished to be produced. If the object be to contract the capacity of the vessels, as after amputation, the temperature should be 60° Fah.; if, on the contrary, the desire be to promote gentle secretion with diminished capillary action, the temperature should be 80° Fah.—I am, sir,

Your obedient servant,

JESSE LEACH, M.R.C.S.L.

Fellow of the Royal Medical and Chirurgical Society of London, &c. &c.

Heywood, Lancashire, May 23, 1843.

CASE I.—A young man, of spare habit and healthy aspect, was caught by machinery, and had his wrist torn from his forearm, with fracture of the humerus. I performed the circular operation three inches below the elbow, and adjusted the fractured humerus in the usual way. The vessels being secured, the limb was sponged well

with water of 60° Fah. until the bleeding from the small vessels had entirely ceased. I then drew the edges of the incision together by a strip of adhesive plaster, one inch broad and six long, using two such strips for the incision: a fold of lint was then applied around the limb, enclosing the end within its fold, to be kept constantly wet with water of 60° Fah. for six hours, when a wet circular bandage was applied, and kept as cool as agreeable to the feelings of the patient. On the fourth day the dressings were removed, and the limb, held by an assistant with a gentle declivity over a receiving mug, and five gallons of spring water, heated to 80° Fah., was poured from a jug in a stream held a foot above the limb, allowing the stream to come in contact with the limb four inches above the incision, and suffered to run over the wound.

For the space of two inches the wound is healed by the first intention, and the remaining portion is healthy: the temperature of the limb is natural: there is little fever or irritation. On every second day the irrigation and water-dressings were repeated, and in fourteen days from the accident the wound was healed.

The secretion of matter was small throughout, and destitute of fœtor; the granulations were clean and healthy, with little pain.

CASE II.—A collier, with scrofulous disease of the knee joint: the limb was very œdematous, the patient of very dissipated habits, but free from visceral organic disease: amputation was performed with the circular incision at the upper third of the thigh. The same dressings and after treatment were followed as in the preceding case, and the stump was healed in four weeks. A practical surgeon who assisted me in the operation, remarked that the case was likely to have a protracted healing, with a prospect of sloughing; the granulations at first were shining and flaccid; the cellular tissue discharged large quantities of serum: nevertheless, a perseverance in the water dressings, with irrigation, caused firm granulation, with a moderately healthy suppuration. The fever and debility in this case were counteracted by bark, ammonia, and wine. Although the patient recovered, and enjoyed good health for twelve months after, a resumption of his

old associates and intemperate habits brought on spontaneous mortification of the other leg, and the man sank under an accumulation of disease, until death put an end to his sufferings.

CASE III.—A young man was caught by machinery, and had his arm torn off above the elbow-joint: amputation was performed with the circular incision, four inches below the shoulder joint; the stump was dressed in the same manner as Case I., and the wound was healed in three weeks with little pain, moderate suppuration, healthy granulations, and a firm stump, although the family are of the scrofulous diathesis.

CASE IV.—A boy, 14 years old, was caught by machinery, and had his foot snapped off three inches above the ankle-joint; amputation was performed four inches below the knee. The wound was healed in three weeks. The same dressings and treatment were used as in the former case.

CASE V.—A man, 50 years old, of intemperate habits, and subject to epilepsy, with a bloated, doughy, and unhealthy aspect, had his right hand torn by machinery. The tendons, muscles, and bones, of the two first fingers and their metacarpal bones, were torn so as to coil like a cord in any direction; the bones of the thumb, ring and little fingers, were more or less injured. On a consultation with two other surgeons, Messrs. Pickford and Taylor, it was agreed that I should dissect off the two first fingers with their metacarpal bones, thus leaving a thumb, ring and little fingers, which were placed upon a flat board and dressed in the usual way: irrigation and water dressings were employed as in the preceding cases, and the wound was healed in five weeks from the receipt of the injury. A little stiffness remained for some time in the remaining fingers; but on the whole the man has a useful hand.

The intemperate habits, unhealthiness of the constitution, and extent of laceration, in this case, constituted important chances for sloughing and unfavourable termination.

CASE VI.—A young man, of healthy aspect, had his right arm caught in machinery, which laid bare the extensor tendons of the fingers by stripping the integuments and fascia off the *back of the hand* as high as the wrist,

fracturing in three situations the metacarpal bones of the index and second fingers, and severely crushing the fingers throughout their course. I dissected off the index and second fingers, with their metacarpal bones, secured the bleeding vessels, placed the remaining portion of the hand upon a flat board, and dressed with water, after binding the thumb and two fingers together with two strips of adhesive plaster.

The hand was very easy for the first two days, when he complained of pain and irritation. On removing the dressings on the fourth day, three live maggots were crawling in the metacarpal spaces in a mass of pus and coagulable blood, and on attempting to displace them they receded out of sight. I used the irrigation, but could not obtain a clean wound, the edges of the incision being of a dusky purple colour. I dressed the wound with pledgets of lint saturated with liquid chloride of lime, with a view of stimulating dormant vascular action, and destroying the live maggots which were still imbedded in the wound. In two days the dressings were removed; the wound was looking healthy, no maggots visible, and the mass of matter in the spaces becoming separable. I continued my chloride of lime dressings once more, which were succeeded, the next day with water dressings; and had the satisfaction to see the wound healed in four weeks from the accident.

Such, sir, are the results of six cases of amputated stumps, treated with irrigation by stream and water dressings. From their description, it will be manifest some were very unfavourable cases to make trial of its use and efficacy; yet there was neither a slough, tetanus, nor death, in any of the cases. Five out of six had little fever or constitutional derangement; and I am convinced a more speedy cure was accomplished in all than would have occurred under any other treatment.

In conclusion, it will be highly gratifying for me to hear that this treatment, when adopted, is as successful in the practice of other gentlemen of the profession as it has been in mine, and if, on trial, it be found so, it will confer comparative ease and comfort under affliction caused by loss of limb.

SOME OBSERVATIONS
ON THE
STATISTICS OF THE VIBRIO
HUMANA.

(*Trichina Spiralis*.)

By DR. KNOX.

(*For the London Medical Gazette.*)

IN the spring of 1836 a case occurred in the Practical Rooms, Old Surgeons' Hall, of the occurrence of this very curious entozoon infesting the human muscles. Numerous specimens of the worm and its sac were examined with great care by my brother and by myself, and the attention of the profession here was very generally directed to the case. The memoir was published in the July number of the Edinburgh Medical and Surgical Journal of the same year, viz. 1836. Since then, *one case only* has occurred in my Practical Rooms, viz. in October 1839, in almost every respect so much resembling the first, that it would be a waste of time to give any details respecting it. Now in the interval more than a hundred persons had been examined anatomically, and with such care as to render it nearly impossible that the presence of the worm could have escaped observation had it really occurred. Again, the comparative rarity of its occurrence in Scotland with what has been stated to be the case in England or in Ireland, induced me to address a note to my anatomical colleagues here, and from them I have very politely received the following answers to my queries.

DEAR SIR,—I have not met with an instance of the very curious entozoon (the vibrio humana, or trichina spiralis of Farre) discovered by Messrs. Hilton and Paget, of London, although I have turned my attention to it. The number of bodies which have been dissected in my Rooms, and under my superintendence, amounts to one hundred and forty-three.—I am, dear sir,

Yours faithfully,

P. D. HANDYSIDES.

Feb. 6, 1840.

MY DEAR SIR,—In answer to your inquiry, I beg to state that I have seen but one subject in the muscles of which the trichina spiralis was developed. The subject was a female, about 50

years of age, and of rather spare habit; the muscles were pale and soft. The trichinae were very numerous, at once detected with the naked eye, and contained, as usual, in a minute white cyst. I regret now that I did not take notes of all the muscles in which they were contained. I have superintended the dissection of between two and three hundred subjects, and this is the only case in which they were found.

I remain, my dear sir,

Yours sincerely,

ALEXANDER S. LIZARS.

1, Surgeons' Square, Edinburgh,
Feb. 13, 1840.

In addition to these notes from Drs. Handysides and Lizars, Mr. Mackenzie, who superintends Dr. Monro's Practical Rooms, has had the kindness to make me a lengthened verbal communication on the subject. He assures me that since the publication of my memoir the matter had received from him every attention, and he feels assured, that if any case had occurred in his Practical Rooms it could hardly have escaped observation; yet no case up to this date (February 1840), had ever occurred to him. Mackenzie comes therefore to the same conclusion as I and my other anatomical friends in town here have arrived at, viz. that the occurrence of the vibrio humana is very rare in Scotland, since of about 500 persons examined anatomically there had occurred but *three cases*. This of course refers more especially to the poorest class of society. What the average may be in the wealthier classes may, perhaps, be never ascertained.

REMOVAL OF DROPSICAL OVARIA.

To the Editor of the Medical Gazette.

SIR,

HAVING been so intimately connected with Mr. Walne's second case of ovarian operation performed on the 30th of May, 1843, it was with deep interest that I perused the details of Dr. Bird's case of the 26th of June, recorded in a recent number of your journal—a case so highly creditable to his management and tact.

It is not my intention to enter into the comparative merits of the major

and minor operations, and it is probable that I should not have addressed you on the subject at all, but for a remark in Dr. B.'s case as to his having "profited so little by Dr. Clay and Mr. Walne's recorded cases." Now, sir, in my perusal of Dr. Bird's case, what struck me most forcibly was the care with which he had pursued Mr. Walne's plan of treatment both before and after the operation (upon which, in my opinion, so much of its success depends), and I could not but feel how wisely he had acted in availing himself to the utmost of Mr. W.'s experience. Knowing, moreover, that the minute details of this (*then unrecorded*) operation, and its before and after management, were communicated to Dr. B. almost day by day during its progress, I regret exceedingly that he should have inserted such a paragraph in the report of his case.

It will, in my opinion, not lessen, but increase, the fair fame of every professional man to avail himself to the utmost of the experience of those who have gone before him; nay, it is a solemn responsibility which he is under to do so; but when communicating the results of successful experience let us do it in the spirit of the injunction of "in honour preferring one another."

I am, sir,

Your obedient servant,

JOHN M. CAMPLIN.

11, Finsbury Square, Aug. 29, 1843.

THE LATE SIR C. NIGHTINGALE.

To the Editor of the Medical Gazette.

SIR,

ON reading Mr. Lambert's account of the illness of Sir Charles Nightingale, and the post-mortem examination of the body, I was so surprised at the conclusion at which that gentleman seemed to have arrived, that I felt convinced there must be some circumstances omitted in the published account, which had materially influenced his judgment; his second communication, however, in no way removes the difficulty I felt in reconciling the inference drawn, with the symptoms from which it was deduced. Mr. Lambert's account of the case is very incomplete (for instance, there is no history given

of the symptoms previous to his first visit); but as he comes forward as the advocate of truth and justice, I will, with your permission, and with a view to elicit truth and to do justice, place the case in a different (and, as it appears to me, more natural) point of view to that taken by Mr. Lambert. The age of the deceased is not mentioned; but when a man at any age has emphysema of the lungs, dilatation of the left ventricle of the heart, chronic disease of the liver, and Bright's disease of the kidneys in an advanced stage, his constitution must have been a tolerably good one, if it has not given strong indications of what is commonly termed "breaking up." It would hardly surprise a medical man, who had arrived at a correct diagnosis in such a case, to find, in the latter stages of the combined diseases, effusion taking place into the cavities of the pleura and peritoneum; and if, urged by a desire to relieve his patient from some of his more urgent symptoms, he had recourse to the operation of tapping, it would scarcely be with a very sanguine hope that peritonitis would fail to swell the list of the allies of death. So far as we can judge from Mr. Lambert's account, this appears to have been the progress of the case; but we are not informed whether the tapping was done previous to his first visit, or subsequently; we are therefore left in uncertainty as to the operation being the cause of the peritonitis, the symptoms of which existed on the 4th.

Mr. Lambert, considering the combination of the diseases I have enumerated insufficient to cause death, seems to have cast about for some agent, the operation of which should satisfactorily account for the symptoms observed; and in "some irritant poison" he finds the solution to the difficulty. It is true, that in opposition to this idea stands the fact, that not only were there no symptoms during life indicating the action of poison, but that "there was not the slightest appearance in the mucous membrane (of the stomach) of inflammation or ulceration; it was more than usually pale." But Mr. Lambert gets over this difficulty very easily: he says, "but what *would* have been the appearances in the stomach if the vessels had not emptied

MEDICAL GAZETTE.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

VITAL STATISTICS OF SHEFFIELD.

MUCH has been done of late years to describe to Englishmen the state of England; to show one half of society how the other half lives; and thus to lighten the task of the legislator and the philanthropist, by pointing out what evils are the most pressing, and the most capable of being alleviated. Reports and books of this kind continue to appear in swarms. But as they commonly assume the shape of statistical works, a middleman, (or commentator) is required between the author desirous of being read, and the reader affrighted by long rows of figures; and we have, therefore, often thought it our duty to give the pith of a folio in an article, and lend the wings of the MEDICAL GAZETTE to facts which would otherwise have slumbered for ever on the shelves consecrated to Parliamentary literature. A work on the Vital Statistics of Sheffield, lately published by Dr. Holland, of that town, belongs partly, though not altogether, to this species. It will be consulted rather by members of parliament, and political economists, than by our professional brethren; and we shall therefore be doing some service to the latter, if we eliminate a few facts from the statistical volume of Dr. Holland.

The geological position of Sheffield is the foundation of its prosperity. Iron ore, and excellent coal, are plentiful; carboniferous limestone (used as a flux in smelting) is within the distance of a few miles; magnesian limestone for building costs only a few shillings a

themselves by secretion during the last stages of life?”! Panting is one of the symptoms on which much stress is laid by Mr. Lambert. One cannot help suspecting that the mode of breathing observed is inaccurately described by the term “panting,” for, with emphysema of one part of the lungs, congestion of another part, and effusion of fluid into both pleural cavities, it is difficult to conceive how the deep, hurried respiration, properly called panting, could be performed. That the breathing should be disordered, even had the lungs been healthy, would excite no surprise, for it is commonly observed to be so in peritonitis. Another symptom of peritonitis, the continual drawing up of the legs, is ascribed to “spasmodic action of the flexor muscles,” depending on spinal irritation. The mucous secretion, the vomiting, panting, icy coldness of the hands, are ascribed to irritation communicated to the solar plexus of nerves and spinal marrow; and the cause of this irritation is assumed to be poison!

It appears to me that Mr. Lambert, in his earnestness to advance the cause of truth and justice, has necessarily, either by publishing unfounded suspicions, and giving to them the weight of his character as a medical man, seriously compromised the character of innocent persons; or he has subjected himself to the imputation of doing so by omitting to state some of the grounds on which he comes to the conclusion he has drawn. If poison was the cause of death the symptoms must have corresponded with those usually produced by some known poison, which, in my opinion, they do not; and the circumstances under which the illness commenced would have been such as to indicate the mode of its administration. We do not learn from Mr. Lambert that such was the case. Disliking as much as Mr. Lambert controversial discussion, I think it hardly consistent with justice to insinuate criminality and deprecate inquiry.—I am, sir,

Your obedient servant,

G. D. HEDLEY, M.R.C.S.

Bedford, Aug. 28, 1843.

ton; while quarries of freestone exist in every direction round the town.

With these advantages, Sheffield has long been the head-quarters for the manufacture of hardware; in addition to which it is also a great, or perhaps the chief source of plate and plated goods. The hardware is exported to the whole world; the plated goods are chiefly for home consumption.

The working men of Sheffield are higher in morals, intelligence, and physical condition, than in towns, such as Leeds and Manchester, where machinery is extensively used, and where the steam-engine has too often brought down its human fellow-labourer to the starving point. Yet distress, severe distress, has now been the lot of the population of Sheffield for several years. The proofs of this are but too manifest. Nevertheless, so delusive are figures, unless we know all the elements on which they depend, that in one instance an important fact which seems to prove the increase of distress among the poor, is annulled by comparing it with another fact. The number of uninhabited houses at Sheffield in 1831 was 914; in 1841 it was 3,260. The second or corrective fact, however, is, that while the population of Sheffield and the neighbouring townships had only increased from 91,692, in 1831, to 112,492 in 1841, the number of inhabited houses had increased from 18,331 to 22,753; so that the population had rather more room to live in than before. In a word, the prodigious number of uninhabited houses arose not from a greater crowding of the poorer classes, but from the mania of speculators in building.

On the other hand, an equally false conclusion might be drawn, and often has been drawn, from the prosperity of Savings' Banks. At Sheffield, for instance, in the years from 1838 to 1842 (both inclusive), the number of de-

positors increased from 5046 to 3257, and the sum total deposited from £152,560 to £162,170.

In spite of this, however, distress has been constantly on the increase. How can this be? The answer is a simple one. A part of the depositors consist of persons not dependent on trade, and a part of persons but little affected by its fluctuations. Thus among the depositors we find 221 cutlers. It is not difficult to imagine that of the 5000 cutlers of Sheffield, 221 may get constant employment in the worst times, while a great part of the remainder, men of average skill and conduct, may suffer the pangs of extreme want.

The four hundred and fifty or five hundred workmen employed in the silver plated manufacture, furnish 89 depositors; yet even this prosperous division of Sheffield workmen has, no doubt, its share of hunger and nakedness; so that while the poorest classes of workmen furnish some depositors, the richest must send out many claimants of charity. The greatest proportion of depositors, says Dr. Holland, "is found amongst the best paid artisans, as forgemen, edge tool makers, steel melters, scythe and saw makers." This is natural enough; yet Dr. Holland thinks, in the same chapter, that it is questionable whether prosperity be as conducive to the augmentation of the deposits, as adversity! He means, we believe, that times of general distress increase the predisposition to save among those who are unscathed by the calamities around them.

So that, on the whole, while a host of contributors to a given savings' bank show that the distress in that town is far from universal, they are far from proving the absence of a large mass of misery.

In his comparison between past and present periods of manufacturing dis-

tress, Dr. Holland triumphs in the economy with which relief is now doled out to the distressed poor. We cannot share in his exultation, especially when we read what he says in another place, that "the deaths of hundreds in this town are to be traced to a deficiency of the necessaries of life. They may die of disease, but this is induced by poor living, conjoined with laborious exertion. We speak from a personal and extensive knowledge of the condition of the working classes."

According to the scale of relief to the casual poor, a single man receives for six days' work, eighteen pence in money, with nine pounds of bread and three pints of soup.

Supposing the soup to be a *potage à la poor-law*, or *Decoct. Avenæ dil.*, we may set down its value at a penny a pint; and if the bread is worth two-pence a pound, the wages of the man's labour will be 3s. 3d. a week—a reward which certainly does not err on the side of extravagance.

As an additional illustration of the doctrine that while the poor are sinking into misery, the upper and middle classes may be rising into luxury, we may quote the instance of Sheffield. "The immediate neighbourhood gives evidence of new life, activity, and happiness; and the changes in the picture have been effected chiefly within the last ten years. All classes, save the artisan and the needy shopkeeper, are attracted by country comfort and retirement. The attorney, the manufacturer, the grocer, the draper, the shoemaker, and the tailor, fix their commanding residences on some beautiful site, and adorn them with the cultivated taste of the artist." The Sheffield attorneys, in particular, flourish exceedingly. Out of sixty-six, "forty-one live in the country, and generally in the most costly mansions; and of

the twenty-five remaining in the town, ten have been in practice only about five years."

Many points concerning the good town of Sheffield we must pass over with the briefest notice. The public roads in the township are good; the sewers very tolerable. The new houses or cottages are built with the slightest possible outlay of materials. Dr. Holland's account reminds one of the old pleasantries about houses in the outskirts of London, where dancing is forbidden in the leases, lest it should bring the walls down. "In ordinary buildings, the bond timber which is inserted into the walls is generally three inches thick; but in these modern structures it is usually an inch, and occasionally not more than three-quarters of an inch."

The deaths from typhus fever at Sheffield are few to an inexplicable degree. Out of 100,000 deaths in Leeds, 4,688 are from this disease; 5,338 in Birmingham; 7,855 in London; and 6,390 in England and Wales; but only 1,551 in Sheffield. Whether this is an accident arising from the mean of only three years having been taken, or whether there is something febrifuge in the air of Sheffield, remains for time to show.

Among the causes which tend to lower the tone of morals in a manufacturing population, Dr. Holland enumerates—1. The crowding together of the working classes into filthy lanes and alleys. 2. The fluctuation of manufactures: prosperity produces dissipation, and penury breaks down the self-respect of the starving artisan. 3. The early employment of children. 4. The employment of women and girls. No school can be worse for a future wife than the workshop.

Dr. Holland truly says, that "the progress of civilization must not be

measured by the creation of wealth, nor does the latter afford a just indication of the amount of happiness pervading society. * * * The imposing expression of independence and affluence in the few must not mislead us in our estimate of the condition of the many. To appreciate this, we must take into consideration the urgent difficulties experienced by the masses to procure the common necessities of life; the melancholy failure of the attempt, as shown by the appalling fact, that in many manufacturing districts from one-seventh to one-tenth of the population is altogether dependent on parochial relief."

Dr. Holland, who is unfortunately a Malthusian, approves of the New Poor Law, which, he says, was passed to prevent the upper and middle classes being swallowed up in the growing degradation and necessities of the masses. He observes that we have enlarged our prisons, and made the paying of debts very easy, "yet when it is proposed to educate the poor, we are at once in arms, afraid that they will be enlightened and made good according to an established system, when the great truths of this system are the common truths on which all believers rest."

We must postpone to another occasion the account of the principal trades carried on at Sheffield, with the resources and relative position of the workmen.

COLLEGE OF SURGEONS — NEW CHARTER.

We understand that the College of Surgeons have not actually obtained a new charter, but have every prospect of speedily doing so. The chief changes contemplated are:—The establishment of a body of "Fellows," amounting to 300, to be composed of members of a certain standing, not

practising pharmacy. The Council to be periodically elected by the Fellows. The Court of Examiners to be appointed by the Council, but not necessarily to be members of that body.

CIRCULAR TO LECTURERS.

Royal College of Surgeons in London,
August 15, 1843.

Sir,—I am directed by the President of this College to transmit to you the inclosed copy of their Amended Regulations respecting the professional education of candidates for their diploma; and, at the same time, to express the opinion of the Council that it is highly inexpedient that the pursuits of the students should be interrupted by a vacation at Christmas, or at any other period of the winter, and to state that they strongly recommend that the vacation hitherto allowed should be discontinued.—I am, sir,

Your most obedient servant,
EDM. BELFOUR, Sec.

REGULATIONS OF THE COUNCIL

Respecting the professional education of candidates for the diploma, August 15, 1843.

I. Candidates will be required, in addition to a Certificate of being not less than twenty-one years of age, to bring proof

1. Of having been engaged in the acquirement of professional knowledge for not less than four years; during which period they must have studied practical pharmacy for six months, and have attended one year on the practice of physic, and three years on the practice of surgery, at a recognised hospital or hospitals in the United Kingdom*;—three months being allowed for a vacation in each year.

2. Of having studied anatomy and physiology, by attendance on lectures and demonstrations and by dissections, during three winter sessions, of not less than six months each.

3. Of having attended at least two courses of lectures on the principles and practice of surgery, delivered in two distinct periods or seasons, and one course, on each of the following subjects, viz. the practice of physic—chemistry—materia medica—and midwifery with practical instruction.

II. Members and licentiates in surgery of any legally constituted College of Surgeons in the United Kingdom, and graduates in

* By a Resolution of the Council on the 7th of November, 1839, no provincial hospital will in future be recognised by this College which contains fewer than 100 patients, and no metropolitan hospital which contains fewer than 150 patients.

surgery of any university requiring residence to obtain degrees, will be admitted for examination on producing their diploma, license, or degree, together with proofs of being twenty-one years of age, and of having been occupied at least four years in the acquirement of professional knowledge.

III. Graduates in medicine of any legally constituted College or University requiring residence to obtain degrees, will be admitted for examination on adducing, together with their diploma or degree, proof of having completed the anatomical and surgical education required by the foregoing regulations, either at the school of the university where they shall have graduated, or at a recognised school or schools in the United Kingdom.

IV. Certificates will not be recognised from any hospital unless the surgeons thereto be members of one of the legally constituted Colleges of Surgeons in the United Kingdom; nor from any school of anatomy, physiology, or midwifery, unless the respective teachers be members of some legally constituted College of Physicians or Surgeons in the United Kingdom; nor from any school of surgery, unless the respective teachers be members of some legally constituted College of Surgeons in the United Kingdom.

V. Certificates will not be received on more than one branch of science from one and the same lecturer; but anatomy and physiology—demonstrations and dissections—will be respectively considered as one branch of science.

VI. Certificates will not be received from candidates for the diploma who have studied in London, unless they shall have registered their tickets at the College, as required by the regulations, during the last ten days of January, April, and October, in each year; nor from candidates who have studied elsewhere, unless their names regularly appear in the registers transmitted from their respective schools.

N.B. In the certificates of attendance on hospital practice and on lectures, it is required that the dates of commencement and termination be clearly expressed; and no *interlineation, erasure, or alteration* will be allowed.

Blank forms of the required certificates may be obtained on application to the Secretary, to whom they must be delivered, properly filled up, ten days before the candidate can be admitted to examination; and all such certificates are retained at the College.

By order of the Council,

EDM. BELFOUR, Sec.

FELLOWS' CLINICAL PRIZE REPORTS.

BY ALFRED J. TAPSON.

University College Hospital, 1842.

[Continued from p. 751.]

CASE XVI.—*Acute bronchitis, with vesicular emphysema and cretaceous concretions in the lungs; dilated hypertrophy of the heart, and disease of the aortic valves; also disease of the liver, kidneys, &c.; fatal termination; sectio cadaveris.*

MARY M——, ætat. 42, admitted May 9, 1842, under Dr. Taylor. She is a tall, slight, pale and nervous looking woman; is married, and has had three children, besides miscarrying three times; her father is living and healthy; her mother died of consumption. Her habits of life have been regular, and she has never been in want; is a native of Scotland, but has been living near Tottenham Court Road for three years, in a close damp house, and has never been well since she has been there. She is habitually delicate, subject to headache and indigestion, with rising of a bitter greenish fluid into her mouth whenever she drank any beer or spirits, or took more food than usual. Menstruation perfectly regular. She had the measles and whooping-cough when six years old, and has ever since had a hard cough, especially in the winter; and for nearly twenty years she used to spit up blood occasionally; but this last symptom ceased ten years ago, about the time she was married. Her breath is always short, particularly in the night, and in foggy weather; and lately she has frequently had fits of asthma. She never had palpitation or pain in the region of the heart, and was never laid up with rheumatism, though she has had many slight attacks of it.

She attributes her present illness to a cold which she caught two months ago, from walking out in very thin shoes when the weather was very cold. She was attacked with pain in the left side, increased difficulty of breathing, and her cough was much worse. During the last fortnight the pain has increased, and the cough has been very severe, and attended with expectoration of mucus.

Present symptoms.—Her face is rather pallid, but there is notwithstanding a slight amount of lividity; the lips are swollen, and of a very deep red colour; the nose is also very red. She complains of a severe pain in the left side, rather low down, about the ends of the false ribs, and also in the pit of the stomach; it is increased by pressure and by a deep inspiration. The breathing is

very quick and laboured, and increased in regular paroxysms, during which the urine passes off involuntarily. She has a good deal of cough, attended with frothy mucous expectoration. The skin is cool and moist; the pulse quick, but small and soft. She lies habitually on her left side, but can lie on either side. She complains of numbness of the left hand and fore-arm.

Physical signs.—Anteriorly the right side of the chest seems rather fuller than the left; during inspiration the ribs rise in a perpendicular plane with the sternum, and very little expansion takes place. The sound on percussion is very clear under both clavicles; it is rather clearer on the left side than on the right, in the lower third of the chest: on the right side percussion is dull below a line drawn from the lower end of the sternum to the sixth ribs laterally, and the dulness extends two or three inches below the margin of the ribs. The respiration is very loud, but scarcely any vesicular murmur can be heard, and there is a good deal of sonorous rhonchus. Posteriorly there is dulness on percussion over the lower third of the right lung, and sonorous and a little mucous rhonchus in the lower part of the chest, loudest on the left side. There is a distinct double murmur with the heart's sound, heard most distinctly over the base and at the lower third of the sternum; it is heard also in the neck. The impulse of the heart is increased in extent.

Applic. Cucurb. Cruent. infra scap. sinist. ad f3viii.

R. Antim. Potassio-Tart. gr. ss.; Mist. Camph. f3iiss. ft. haust. 6tis horis sumend. Low diet.

May 10th.—Has had no sleep at all during the night, but her breathing has been easier ever since her admission into the hospital. She feels weak and faint, and sick; she vomited once after taking the medicine. The pain in the side is not much relieved, and the pain at the epigastrium is worse. She has not much cough, but spits up a good deal of mucus. The bowels have not been opened. The urine is scanty, and deposits a copious, light, flesh-coloured sediment, soluble in liquor potassæ; reaction acid, not albuminous.

In the evening the breathing was very distressing; the countenance livid; the abdomen swelled and tympanitic. She was ordered a purgative enema.

11th.—The bowels have been opened twice; the dyspnoea and cough are less troublesome, but she cannot lie on the left side, which is the side she usually does lie on. The skin is cool.

Sumat. Antim. Potassio-Tart. gr. $\frac{1}{2}$, tantum pro dosi.

12th.—The pain in the side prevents her from sleeping, and she cannot lie down at all now from the dyspnoea; complains of palpitation; the abdomen tympanitic and swelled; the menses appeared last night, which is, she says, a week before the proper time.

Habeat haustus purgans.

About noon she had severe pain about the umbilicus, which was relieved by pressure and by hot drinks, which caused the evacuation of wind. After this she became very much excited and delirious; the countenance extremely pallid, pulse 116 and weak, and was obliged to be pillowed up in bed. The urine was scanty, sp. gr. 1030; it contained an abundant sediment, and also a considerable quantity of albumen, as shown by heat and nitric acid, the precipitate filling one-fifth of the test-tube after standing twenty-four hours.

13th.—Pain and dyspnoea diminished; cough easier; mucous expectoration abundant and tinged with blood; pulse 104, soft, and rather jerking; feet and ankles slightly œdematous; she states that they used to swell, but have not lately; the bowels have been freely opened, and the motions were of a deep yellow colour, whereas hitherto they have been pale; tongue flabby, and covered with a whitish fur; she is very thirsty, but says that when she attempts to drink it always chokes her; still feels sick after taking the medicine; physical signs much the same as on her admission.

Omittatur haustus Antimonialis.

R. Pil. Assafoetid. Comp. gr. x. ft. pil. ij. ter die sumendæ. Low diet, and pint of milk.

14th.—Sleeps very little, and frequently screams in the night; the breathing and the palpitation are much relieved, and she can now lie down again; feels very weak, cries frequently, and is troubled with globes; complains of a burning pain in the epigastrium, and whatever she takes is immediately vomited; there is tenderness on pressure in the upper part of the dorsal spine on the left side; pulse 108, jerking; tongue dry and brownish; papillæ enlarged; thirst great; bowels very open; urine plentiful, acid reaction, sp. gr. 1022, tolerably clear, but still contains albumen. In the afternoon she was ordered—

Sp. Æth. Sulph. f3ss.; Aq. Menth. Pip. f3iiss.

which gave her much relief.

15th.—Slept better last night, and feels more comfortable.

16th.—Has been very restless again, making a great noise, crying, &c.; the breathing is more free, but she still feels a catching if she lies down; has no palpitation;

pulse 104, tolerably full; tongue moist and brown; urine still decidedly albuminous.

17th.—Last evening she became very outrageous, crying and making much disturbance, and about 10 o'clock she was ordered a draught containing half a grain of morphia: she went to sleep after a time, and the nurse found her dead between 3 and 4 o'clock. She had died without any convulsion, &c.

Sectio cadaveris 60 hours after death.—We may mention that, in consequence of the examination being made at the house in which the deceased had lived, some points were not so fully examined as they otherwise would have been. The body generally was considerably emaciated. The head was not opened.

Thorax.—The lungs scarcely collapsed at all when the thorax was opened. The right pleura contained about two pints of serum, and the left about half a pint; there were some old firm adhesions at the upper and back part of the right lung, but none on the left side; both lungs were somewhat distended with air, and the air-cells were distinctly enlarged everywhere; when squeezed, the air readily passed under the pulmonary pleura. The apex of the left lung presented an irregular puckered appearance, and on cutting into the substance a little beneath this there were several small calcareous concretions found. On making a section of the lungs, a good deal of frothy reddish serum exuded, and the bronchial tubes projected from the cut surface, being much thickened and indurated; they contained the same kind of bloody mucus as had been expectorated during life: the mucous membrane was not redder than usual. The pericardium contained about two ounces of a reddish serum. The heart was considerably enlarged, weighing fourteen ounces. The left ventricle was dilated, and its walls as thick as natural. The aorta measured two inches and six lines in circumference; there were no spots on it: the aortic valves were much diseased; one of them had a large vegetation growing from it, and the other two were thickened and somewhat diminished in size. The mitral valve was of the natural size, and so was the left auricle. The right ventricle was enlarged, and its lining membrane rather opaque; the tricuspid valve of the natural size; the pulmonary artery measured the same in circumference as the aorta; the semilunar valves were healthy; the right auricle was somewhat dilated, and contained a large, thin, dark coagulum.

Abdomen.—The cavity of the peritoneum contained some serous effusion. The liver was enlarged, chiefly the right lobe, which was very thick, measuring quite three inches and a half at the thickest part; the cut surface had a mottled aspect, there being small isolated brown spots, surrounded by a light

yellow tissue, and on the upper surface, over a considerable part of the right lobe, there was nothing but this yellow tissue for the depth of half an inch, looking as if all the blood had been driven from this part. The stomach was very large, and was somewhat constricted in the middle, otherwise apparently healthy. The spleen was very much enlarged, being about twice the natural length, and having a large rounded projection on the upper and inner part, which received quite a distinct set of vessels. The substance of the spleen was very firm, and contained very little fluid matter. Both kidneys were enlarged, and a little uneven on the surface; the investing membrane was firm, and adherent to the subjacent substance, small portions of this coming away with it when it was removed; the substance was pale, and of about the usual consistence. The intestines were not opened. The uterus was apparently healthy; the right ovary was very hard, and contained several small hard bodies about the size of a pea, and a small cyst filled with a dark coagulum of blood; the left ovary also was hard, contained several small cysts on the surface and in the substance filled with blood and bloody serum, also some small bodies as hard as cartilage.

REMARKS.—It is evident, from the preceding account of the symptoms which existed during life, and of the appearances after death, that the patient had laboured under a complication of diseases, most of which were of long standing, but some more recent. We shall, for the sake of perspicuity, arrange the symptoms in groups according to the different diseases on which they may be supposed to have depended, and introduce with them as much of the previous history and post-mortem appearances as seems necessary for the elucidation of the different parts of the case. In this way we cannot avoid considerable repetition.

1st. *As to the diseases of the lungs. (a.) History.*—She was predisposed to phthisis, as her mother had died of that disease. She had hooping-cough when six years of age, and had ever since been troubled with a hard cough and shortness of breath; worse in the winter, and especially in foggy weather; also for nearly twenty years she used to spit up blood frequently. The cough and dyspnoea had been much worse for two months, and she had, during the same time, bad pain in the left side.

(b.) *General symptoms and physical signs on admission.*—Lividity of the features; great dyspnoea, increased in paroxysms; frequent cough, accompanied with copious frothy mucous expectoration, and pain in the left side. Peculiar costal respiration; very clear sound on percussion all over the front of the chest, except at the

lower part of the right side, where, as well as posteriorly on the same side, percussion was dull (this was attributed to enlargement of the liver); very feeble vesicular murmur; sonorous rhonchus, loudest on the left side, and a little mucous rhonchus posteriorly.

(c.) *Post-mortem appearances.*—Serous effusion in both pleuræ; permanent distension of both lungs with air; enlargement of the air-cells; hypertrophy of the bronchial tubes; bloody mucus in them; puckering of the apex of the left lung, and calcareous concretions just beneath the puckered part.

Such were the most important points concerning the lungs as a whole, but as we believe that they indicate three distinct diseases, viz., emphysema, bronchitis, and tubercular remains, we must briefly rearrange them under these three heads. Thus, to the emphysema belong the long-standing dyspnoea, increased in paroxysms, the peculiar respiration, the cough, the morbidly clear sound on percussion, and feeble vesicular murmur, together with the distension of the lungs and dilatation of the air-cells observed after death, which are quite distinctive of emphysema: secondly, to the bronchitis (to the chronic form of which we presume she had been subject), belong probably part of the winter cough and dyspnoea, the great aggravation of these during the last two months, the frothy mucous expectoration, which became tinged with blood a few days before death, the pain in the left side of the chest, the sonorous and mucous rhonchi, together with hypertrophy of the bronchial tubes, and bloody mucus found in them after death: and thirdly, we believe that the frequent hæmoptyses during nearly twenty years, the puckering of the apex of the left lung, and the cutaneous matter found in the lung just beneath the puckered part, are sufficient, when taken in connection with the predisposition to phthisis and the winter cough, &c., to prove that tubercles had formed in the apex of the left lung, that they had undergone that series of changes which ends in the formation of cretaceous masses, and had produced the puckering of the surface by exciting pleuritis, with effusion of lymph, which subsequently contracted.

There is yet another point which requires notice before leaving the lungs, viz., the effusion that was found in the pleuræ after death, amounting to two pints in the right pleura, and half a pint in the left. Did this depend on pleuritis? We think not; because there were not any other marks of inflammation of the pleura, no redness, or recent lymph, or false membranes, &c. It was probably due to the same cause as had produced the oedema of the ankles during life, viz., the disease of the heart: this opinion is confirmed by the coexistence of

effusion into the pericardium and peritoneum, and also by the strong probability that it only came on a day or two before her death, about the same time as the oedema came on. It is true that there was dulness on the right side even on her admission, and supposing this to have depended on fluid in the pleura it would also explain the fulness of the right side of the chest, and the great dyspnoea and inability to lie on the left side, and afterwards to lie down at all; yet we think that had so much fluid been present it would have been detected; and even admitting that it might have escaped detection (for we should mention that it was very difficult to make a careful examination of the physical signs, owing to the very nervous and excited state of the patient), how are we to explain the disappearance of the orthopnoea, as is stated in the report of the 14th May, unless the fluid had been absorbed: besides there were other causes which would explain the dulness and the symptoms that were present.

2d. *Diseases of the heart.* (a.) *The previous history* did not throw much light on these. She had been subject to rheumatism, but had never had a severe attack, and never had any particular symptoms of disease of the heart, as pain, palpitation, &c., at least she said she had not; but considering that she was always very nervous, any symptoms of the kind that might have existed would probably have been attributed to nervousness.

(b.) *The symptoms and signs* on her admission clearly indicated considerable disease of the heart; probably the lividity of the face was partly due to this cause, and also the palpitation and oedema, which came on subsequently, and the jerking character of the pulse. The impulse was increased in extent, and there was a distinct double murmur, loudest over the base of the heart and lower half of the sternum, heard also in the neck. These would indicate hypertrophy of the heart, and probably such disease of the aortic valves as would cause obstruction and permit regurgitation.

(c.) *The post-mortem appearances* quite confirmed the diagnosis which was made during life. The heart was considerably enlarged, being nearly double the average weight of the heart in females; both ventricles and the right auricle were enlarged, and the walls of the natural thickness: there was therefore "dilated hypertrophy." All the orifices were of the natural size, except the aortic, which was obstructed by the presence of a large vegetation on one of the valves, whilst the other two valves were thickened and rather diminished in size. The morbid growth was evidently such as would produce considerable obstruction to the flow of the blood into the aorta, and also,

by preventing the perfect closure of the orifice, would permit of regurgitation into the ventricle, and was quite sufficient to explain the double murmur which had existed.

3d. Disease of the liver. (a.) The previous history.—States that she had always been subject to a rising of a bitter greenish fluid into her mouth on taking beer or spirits, or even a little more food than usual, but she had never had jaundice or any disease of the liver.

(b.) Symptoms and signs on admission.—The chief of these was the increased size of the liver, as indicated by the increased extent of dulness on percussion both upwards and downwards. We may notice in connection with the state of the liver that the bowels were costive and the evacuations pale in colour at first, though subsequently they became of a deep yellow colour, and there were several symptoms of indigestion, as pain in the epigastrium, tenderness on pressure, great flatulences, and afterwards vomiting, &c.

(c.) Post-mortem appearances.—The liver was considerably enlarged and presented the nutmeg appearance, isolated brown spots, surrounded by a continuous yellowish tissue, indicating therefore congestion of the hepatic veins in common with the rest of the venous system.

4th. State of urine and kidneys.—On every occasion on which we tested the urine, except the first, it contained albumen; the specific gravity varied at different times, but we never found it less than 1020; it also contained a sediment of the lithates.

After death the kidneys were found to be enlarged and pale; the surface rather uneven, and the capsule adhered so firmly to the subjacent substance as to tear away small portions of it when it was stripped off; the substance appeared healthy, except being pale.

With these facts before us, what is the conclusion we come to as to whether the albumen in the urine depended on disease of the kidneys, or on some other cause? We know that various causes will temporarily produce albumen in the urine, but its habitual presence there must indicate some deranged state of the kidneys. In this case it was not detected when the urine was first examined, but it was on every subsequent occasion. Other causes existed here which would account for the albumen: thus the disease of the heart and venous obstruction were sufficient causes, and the fact of the specific gravity not being below the healthy standard would rather favour the idea that it did not depend on granular degeneration of the kidneys; but on the other hand the post-mortem appearances were those which are said to indicate the early stage of this dis-

ease; this, therefore, may have been the cause, and the specific gravity, though always low in the advanced stages of this disease, is not always so in the early stages. We cannot, however, decide with certainty whether the albuminous urine depended on the state of the kidneys, or on the obstruction in the circulation.

5th. Menstruation and the state of the ovaries.—The patient died five days after menstruating, and we mention this in order to place it in connection with the condition in which the ovaries were found: whether any of the appearances were due to the menstruation we cannot tell, but certainly the ovaries were affected with a chronic disease, which, if the patient had lived, might perhaps have gone on to ovarian dropsy.

It is scarcely worth while to say anything respecting the condition of the spleen; it was enlarged and indurated, and of a curious shape; the enlargement was probably due to the same cause as the enlargement of the liver, *i. e.* most likely to the state of the heart.

We have now to say a few words on the treatment, causes, prognosis, and cause of death. The disease for which she was admitted, and the only one of the many under which she laboured that was likely to receive much relief from *treatment*, was the bronchitis. We may remark here that notwithstanding the extent and severity of this disease, the skin was cool and moist, contrasting strongly with the great heat and dryness of the skin in the cases of pneumonia which we have reported, and which confirms the usual statement of the much greater heat of skin in the latter disease. The treatment adopted here was local bloodletting by cupping, and the administration of tartar emetic. The last remedy produced much greater inconvenience than it usually does; and this was probably due to the extremely nervous state she was in, and perhaps also to the condition of the digestive organs: it was continued for four days, in which time many of the symptoms of bronchitis were much relieved, but she became so hysterical that there was no possibility of ascertaining the state of the disease. She was then ordered some antispasmodic pills, which did her good, and she seemed much better on the whole, but was very weak and nervous, and she expired rather unexpectedly.

The *causes* of the emphysema must be dated back to the attack of the hooping-cough which she had when six years old; her breathing had been short ever since then, and this disease is well known to be a cause of vesicular emphysema. The same cause may have excited the development of the tubercles on which, we presume, the hæmoptysis depended. The bronchitis, that is, the last attack of it, was caused by walking out

in very cold weather with very thin shoes on. The cause of the diseases of the heart is not very apparent; the hypertrophy may perhaps be attributed to the long-continued increased action consequent on the state of the lungs, and to the hypertrophy we must ascribe the disease of the liver and spleen.

The *prognosis* in a case so evidently complicated could not be otherwise than unfavourable ultimately, but there was no great reason why she should not get the better of this attack; at all events, there seemed to be no cause for immediate apprehension. On the 12th of May she appeared to be almost dying, but recovered again, and then seemed better, and after being exceedingly outrageous she had a very moderate anodyne draught, and went to sleep, and was found dead some hours after. The cause of death was very obscure; it may perhaps have been due to the diseased condition of the heart.

TREATMENT OF GONORRHŒA.

To the Editor of the Medical Gazette.

SIR,
IN Mr. Child's paper relating to the "Treatment of Gonorrhœa by Superficial Cauterization of the Urethra," he wishes to know if any other practitioner than himself had adopted the same mode of treatment.

I had the pleasure of attending Dr. Pereira's lectures with Mr. C., who must well remember Dr. P. relating the cases of two students trying this mode, in one satisfactorily, in the other it produced testitis and a long train of evils. Whilst gonorrhœa can be so easily managed with *weak* injections of the nitrate of silver (gr. ij. ad. Aq. Distillat. ℥viij.), and sulphate of zinc (gr. ij. ad Aq. ℥j.) with or without Bals. Copaib. &c. I cannot think we ought to try this "bold" practice, especially as even in this treatment Bals. Copaib. c. Cubeb. combined must be given.

If Mr. C. will even adopt the injection of cold water frequently repeated, say every half hour or so, he will find the discharge sooner cured, and his patients better pleased, than with his or Dr. P.'s "superficial cauterization of the urethra."

I have the honour to be, sir,
Yours very obediently,
M.D.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XLII.

*On the Treatment of Uterine Inflammation
in Puerperal Women.*

LIKE inflammation of other organs, that of the uterine system varies greatly in severity in different cases and at particular periods, and in some individuals at all periods there is a disposition to the disease manifested after delivery, by tenderness of the hypogastrium on pressure, and by acceleration of the pulse, where inflammation has not been actually developed, or where it has taken place in so slight a degree as to yield readily to the exhibition of opiates, and the application of warm fomentations and poultices over the region of the uterus. Some practitioners have been so convinced of the advantages and necessity of employing these remedies with the view of preventing attacks of the disease, that they caused all their patients recently delivered to take, from time to time, and at intervals more or less distant, small doses of Dover's powder, and have applied emollient poultices to the hypogastrium. In cases of intestinal irritation, after-pains, and various spasmodic affections of the uterus and abdominal viscera, this plan of treatment will prove successful. In slight inflammatory affections of other organs it is not unusual for the symptoms to subside without the employment of more active remedies, and it scarcely admits of a doubt that in some of the milder varieties of inflammation of the

uterus a spontaneous solution of the disease not unfrequently takes place. But where inflammation of the peritoneal coat of the uterus is fully developed, and where the affection occurs in a severe sporadic or epidemic form, the soothing plan of treatment, by opiates and warm poultices over the hypogastrium, will prove wholly insufficient to arrest its course, and unless blood-letting, general and local, and other antiphlogistic remedies, be early and vigorously employed, it will, in most cases, proceed to a fatal termination. In no inflammatory affection of the internal organs are the good effects of blood-letting, general and local, more strikingly displayed than in puerperal peritonitis; but the results of my experience do not confirm the accuracy of the opinion, that in all cases, by the employment of these means, we can succeed in arresting the progress of the disease, which is always attended with the greatest danger, and not unfrequently rapidly runs its course to a fatal termination in spite of the most prompt and copious depletion, and the application of all other remedies. When the symptoms of puerperal peritonitis manifest themselves as before described, and especially when there is intense pain of the uterus, increased by pressure, twenty or even more ounces of blood should be immediately abstracted from the arm by a large orifice, and while the patient has the shoulders and trunk considerably elevated in bed. We should not be deterred from employing the lancet freely, because the pulse is small and contracted, provided it does not exceed 120 or 130 in the minute, for in some cases the pulse has become fuller and stronger during the time the blood has been flowing, or soon after. Even where the pulse is still more rapid and feeble, if the local pain be very great—this is here a far safer guide than the pulse—we must not be deterred from employing venesection to the requisite extent, and in all cases, if possible, a decided impression should be made upon the system, and

where syncope or faintness follows the blood-letting, it increases the salutary effect. In no case of inflammation of the peritoneal surface of the uterus and peritoneal sac have I seen any bad consequence to result from depletion carried to this extent, and in many, from its early use, the force of the disease has at once been completely broken, which could not have been the case had the inflammation been erysipelatous or of a specific nature. In reflecting upon the cases contained in the accompanying tables, and observing the number which terminated fatally, it is impossible to avoid the conclusion, that some patients were lost from the want of active depletion at the commencement of the attack. In many, the disease had been fully formed twenty-four hours or longer before the patients were seen, and then blood-letting was employed so sparingly as to exert no influence on the progress of the disease. When the attack of peritoneal inflammation is violent, and when the pain is but slightly relieved, the venesection should be followed without loss of time by the application of one, two, or three dozen of leeches to the hypogastrium, proportioning their number to the urgency of the symptoms. When the leeches have fallen off, the bleeding from their bites should be encouraged by warm fomentations, or by a thin warm linseed meal poultice, which should be frequently renewed while the bleeding continues. At the same time five grains of calomel should be administered in combination with five grains of James's powder, and gr. iss. or gr. ii. of opium, or with six or eight of Dover's powder, and this should be repeated every three or four hours until the symptoms begin to subside. The exhibition of purgatives along with the calomel till the bowels are freely evacuated, is always of the utmost consequence. There are comparatively few cases in which it is necessary to have recourse to a second bleeding from the arm, and where the propriety of this is indicated by an imperfect relief, or renewal of pain, the quantity of blood taken away seldom ought to exceed fifteen ounces. The quantity which requires to be withdrawn in the first bleeding seldom exceeds xxxv . and in the second xxv .; but there are exceptions to this, and cases of puerperal peritonitis undoubtedly have occurred in which more copious depletion was had recourse to with decided advantage. Where the pulse has become much more rapid and feeble after the first bleeding, and the strength has appeared to be much impaired, even if the uterine pain continues, blood should not be drawn a second time from the arm. Six or eight hours after the first bleeding, should the pain continue undiminished in violence, and the pulse be full and not very rapid, and the strength of the patient but little im-

paired, a second venesection to the extent above stated may be ordered, not only with safety but with decided advantage. The great mortality which has taken place in this and in the other varieties of uterine inflammation certainly cannot be attributed to the abuse of blood-letting, for you will observe in the tables that the greater number of those patients who were bled early and copiously recovered, and that most of those who died were either not bled at all, or very late and sparingly, or took stimulants. After the violence of the attack has been subdued, it is proper to continue the use of the mercury, but in diminished doses: two grains instead of five every four or six hours, combined with opium or Dover's powder, will be sufficient, and this should be continued until the mouth becomes affected, or until the uterine tenderness be greatly relieved. The object in administering mercury in uterine inflammation is the same as in iritis; to remove the congested and inflamed state of the vessels of the peritoneum, and to prevent the disease from terminating by effusion, when all remedies are generally unavailing. Blood-letting, general and local, the exhibition of mercury with opiates and purgatives, are the principal means which we possess in the treatment of cases of puerperal peritonitis, and they often check the progress of the disease. But they have little influence over inflammation of the veins, absorbents, and muscular coat of the uterus, and I am not aware of the existence of any means by which it is possible for us to stop the progress, or counteract the effects, of such destructive morbid actions as those which produce suppurative inflammation of the uterine veins, and of the ovaria and fallopian tubes, and gangrenous softening of the walls of the uterus. The greater number of these cases will, I fear, always terminate fatally whatever plan of treatment be adopted: the lesions discovered by morbid anatomy have rendered this too obvious. The symptoms in these cases from the commencement have generally been such as to contraindicate the use of general blood-letting. Where the reaction at the invasion of the inflammation has been violent, and venesection has been employed, the relief obtained has only been temporary, if at all experienced; in some, blood would not flow when a vein was opened in the arm; and in a few others, the abstraction of only a few ounces has produced alarming faintness. When the local pain is severe, which it seldom is, leeches and warm fomentations seem to be the appropriate remedies; but as I have already stated, we possess none which effectually control the progress of deep-seated inflammation of the uterus. Some foreign physicians are, however, of a contrary opinion,

and are satisfied that we possess a powerful remedy, even in the worst cases, in mercury employed so as to excite salivation. In several cases of uterine phlebitis I have pushed this remedy, by inunction, to a great extent, and brought the system under the influence of mercury in less than 24 hours; yet the progress of the symptoms was not arrested, and the patients died as others had done where the remedy had not been administered. In other cases I have employed mercury to a great extent internally, without the slightest benefit; and it may justly be doubted, from the results of M. Desormeaux's practice, whether or not it possesses the influence M. Tonellé supposes; for of forty-three cases where mercury was used as the chief remedy, only fourteen recovered. In the latter stages of inflammation of the deep-seated structures of the uterus, the great depression of the powers of the system renders the liberal administration of stimulants necessary; and in a few cases of uterine phlebitis the lives of the patients appeared to be preserved by them.

In the *Elements of the Practice of Physic*, by Dr. Craigie, there is contained the following excellent account of blood-letting in uterine inflammation. You will see that he has recommended a much more vigorous application of it than I have done; and probably he is right in this, and that I would have been more successful if I had been more energetic in the use of the remedy.

"That blood-letting is a powerful and effectual remedy is shown, not only by the experience of Hulme, Leake, and Gordon, but more recently by that of Hey and Armstrong. But, in order that it be effectual, two things are requisite: first, that it be carried to sufficient length; and secondly, that it be practised as early as possible, at the commencement, or at least within the first twenty, in many within the first twelve, hours of the disease. On the quantity of blood to be taken a great revolution has taken place in this and other inflammatory disorders. Thus, Hulme and Leake talk of eight or ten ounces as a great bleeding, which will do much good; whereas Gordon carried it to twenty or twenty-four: and as all his patients who were blooded to that extent in the beginning had speedy and perfect recoveries he did not think it expedient to carry it further. It is different with Armstrong and Hey, the former of whom occasionally carried it to thirty ounces at the first, and the latter in one case to fifty-two ounces (24th); and I found it necessary to detract forty ounces from a plethoric young woman at once, with the best effect, in puerperal fever. But though I mention these facts to give some idea of the quantity requisite to

to produce some check on the disease, it must not be imagined that it is possible to fix it in precise terms. In one subject, sixteen or twenty ounces may produce as great an effect as thirty or forty in another; and the best rule is to bleed until we have proof that the effect is produced. The most decisive and least equivocal proofs are, fainting, either approaching or actually come on, and abatement or entire cessation of pain in the belly. If one blood-letting be not succeeded by one or other of these effects, a second, third, or even a fourth, at the interval of even a few hours, ought to be practised. This is the manner in which Hey and Armstrong appear to have practised blood-letting, rather than by one copious evacuation; and in some instances fifty, sixty, or even eighty, ounces of blood were lost before the disease began to yield. In one of Armstrong's cases, fifty ounces were drawn in three operations; and in another, by four copious bleedings and two small ones, eighty ounces were lost before the abdominal inflammation was subdued. In like manner, in one of Hey's cases, thirty ounces within the first four hours were taken at one blood-letting; at a second, ten; and at a third, eleven — fifty-one before the symptoms of abdominal soreness had abated; yet, as pain returned, fifteen more ounces were taken from the arm, and a few from the belly, by cupping and leeches. In another case twenty-five ounces were drawn at the first; after the interval of a few moments nine ounces more; and before the arm was finally tied up six ounces more; —making in all forty ounces, after which the patient became faint, and the pulse fell from 112 to 88; yet pain recurred, and was relieved permanently only by taking eight ounces more about six hours after. In another (22d) twenty-four ounces were taken at the first, with the effect of causing faintness and reduction of the pulse from 100 to 72, and about twelve hours after, in consequence of the pain returning, twelve ounces more, in all thirty-six. In a fourth case, (25th,) five hours after the first sensations of pain, thirty-three ounces were taken from a large orifice, and quickly, with the effect of removing soreness and pain, but without causing fainting, and about twelve hours after twenty ounces ere the symptoms of the disease were sensibly abated. In short, the simplest rule is to detract blood quickly and from a large opening, till the pulse becomes softer, or less frequent, or the pain is relieved, or the patient begins to faint. In some cases the pulse remains unchanged, or, instead of becoming slower, becomes quicker; and then it is best to be guided by the approach or occurrence of alleviation of pain; and in the

where syncope or faintness follows the blood-letting, it increases the salutary effect. In no case of inflammation of the peritoneal surface of the uterus and peritoneal sac have I seen any bad consequence to result from depletion carried to this extent, and in many, from its early use, the force of the disease has at once been completely broken, which could not have been the case had the inflammation been erysipelatous or of a specific nature. In reflecting upon the cases contained in the accompanying tables, and observing the number which terminated fatally, it is impossible to avoid the conclusion, that some patients were lost from the want of active depletion at the commencement of the attack. In many, the disease had been fully formed twenty-four hours or longer before the patients were seen, and then blood-letting was employed so sparingly as to exert no influence on the progress of the disease. When the attack of peritoneal inflammation is violent, and when the pain is but slightly relieved, the venesection should be followed without loss of time by the application of one, two, or three dozen of leeches to the hypogastrium, proportioning their number to the urgency of the symptoms. When the leeches have fallen off, the bleeding from their bites should be encouraged by warm fomentations, or by a thin warm linseed meal poultice, which should be frequently renewed while the bleeding continues. At the same time five grains of calomel should be administered in combination with five grains of James's powder, and gr. iss. or gr. ii. of opium, or with six or eight of Dover's powder, and this should be repeated every three or four hours until the symptoms begin to subside. The exhibition of purgatives along with the calomel till the bowels are freely evacuated, is always of the utmost consequence. There are comparatively few cases in which it is necessary to have recourse to a second bleeding from the arm, and where the propriety of this is indicated by an imperfect relief, or renewal of pain, the quantity of blood taken away seldom ought to exceed fifteen ounces. The quantity which requires to be withdrawn in the first bleeding seldom exceeds xxxv . and in the second xxv .; but there are exceptions to this, and cases of puerperal peritonitis undoubtedly have occurred in which more copious depletion was had recourse to with decided advantage. Where the pulse has become much more rapid and feeble after the first bleeding, and the strength has appeared to be much impaired, even if the uterine pain continues, blood should not be drawn a second time from the arm. Six or eight hours after the first bleeding, should the pain continue undiminished in violence, and the pulse be full and not very rapid, and the strength of the patient but little im-

paired, a second venesection to the extent above stated may be ordered, not only with safety but with decided advantage. The great mortality which has taken place in this and in the other varieties of uterine inflammation certainly cannot be attributed to the abuse of blood-letting, for you will observe in the tables that the great number of those patients who were bled early and copiously recovered, and that most of those who died were either not bled at all or very late and sparingly, or took stimulants. After the violence of the attack has been subdued, it is proper to continue the use of the mercury, but in diminished doses. Two grains instead of five every four or six hours, combined with opium or Dover's powder, will be sufficient, and this should be continued until the mouth becomes affected, or until the uterine tenderness is greatly relieved. The object in administering mercury in uterine inflammation is the same as in iritis; to remove the congested and inflamed state of the vessels of the peritoneum, and to prevent the disease from terminating by effusion, when all remedies are generally unavailing. Blood-letting, general and local, the exhibition of mercury with opiates and purgatives, are the principal means which we possess in the treatment of cases of puerperal peritonitis, and they often check the progress of the disease. But they have little influence over inflammation of the veins, absorbents, and muscular coat of the uterus, and I am not aware of the existence of any means by which it is possible for us to stop the progress, or counteract the effects, of such destructive morbid actions as those which produce suppurative inflammation of the uterine veins, and of the ovaria and fallopian tubes, and gangrenous softening of the walls of the uterus. The greater number of these cases will, I fear, always terminate fatally whatever plan of treatment be adopted: the lesions discovered by morbid anatomy have rendered this too obvious. The symptoms in these cases from the commencement have generally been such as to contraindicate the use of general blood-letting. Where the reaction at the invasion of the inflammation has been violent, and venesection has been employed, the relief obtained has only been temporary, if at all experienced; in some, blood would not flow when a vein was opened in the arm; and in a few others, the abstraction of only a few ounces has produced alarming faintness. When the local pain is severe, which it seldom is, leeches and warm fomentations seem to be the appropriate remedies; but as I have already stated, we possess none which effectually control the progress of deep-seated inflammation of the uterus. Some foreign physicians are, however, of a contrary opinion.

and are satisfied that we possess a powerful remedy, even in the worst cases, in mercury employed so as to excite salivation. In several cases of uterine phlebitis I have pushed this remedy, by inunction, to a great extent, and brought the system under the influence of mercury in less than 24 hours; yet the progress of the symptoms was not arrested, and the patients died as others had done where the remedy had not been administered. In other cases I have employed mercury to a great extent internally, without the slightest benefit; and it may justly be doubted, from the results of M. Desormeaux's practice, whether or not it possesses the influence M. Tonellé supposes; for of forty-three cases where mercury was used as the chief remedy, only fourteen recovered. In the latter stages of inflammation of the deep-seated structures of the uterus, the great depression of the powers of the system renders the liberal administration of stimulants necessary; and in a few cases of uterine phlebitis the lives of the patients appeared to be preserved by them.

In the *Elements of the Practice of Physic*, by Dr. Craigie, there is contained the following excellent account of blood-letting in uterine inflammation. You will see that he has recommended a much more vigorous application of it than I have done; and probably he is right in this, and that I would have been more successful if I had been more energetic in the use of the remedy.

"That blood-letting is a powerful and effectual remedy is shown, not only by the experience of Hulme, Leake, and Gordon, but more recently by that of Hey and Armstrong. But, in order that it be effectual, two things are requisite: first, that it be carried to sufficient length; and secondly, that it be practised as early as possible, at the commencement, or at least within the first twenty, in many within the first twelve, hours of the disease. On the quantity of blood to be taken a great revolution has taken place in this and other inflammatory disorders. Thus, Hulme and Leake talk of eight or ten ounces as a great bleeding, which will do much good; whereas Gordon carried it to twenty or twenty-four: and as all his patients who were blooded to that extent in the beginning had speedy and perfect recoveries he did not think it expedient to carry it further. It is different with Armstrong and Hey, the former of whom occasionally carried it to thirty ounces at the first, and the latter in one case to fifty-two ounces (24th); and I found it necessary to detract forty ounces from a plethoric young woman at once, with the best effect, in puerperal fever. But though I mention these facts to give some idea of the quantity requisite to be taken in order

to produce some check on the disease, it must not be imagined that it is possible to fix it in precise terms. In one subject, sixteen or twenty ounces may produce as great an effect as thirty or forty in another; and the best rule is to bleed until we have proof that the effect is produced. The most decisive and least equivocal proofs are, fainting, either approaching or actually come on, and abatement or entire cessation of pain in the belly. If one blood-letting be not succeeded by one or other of these effects, a second, third, or even a fourth, at the interval of even a few hours, ought to be practised. This is the manner in which Hey and Armstrong appear to have practised blood-letting, rather than by one copious evacuation; and in some instances fifty, sixty, or even eighty, ounces of blood were lost before the disease began to yield. In one of Armstrong's cases, fifty ounces were drawn in three operations; and in another, by four copious bleedings and two small ones, eighty ounces were lost before the abdominal inflammation was subdued. In like manner, in one of Hey's cases, thirty ounces within the first four hours were taken at one blood-letting; at a second, ten; and at a third, eleven — fifty-one before the symptoms of abdominal soreness had abated; yet, as pain returned, fifteen more ounces were taken from the arm, and a few from the belly, by cupping and leeches. In another case twenty-five ounces were drawn at the first; after the interval of a few moments nine ounces more; and before the arm was finally tied up six ounces more; —making in all forty ounces, after which the patient became faint, and the pulse fell from 112 to 88; yet pain recurred, and was relieved permanently only by taking eight ounces more about six hours after. In another (22d) twenty-four ounces were taken at the first, with the effect of causing faintness and reduction of the pulse from 100 to 72, and about twelve hours after, in consequence of the pain returning, twelve ounces more, in all thirty-six. In a fourth case, (25th,) five hours after the first sensations of pain, thirty-three ounces were taken from a large orifice, and quickly, with the effect of removing soreness and pain, but without causing fainting, and about twelve hours after twenty ounces ere the symptoms of the disease were sensibly abated. In short, the simplest rule is to detract blood quickly and from a large opening, till the pulse becomes softer, or less frequent, or the pain is relieved, or the patient begins to faint. In some cases the pulse remains unchanged, or, instead of becoming slower, becomes quicker; and then it is best to be guided by the approach or occurrence of fainting, and alleviation of pain; and in the

where syncope or faintness follows the blood-letting, it increases the salutary effect. In no case of inflammation of the peritoneal surface of the uterus and peritoneal sac have I seen any bad consequence to result from depletion carried to this extent, and in many, from its early use, the force of the disease has at once been completely broken, which could not have been the case had the inflammation been erysipelatous or of a specific nature. In reflecting upon the cases contained in the accompanying tables, and observing the number which terminated fatally, it is impossible to avoid the conclusion, that some patients were lost from the want of active depletion at the commencement of the attack. In many, the disease had been fully formed twenty-four hours or longer before the patients were seen, and then blood-letting was employed so sparingly as to exert no influence on the progress of the disease. When the attack of peritoneal inflammation is violent, and when the pain is but slightly relieved, the venesection should be followed without loss of time by the application of one, two, or three dozen of leeches to the hypogastrium, proportioning their number to the urgency of the symptoms. When the leeches have fallen off, the bleeding from their bites should be encouraged by warm fomentations, or by a thin warm linseed meal poultice, which should be frequently renewed while the bleeding continues. At the same time five grains of calomel should be administered in combination with five grains of James's powder, and gr. iss. or gr. ii. of opium, or with six or eight of Dover's powder, and this should be repeated every three or four hours until the symptoms begin to subside. The exhibition of purgatives along with the calomel till the bowels are freely evacuated, is always of the utmost consequence. There are comparatively few cases in which it is necessary to have recourse to a second bleeding from the arm, and where the propriety of this is indicated by an imperfect relief, or renewal of pain, the quantity of blood taken away seldom ought to exceed fifteen ounces. The quantity which requires to be withdrawn in the first bleeding seldom exceeds xxxv . and in the second xxv .; but there are exceptions to this, and cases of puerperal peritonitis undoubtedly have occurred in which more copious depletion was had recourse to with decided advantage. Where the pulse has become much more rapid and feeble after the first bleeding, and the strength has appeared to be much impaired, even if the uterine pain continues, blood should not be drawn a second time from the arm. Six or eight hours after the first bleeding, should the pain continue undiminished in violence, and the pulse be full and not very rapid, and the strength of the patient but little im-

paired, a second venesection to the extent above stated may be ordered, not only with safety but with decided advantage. The great mortality which has taken place in this and in the other varieties of uterine inflammation certainly cannot be attributed to the abuse of blood-letting, for you will observe in the tables that the greater number of those patients who were bled early and copiously recovered, and that most of those who died were either not bled at all, or very late and sparingly, or took stimulants. The symptoms in these cases from the commencement have generally been such as to contraindicate the use of general blood-letting. Where the reaction at the invasion of the inflammation has been violent, and venesection has been employed, the relief obtained has only been temporary, if at all experienced; in some, blood would not flow when a vein was opened in the arm; and in a few others, the abstraction of only a few ounces has produced alarming faintness. When the local pain is severe, which it seldom is, leeches and warm fomentations seem to be the appropriate remedies; but as I have already stated, we possess none which effectually control the progress of deep-seated inflammation of the uterus. Some foreign physicians are, however, of a contrary opinion,

and are satisfied that we possess a powerful remedy, even in the worst cases, in mercury employed so as to excite salivation. In several cases of uterine phlebitis I have pushed this remedy, by inunction, to a great extent, and brought the system under the influence of mercury in less than 24 hours; yet the progress of the symptoms was not arrested, and the patients died as others had done where the remedy had not been administered. In other cases I have employed mercury to a great extent internally, without the slightest benefit; and it may justly be doubted, from the results of M. Desormeaux's practice, whether or not it possesses the influence M. Tonellé supposes; for of forty-three cases where mercury was used as the chief remedy, only fourteen recovered. In the latter stages of inflammation of the deep-seated structures of the uterus, the great depression of the powers of the system renders the liberal administration of stimulants necessary; and in a few cases of uterine phlebitis the lives of the patients appeared to be preserved by them.

In the *Elements of the Practice of Physic*, by Dr. Craigie, there is contained the following excellent account of blood-letting in uterine inflammation. You will see that he has recommended a much more vigorous application of it than I have done; and probably he is right in this, and that I would have been more successful if I had been more energetic in the use of the remedy.

"That blood-letting is a powerful and effectual remedy is shown, not only by the experience of Hulme, Leake, and Gordon, but more recently by that of Hey and Armstrong. But, in order that it be effectual, two things are requisite: first, that it be carried to sufficient length; and secondly, that it be practised as early as possible, at the commencement, or at least within the first twenty, in many within the first twelve, hours of the disease. On the quantity of blood to be taken a great revolution has taken place in this and other inflammatory disorders. Thus, Hulme and Leake talk of eight or ten ounces as a great bleeding, which will do much good; whereas Gordon carried it to twenty or twenty-four: and as all his patients who were blooded to that extent in the beginning had speedy and perfect recoveries he did not think it expedient to carry it further. It is different with Armstrong and Hey, the former of whom occasionally carried it to thirty ounces at the first, and the latter in one case to fifty-two ounces (24th); and I found it necessary to detract forty ounces from a plethoric young woman at once, with the best effect, in puerperal fever. But though I mention these facts to give some idea of the quantity requisite to be taken in order

to produce some check on the disease, it must not be imagined that it is possible to fix it in precise terms. In one subject, sixteen or twenty ounces may produce as great an effect as thirty or forty in another; and the best rule is to bleed until we have proof that the effect is produced. The most decisive and least equivocal proofs are, fainting, either approaching or actually come on, and abatement or entire cessation of pain in the belly. If one blood-letting be not succeeded by one or other of these effects, a second, third, or even a fourth, at the interval of even a few hours, ought to be practised. This is the manner in which Hey and Armstrong appear to have practised blood-letting, rather than by one copious evacuation; and in some instances fifty, sixty, or even eighty, ounces of blood were lost before the disease began to yield. In one of Armstrong's cases, fifty ounces were drawn in three operations; and in another, by four copious bleedings and two small ones, eighty ounces were lost before the abdominal inflammation was subdued. In like manner, in one of Hey's cases, thirty ounces within the first four hours were taken at one blood-letting; at a second, ten; and at a third, eleven — fifty-one before the symptoms of abdominal soreness had abated; yet, as pain returned, fifteen more ounces were taken from the arm, and a few from the belly, by cupping and leeches. In another case twenty-five ounces were drawn at the first; after the interval of a few moments nine ounces more; and before the arm was finally tied up six ounces more; —making in all forty ounces, after which the patient became faint, and the pulse fell from 112 to 88; yet pain recurred, and was relieved permanently only by taking eight ounces more about six hours after. In another (22d) twenty-four ounces were taken at the first, with the effect of causing faintness and reduction of the pulse from 100 to 72, and about twelve hours after, in consequence of the pain returning, twelve ounces more, in all thirty-six. In a fourth case, (25th,) five hours after the first sensations of pain, thirty-three ounces were taken from a large orifice, and quickly, with the effect of removing soreness and pain, but without causing fainting, and about twelve hours after twenty ounces ere the symptoms of the disease were sensibly abated. In short, the simplest rule is to detract blood quickly and from a large opening, till the pulse becomes softer, or less frequent, or the pain is relieved, or the patient begins to faint. In some cases the pulse remains unchanged, or, instead of becoming slower, becomes quicker; and then it is best to be guided by the approach or occurrence of fainting, and alleviation of pain; and in the

event of this last symptom, with or without quick pulse recurring, it is always wisest to repeat the evacuation. If the pain and soreness of the belly be not removed or very materially alleviated in six hours, the blood-letting ought to be repeated; nor should a considerable degree of faintness, or even absolute *deliquium animi*, warrant the opinion that further blood-letting is either unsafe or unnecessary, so long as pain of the belly continues.

"The rapid course of this disease renders early blood-letting of the utmost importance. It is not well ascertained at what precise period of the disorder the inflammation may be incapable of being rendered amenable to suitable evacuation. Hey remarks, on this subject, that the disease may terminate fatally in forty-eight, or even in twenty-four hours, and he records one in which this took place in less than eighteen hours. But though these facts be of some consequence in showing with what promptitude remedial measures ought to be administered, they do not inform us how far blood-letting may be expected to be beneficial at any given period of the disease. The great point is to institute this remedy before effusion of sero-purulent fluid has taken place, or at least before it has gone to much extent; but as nothing very certain is known regarding this, further than that it will take place at different periods in different cases, it is manifest that no general rule can be established, and that the practitioner must draw his conclusions as to the propriety of using it, from the history of the case and the existing symptoms. Hey states that he knew blood-letting successful in a few cases in which a delay of more than twenty-four hours had been incurred, and he instances several of his own cases in which blood-letting was practised with success, thirty, and even forty hours after the commencement. This delay, however, ought never, if possible, to be permitted to take place, and it is always desirable to institute the evacuation at least within twelve hours from the first sensations of pain in the belly. In cases where earlier notice is given, this evacuation will be more effectual the nearer it is performed to the commencement of the disease. The most difficult and delicate point is to determine when it is too late to practise blood-letting. It is evident that the longer it is deferred, the more violent will the disease become; and as its effects very early begin to take place in lymphic exudation, and sero-purulent effusion within the peritoneum into the substance of the ovaries and the fallopian tubes, the great object is either to prevent or to arrest this process by timely suspension of inflammatory action. For the purpose of establishing

a rule as to the time and period of blood-letting, Armstrong has divided the disease into the two stages of excitement and collapse, in the first of which only this remedy is admissible. But as it may terminate in twenty hours, or extend to seventy in the acute forms of the disease, and is even more protracted in that which is termed subacute, it is obvious that no very precise rules can be derived from this principle. It is also to be remembered that, in not a few cases of puerperal fever, especially if attended with symptoms of uterine *phlebitis*, even the first or inflammatory stage presents so many marks of languor, oppression, and weakness, that an experienced observer might imagine the termination of the disease to be at hand, when blood-letting, if not injurious, must at least be useless. It is therefore indispensable not only to attend to the existing symptoms, but to inquire into their previous course and duration. When this has been determined, blood-letting should be performed, only if pain of the belly be still felt, if the skin and extremities are not cold and moistened with sweat, and if there be reason to believe that effusion has not taken place or is inconsiderable. If, on the contrary, there is no pain but weight of the belly, if, with an extremely quick thready pulse, the extremities are cold, and the person covered partially with chill damp sweats, and if the belly be distinctly distended with much sero-purulent fluid, no benefit can be expected from blood-letting."

Other means, besides those now described, have been recommended by different authors in the treatment of uterine inflammation; such as oleum terebinthinæ, ipecacuan, digitalis, colchicum, and camphor.

Since the oil of turpentine was introduced into practice by Dr. Brennan, the most contradictory statements have been published respecting its effects. In a paper published in the Dublin Hospital Reports, Dr. Douglas observes that in the epidemical and contagious puerperal fever, $\mathfrak{z}\text{iii}$. of the ol. terebinth., with an equal quantity of syrup and $\mathfrak{3}\text{vi}$. of water, should be given three or four hours after the exhibition of the first dose of the calomel; and that after the lapse of another hour this should be followed by an ounce of castor oil, or some other briskly purgative medicine. In some instances the oil of turpentine and castor oil may be combined in one draught. The internal use of turpentine is not to be repeated more than twice in any case whatever. "In several cases," Dr. Douglas adds, "where the debility is very considerable, the local bleeding may also be omitted; and in this case a flannel cloth, steeped in oil of turpentine, should be applied to the abdomen, and allowed to remain on for

the space of fifteen minutes. This external application of turpentine, without either its internal use or the aid of bloodletting, I have frequently experienced to be entirely efficacious in curing puerperal attacks; and although I have hitherto omitted to speak of turpentine for the cure of the other varieties of this disease, yet I would not feel as if I were doing justice to the community if I did not distinctly state that I consider it, when judiciously administered, more generally suitable and more effectually remedial than any other medicine yet proposed. I can safely aver I have seen women recover apparently by its influence from an almost hopeless condition; certainly after every hope of recovery under ordinary treatment had been relinquished."

I have not ventured to prescribe in many instances the internal use of *ol. terebinth.* either in the superficial or deep-seated inflammatory affections of the uterus; but whenever this has been done, it has not only produced a renewal of the pain, but has excited the most distressing nausea and sickness. The results of my own observations, and those of the most accurate observers in this country, coincide very nearly with those which are described as having taken place in the practice of Dr. Joseph Clarke. "In addition to the usual routine of practice," he observes, in his letter to Dr. Armstrong, "numerous trials were made of the rectified oil of turpentine, in doses of from six to eight drachms, sometimes in plain water, sometimes combined with an equal quantity of castor oil. The first few doses were generally agreeable to the patient, and seemed to alleviate pain. By a few repetitions it became extremely nauseous, and several patients declared 'they would rather die than repeat the dose.' In more than twenty trials of this kind not a single patient recovered." In favour of the use of *digitalis* and *colchicum* in puerperal fever, little evidence that is satisfactory has hitherto been adduced.

Willis, White, and other physicians, employed *emetics*, and more particularly *ipeacacuan*, in the treatment of puerperal fever, before the year 1782, when Doulcet recommended the exclusive use of these remedies at the Hôtel Dieu. Most exaggerated reports of the success of his method of treatment were speedily propagated throughout Europe, and many were disposed to consider the results at the Hôtel Dieu as affording unequivocal proofs of the power of *emetics* to arrest the progress of the disease when occurring in the most malignant forms. Two hundred women were represented as having been saved to society in the course of one epidemic in Paris, by the administration of *ipeacacuan* at the onset of the attack. It

appears, however, from the statement of Alphonse le Roi, that the recovery of so many individuals was attributed, without any just ground, to the peculiar treatment adopted; for the employment of *ipeacacuan* and *Kermes mineral*, according to him, was commenced by Doulcet in the lying-in wards of the Hôtel Dieu when the epidemic was ceasing, but these means were wholly inefficacious in the months of November and December, and at the beginning of the following year, when the mortality was greater than in 1780, before the remedy of Doulcet was known. M. Tenon affirms that in 1786 the complicated puerperal fever was curable by no means then discovered. From the intense pain of the abdomen, aggravated by the slightest pressure of the hand or by compression of the abdominal muscles, and from the early occurrence of nausea and vomiting in the worst cases of the disease, *emetics* obviously appear to be little calculated for the relief of the symptoms, and few enlightened practitioners have employed them in this country for the last forty years. Some have gone so far, indeed, as to declare that they are sufficient to produce inflammation where it does not already exist, and that their employment is not only useless, but dangerous and absurd.

Several distinguished continental physicians, as Hufeland, Oslander, and Desormeaux, have, however, continued to employ *emetics* in the treatment of puerperal fever, and have supposed that they have derived benefit from their use. M. Tonellé states that M. Desormeaux first made trial of them about the end of 1828, and that great advantage resulted from it. During the greater part of the following year they were again employed, but they succeeded in only a few isolated cases, and most frequently they entirely failed; they never, however, appeared to produce any aggravation of the pain or other symptoms. A new trial was made of them after this, and they were again followed by the most happy results. At the commencement of September, 1829, in the course of a fatal epidemic, and during a cold and moist season, *emetics* were again had recourse to; and for the two months during which this treatment was pursued, all the sick were not relieved, but a great number were delivered from their sufferings as if by enchantment, and for an instant there seemed to be a renewal of that brilliant success which had followed the adoption of this method by Doulcet and the physicians of the Hôtel Dieu. But at the end of October *emetics* gradually lost their influence; and towards the middle of November no advantage whatever was derived from them. In some of the successful cases related by M. Tonellé it ought to be observed, that forty leeches, and

warm cataplasms, had been applied to the hypogastrium before the emetic was given, and in those where the relief was most decided the ipecacuan either produced a profuse perspiration, or acted freely upon the bowels, causing numerous, copious, and bilious alvine evacuations. It is highly probable, from the histories of the successful cases, that the effects of the treatment were referrible rather to the action of the ipecacuan on the skin and intestines than on the stomach, for the relief experienced did not immediately follow the vomiting. M. Tonellé admits that where effusion or suppuration had taken place, emetics were of no avail; and he also relates a number of cases in which the application of leeches to the hypogastrium, and the employment of other antiphlogistic remedies, were followed by speedy and complete relief where emetics had entirely failed to procure this. In the milder forms of uterine inflammation (and many of the cases related by Tonellé were of this description), it is highly probable that an emetic, which would produce a sudden determination to the skin and a free action of the intestinal canal, would relieve the congested and inflamed state of the uterus, and thus cut short the disease. I have met with no case, however, in which I have considered it safe to administer emetics in any stage of the complaint, and I cannot conceive it possible for a case to occur in which the treatment should chiefly or exclusively be conducted upon the plan of Doulcet.

The application of blisters to the hypogastrium and inside of the thighs and legs, has often been found advantageous where the pain of the hypogastrium has continued severe after the general and local bleeding. The external use of the oleum terebinthinæ has also in some cases unquestionably been followed by considerable relief of the pain; and its effect is more sudden than that of a blister.

Both general and local warm baths have been highly recommended by foreign practitioners. Where the skin was hot, the pain moderate, the strength of the patient not much depressed, the immersion of the whole body in warm water was often followed by a general perspiration and relief of all the symptoms. On the other hand, they state, that when the pains were excessive, when there was great anxiety, a profuse general or partial perspiration, the strength much reduced, the respiration hurried and anxious, and the face red with intense headache, the patient could not support the warm bath, and derived no benefit whatever from it. The hip-bath was found more generally useful, and was employed almost indiscriminately by M. Desormeaux in all the different varieties of the disease. I have now

repeatedly tried the warm bath, but without benefit.

Recolin, Dance, and Tonellé, highly recommend the injection of warm water into the vagina and cavity of the uterus, by means of an elastic gum cannula. These injections were repeated three or four times in the course of the day, and they not only washed away the putrid matters adhering to the internal surface of the organ, but they appeared to relieve the irritation and inflammation of the organ itself. This practice I have seen followed by good effects, and now generally recommend it. In many cases of puerperal fever severe irritation of the stomach supervenes in the progress of the disease, and this symptom seems occasionally to be aggravated by anodynes and saline effervescing draughts. A drachm of sub-carbonate of potash should be added to 3v. of aquæ menth. virid., and an ounce of this mixture given every two or three hours. The effect of this medicine in allaying the irritability of the stomach has been very remarkable indeed in some cases related to me, but I have often tried it without deriving any advantage from it. Should diarrhoea take place spontaneously, or result from the use of the mercury, it must be moderated by opium. The starch and laudanum clyster is by far the best mode of administering the anodyne.

During the first stage of uterine inflammation, cinchona, camphor, and stimulants, are wholly inapplicable; but when the acute symptoms have been subdued, and the patient is left in a state of great exhaustion, quinine, ammonia, wine, and other stimulants, sometimes produce the happiest effects in rousing the powers of the system. I cannot too strongly urge the necessity of continuing to employ these remedies, and whatever else is judged useful, whilst the slightest hope of recovery can be entertained.

The importance of the prophylactic treatment must be obvious from all that has now been stated. A puerperal woman ought to be as careful of exposing herself to cold and fatigue for a week after delivery, and committing any imprudence in diet, as an individual who is recovering from an attack of continued fever, or inflammation of some important organ. The administration of acrid cathartics should always be avoided for some days subsequent to delivery. After-pains, if severe, should be relieved by anodynes; and the lochial discharge, when scanty, promoted by warm fomentations and poultices over the hypogastrium, and other suitable means. The greatest care should always be taken during the labour, if an operation is required, to avoid inflicting any injury on the uterus.

TABULAR VIEW (No. 2) OF 62 ADDITIONAL CASES OF INFLAMMATION OF THE UTERUS AND ITS APPENDAGES,

Observed by me from January 1831 to the end of April 1835.

[Continued from p. 795.]

No.	Name, Residence, and Delivery.	Date of Attack and Symptoms.	Treatment.	Result and Morbid Appearances.
135	Case; St. Marylebone Infirmary. April 16, 1832.	Second day.—Rigors; acute pain in the region of the uterus; quick pulse and other characteristics; immediate relief followed the bleeding.	V.S. ʒxiv. (blood not buffed), leeches, calomel, opium, poultices.	Recovered.
136	Mrs. Gray; æt. 30; British Lying-in Hospital. Natural labour. April 18, 1832.	Slight rigor; tenderness on pressure in the region of the uterus; tongue white; thirst; bowels open. Twenty-first day: pain gone; pulse rapid; milk secreted. Twenty-seventh day: has continued entirely free from pain; great debility; pulse 120; delirious; tympanites.	Leeches xij., calomel, and opium.	Died.
137	Case with Mr. Prout; Titchfield Street. Natural labour. April 17, 1832.	Second day.—Rigors; pain in the back and left side of the uterus; intense headache; retching; diarrhoea; a tedious recovery after several weeks.	Opium and cathartics.	Recovered.
138	Three cases; British Lying-in Hospital. Between May 12 and 28, 1832.	They all had the characteristic symptoms of peritonitis within three days after delivery; rigors; uterine pain; quick pulse.—In the early part of June a fatal case occurred in the St. James's Infirmary, another in the St. Marylebone Infirmary, and a third in the British Lying-in Hospital.	Copious bleedings, calomel, opium, and cathartics, the only remedies.	Recovered.
139	Mrs. Foster; æt. 30; British Lying-in Hospital. June 25, 1832.	Second day.—Pain in the region of the uterus; no rigor; lochia not suppressed; uterus large and hard; pulse 110; tongue white and dry; pain relieved by the leeches, but returned and extended; nausea; vomiting; swelling of abdomen; delirium.	Leeches xvij. twice, calomel, opium, saline effervescing draughts.	Died.

140	A lady in New Bond Street. Natural labour. July 12, 1832.	Seen in consultation.—The day after slight pain in the region of the uterus; rigors; quick pulse. Sixteenth day: pain in the left groin, and swelling of the left leg and thigh. Eighteenth day: dyspnoea; cough; rapid feeble pulse. Twenty-first day: stupor; face flushed; pupils dilated: pulse 120; tongue covered with aphthæ; left shoulder painful, and a large red patch over it; diarrhoea. Third day.—Rigor; slight pain in the left side of the uterus; rapid pulse; furred tongue; great cerebral excitement. July 23d: pulse 120, not feeble; milk and lochia both continue; face flushed; slight delirium; diarrhoea; no sickness or vomiting. Did not see the patient for several days after delivery; then vomiting; slight uterine tenderness and great debility; rapid pulse; died on the sixth day.	Digitalis, diuretics.	Died.
141	Case; Kilburn. Natural labour. July 1832.	Third day.—Slight tenderness along the brim of the pelvis, on the left side; great depression of spirits; pulse little affected. July 1st: pain in the calf of the left leg, followed by swelling, and tenderness along the course of the iliac and femoral vessels of the same side.	Leeches xxij., starch and laudanum clysters, head shaved, cold lotions, blister to the hypogastrium.	Recovered.
142	Case in a public institution. Distorted pelvis, forceps, and perforation. September 1832.	Third day.—Acute pain on each side of the uterus, with rapid and feeble pulse; loaded tongue; dusky countenance; lochia not suppressed. Twenty-eighth day: pain relieved by bleeding, but the pulse became more rapid, and she gradually sank; tympanites before death.	No treatment adopted at the onset of the disease.	Died. The mucous and muscular coat of the orifice, cervix, and lower part of body of uterus, softened and of a dark colour, broken down, and disorganised; the orifice lacerated in two parts.
143	Case; Leicester Square. Natural labour. June 24, 1832.	Did not see the onset of the disease.—Sickness and acute pain in the region of the uterus; rapid feeble pulse; vomiting; soon sank.	V.S. twice, calomel, opium, and saline medicines.	Died. Both ovaria greatly enlarged, softened, and their structure completely disorganised; the fallopian tubes red and inflamed; peritoneal sac healthy; ʒiv. of red serum effused.
144	Case at Paddington. After natural labour. September 24, 1832.	Did not see the onset of the disease.—Sickness and acute pain in the region of the uterus; rapid feeble pulse; vomiting; soon sank.	V.S. not employed. Leeches, calomel, and opium.	Died. Uterus large, soft, and contracted; uterine appendages on both sides of a dark livid colour; ovaria pulpy; coats of the upper part of the uterus in a soft shreddy state, torn by the slightest touch; a portion of the uterus behind retained the healthy structure.
145	Case; British Lying-in Hospital. November 3, 1842.			

146	Case; St. James's Infirmary, Retained placenta. November 6, 1832.	Eighth day.—Pulse rapid and feeble; dyspnoea; slight pain in the left side of the chest; no pain in the uterine region; sank soon, with diarrhoea and urgent dyspnoea; died 15th of November.	Leeches to the hypogastrium, a large blister to the chest, &c.	Died. No effusion into the peritoneal sac; uterus had contracted and sunk down into the pelvis; near the right round ligament there was an adhesion between the uterus and bladder; an abscess here under the peritoneum of the uterus; ovaria enlarged, red, and soft; at the neck of the uterus the veins full of pus, and the cellular membrane around inflamed; extensive pneumonia on the left side.
147	Mary Gane; near St. Thomas's Hospital. Natural labour. October 21, 1832.	Third day.—Pain and stiffness about the hypogastrium and inguinal regions, extending down the thighs, with pyrexia and headache; rigors; pulse frequent; offensive lochia. Thirtieth day: severe rigors; pain in the symphysis pubis and right groin; thigh swollen, and femoral vein painful; the left limb became affected; diarrhoea; gangrene over the sacrum, and over the right ankle.	V.S. at the commencement, leeches and cupping-glasses, fomentations, calomel, and Dover's powder.	Died. Symphysis pubis separated to the distance of an inch and a half, and its cartilages gone; pus had escaped from it into the pelvis; right femoral vein plugged up with fibrine, and the saphena major filled with pus; vena cava inflamed to a great extent; peritoneum of uterus inflamed.
148	Case; Paddington. Twins; retained placenta; flooding. October 1833.	Six weeks after delivery.—Complained of dyspnoea and pain in the right side of the chest; no rigor. Four days before death, extreme prostration of strength; irregular hectic fever; foetid expectoration; lungs previously healthy.		Died. Pleuritis and hepatization of the lungs on both sides; uterus greatly reduced in size; the ovaria and tubes healthy; left spermatic vein healthy, but the right, from the uterus to its termination in the vena cava, was greatly enlarged, and the coats thickened, and the cavity filled with a layer of lymph and clot of blood of a vermilion tint.

149	Case seen with Mr. Gosna; St. Martin's Parochial Infirmary. After natural labour. November 1833.	Cough; dyspnoea and pain in the chest a week or ten days after delivery; and also tenderness in the region of the uterus; the symptoms of pulmonary disease gradually became worse, and she died five or six weeks after her confinement.	Blisters to the chest, and other remedies to relieve the disease of the lungs.	Died. Extensive inflammation and hepatization of the lungs on both sides; the uterus within the pelvis and reduced to the usual size a month after delivery; the left fallopian tube adhering to the uterus low down behind; the veins of the cervix and body of the uterus filled with pus on the left side; all the branches of the internal iliac and common iliac inflamed, and lower part of vena cava; pus in pulmonary veins.
150	Case seen with Dr. Fergus; St. George's Parochial Infirmary. After tedious labour. July 2, 1834.	Did not see the patient during life; was informed that she had no pain in the region of the uterus; no rigor nor quickness of pulse; but that there was great debility, low muttering delirium; that the skin had a peculiar dark hue; and that the lochia were offensive.		Died. Brain perfectly healthy; red serum effused into the sacs of the pleuræ; one of the lobes of the lungs hepatized; veins of the fundus uteri on the left side filled with pus; veins of the cervix in the same condition; many absorbents on this side full of pus.
151	Case; St. James's Infirmary. After twins, and hæmorrhage. July 23, 1834.	Fifth day.—Intense headache; countenance pallid; slight convulsive twitches of the head and extremities; pulse 140, small; acute pain of uterus for a short time. July 29th: sinking; tremors; mucous rale; abdomen swollen; hypogastrium painful.	V.S. copious, and leeching, stimulants, and cordials.	Died. Peritoneum of posterior part of uterus, broad ligaments, and peritoneum of intestines and liver, coated with lymph; lb. iij. of sero-purulent fluid effused; ovaria large and soft, and tubes filled with pus; absorbents on left side of uterus full of pus.
152	Case of an idiot; St. George's Infirmary. July 24, 1834.	Dr. Fergus stated that the symptoms were: rapid feeble pulse; vomiting and diarrhoea; no uterine pain; purulent discharge from the vagina; the perineum and also os uteri torn during the labour; death took place about a week after delivery. Present at the inspection of the body.	Anodynes, wine, and other stimulants.	Died. Examined the body with Dr. Fergus—slight peritonitis; veins of the cervix and fundus uteri gorged with pus; inflammation of veins appeared to have commenced near the part where os uteri was lacerated.

153	Case; St. Marylebone Infirmary. January 16, 1834.	Tenth day.—Great tenderness confined to the region of the uterus; pulse feeble; lochia scanty and very offensive.	Leeches, calomel, antimony, opium, cathartics.	Recovered.
154	Case of twins; British Lying-in Hospital. November 21, 1834.	Fever from the time of delivery. Fifteen days after: conjunctiva of right eye became red and swollen, and the eye-ball enlarged. Twenty-first day: eye destroyed; left eye similarly affected; excruciating pain in the left elbow and shoulder-joint; tongue brown; no delirium; pulse 150; no tenderness in the region of the uterus; slight fulness along the brim of the pelvis, left side; cough, with dyspnoea; expectoration; sickness.		Died. The whole left spermatic vein inflamed, and filled with pus; pus flowed copiously from the orifice of the veins in the lining membrane of the uterus, where the placenta had adhered; when cut open, this part of the uterus was like a sponge soaked in pus.
155	A young woman; 71, Clarendon Street, Portland Town. Natural labour. December 3, 1834.	Saw this patient first two days before death.—Pulse rapid; rigors; cold extremities; left lower extremities swollen, not discoloured; foot and leg pit on pressure; veins around the knee swollen; great tenderness in the course of crural vein; delirium; offensive lochia; general abdominal tenderness; delirium; diarrhoea; sloughs over sacrum. The usual symptoms of uterine inflammation a few days after delivery; in two months, when I first saw the patient, crural phlebitis in the left lower extremity, and the constitutional symptoms declining. The right inferior extremity had previously been scarcely affected.	Anodynes, stimulants, wine.	Died.
156	Case with the late Mr. Powell, 66, Grove Street, Camden Town. December 8, 1834.		Leeches, fomentations, calomel, and opium.	Recovered.
157	Case; Saffron Hill. After natural labour. January 1835.	A female attended in labour by a surgeon who was at the time obliged, twice or thrice a day, to dress the leg of a gentleman affected with phlegmenoid erysipelas; soon after delivery this woman attacked. In 30 hours after the birth of a putrid child, attacked with the most violent symptoms; headache; stupor; sickness of stomach; severe pain in the lower part of the spine, comparatively little on the abdomen; eyes became enormously swollen and inflamed before death; pulse 120; nervous symptoms severe; great agitation; evidently fatal from the onset; countenance changed, overwhelmed with the disease at first; rapid pulse; hurried breathing.	V.S. ʒxx.	Died. Extensive peritonitis, and inflammation of the veins of the uterus.
158	Mrs. —; Poland Street. January 19, 1835.		V.S. ʒxij., calomel, opium, leeches, cathartics. Every thing escaped by vomiting.	Died. The child died of erysipelas of the nates and abdomen; violent inflammation of the eyes.

- 159 A lady in Westminster.
Protracted labour.
June 17, 1835.
- Acute pain, increased by pressure in the hypogastrium; sickness and vomiting; extreme restlessness; breathing hurried; pulse rapid; lochia not suppressed; pulse rapid and feeble; symptoms relieved for a short time by the bleeding and leeches, but they returned; the abdomen became tympanitic; there was incessant vomiting, and she died in 30 hours. Died 18th of January. Dr. Merriman saw this case in consultation.
- V.S. xxxiv., leeches xxv., leeches l.; calomel gr. x., opium gr. iss., 2da q. q. hora.
- Died. Her infant died soon after from erysipelas.
-
- 160 Case; British Lying-in Hospital.
Twins.
April 25, 1835.
- Depletion not employed. Anodynes and saline diaphoretics I believe were the remedies, and afterwards wine and stimulants.
- Died. Uterus and intestines coated with lymph; left appendages destroyed by inflammation; the placenta had adhered to this side of the uterus; veins of this contained a thin purulent fluid; pus between the muscular fibres of the part, not contained in veins, was a thick yellow lymph; a small quantity of pus in the veins of the cervix.
- Died. Vena cava, left common and internal iliac veins, and femoral, thickened, lined with false membrane, and plugged up with coagula and blood; the internal iliac was most severely inflamed, and its branches contained lymph and pus; the disease of the femoral vein originated in the vein of the cervix uteri.
-
- 161 Case; Bruton Street.
A young unmarried woman.
May 9, 1835.
- Leeches repeatedly, calomel, opium, &c.
- A young woman who had for some time been chlorotic, and had menstruated sparingly. Suffered for some time from pain in the back and left hip, and fever. Two days ago a swelling took place in the upper part of the foot, then in the calf of the leg and thighs. The whole left inferior extremity smooth, swollen, hot, colourless, looking like alabaster. Superficial veins of the limb distended with blood. The femoral vein in the upper part of the thigh hard and painful along its whole course. Vomiting, and symptoms of low typhoid fever, took place, and she died on the 21st May. Exposed to cold.
- Died. Examination made by Dr. H. Davies and Mr. Moss; no peritonitis; pus in considerable quantity in the veins of the fundus uteri, near the superficial angles; the veins gorged where the placenta had adhered.
-
- 162 Case; British Lying-in Hospital.
Natural labour.
May 11, 1835.
- Leeches, fomentations, calomel, opium, saline medicines.
- On the second day after delivery, slight uterine tenderness, which yielded readily to leeching. Diarrhoea took place, with fever, and the conjunctivae of both eyes became red and swollen. I saw this patient only once or twice, but was not present when the body was examined.

A lady at Kennington.
Natural labour.

April 30, 1835.

Third day.—Unusual tenderness of the uterus, rapid pulse, and shivering. The symptoms were relieved, and she seemed to be recovering for some days. May 11th: rapid feeble pulse, 120; tongue foul; sickness; severe nervous symptoms; no tenderness in the region of the uterus; drowsy stupor; profuse perspirations; occasional rigors. May 12th: conjunctivæ of both eyes red and swollen; vision nearly lost. 13th: symptoms aggravated. 14th: tongue dry and brown; teeth covered with sordes; right eye and eyelids greatly swollen; pulse very feeble. Died on the 12th day after delivery. Nervous tremors. I thought suppuration was going on about the uterus.

V.S. 3ij., leeches, calomel, Dover's powder. Wine and stimulants in the latter stage.

Died. Examined the body with Dr. John Webster, May 17, 1838; the muscular coat of the uterus of a dull yellow colour; the fingers penetrate its substance like a rotten apple; no pus in the veins or absorbents the greater portion of the uterus affected in this way; whole inner surface of uterus coated with a yellow lucid layer.

OBSERVATIONS ON SOME OF THE MORE IMPORTANT DISEASES OF CHILDHOOD.

By CHARLES WEST, M.D.

Member of the Royal College of Physicians;
Physician to the Royal Infirmary for Children;
and Physician-Accoucheur to the Finsbury Dispensary.

[Continued from p. 742.]

III.—On some forms of Paralysis incidental to Infancy and Childhood.

In his work on the "Nature and Treatment of the Distortions to which the Spine and the Bones of the Chest are subject," Mr. Shaw devotes a chapter to an "Enquiry into the causes of the partial paralysis and wasting of one of the limbs during infancy, which frequently produce distortion of the spine." He describes some cases in which there was simple atrophy of one limb, unattended with much defect either in the power of motion or of sensation; though a measure of impairment in the motive power came on almost imperceptibly as the wasting of the limb grew by degrees more and more obvious. In other cases to which he alludes, the affection comes on suddenly, almost instantaneously; and the loss of voluntary power over the affected muscles is immediate. Mr. Shaw regards cases of the former kind as being induced by a deranged state of the bowels; "the affection of the brain being, as it were, intermediate between the disturbance of the bowels and the paralytic muscles." Those of the latter kind he conceives to depend on a sudden change in the brain or spinal cord, or in the nerves which supply the affected parts; though they, too, will often be found to be more remotely connected with disordered digestion. These cases occur especially about the period of weaning, and are commonly ascribed to the irritation of teething; sometimes they come on at a late period of childhood, and are consequent on some severe attack of illness, especially of fever, or of the exanthemata. He enters, however, into comparatively few details on the subject, his object being rather to excite general attention to it.

To the best of my knowledge, Dr. Underwood was the first writer on the dis-

eases of children who noticed this affection; but he does not attempt to discriminate between those cases in which palsy is the result of organic disease of the brain, and those which depend on less grave causes. He was aware, however, that serious disease of the brain was not invariably present, and mentions that such curable cases usually recover very rapidly under the employment of brisk purgatives.

Feiler,* relates, under the title of "Aridura Crurum," a case of atrophy of one lower extremity in a girl between twelve and thirteen years of age. The patient was greatly benefited by friction and various stimulant applications to the wasted limb, and to the loins; but the observation is related as an isolated instance of an affection to which nothing analogous had since come under his notice.

In Dr. Marshall Hall's work, "On the Diseases and Derangement of the Nervous System," are some brief remarks on paralysis from dentition,† together with the particulars of a very interesting case of the disease. His observations, however, are rather suggestive, and he enters into no details on the subject.

Dr. Henry Kennedy,‡ has written a valuable paper on the subject of Infantile Paralysis. He seems to be most familiar with the affection as it occurs in the infant at the breast; in whom the upper extremity is in his opinion most frequently attacked. He notices the suddenness of the seizure, and its occurrence during apparently perfect health. He further remarks, that the lower extremity is sometimes affected in a similar manner; that sometimes instead of being paralysed he has seen it contracted and drawn up close to the body; and that in some instances not only is the power of motion gone, but the sensibility of the affected limb is greatly increased, the child crying on the slightest touch. Derangement of the bowels, and the irritation of teething, are the two causes to which he thinks the disorder may usually be referred; but he has also seen it occur after remittent fever. Lancing the gums, purging, and alterative remedies, are the chief means which he recommends for the cure of this affection.

The greater part of the essay, however, is occupied, not with details concerning the disorder itself, but with remarks on other affections with which it may be confounded. These are, either disease of a joint; injury to a limb, as, for instance, fracture; injury to a nerve, as when the arm is allowed to hang over the back of a chair; paralysis dependent on disease of the brain or spinal cord, and lastly, arthritis with suppuration.

A brief notice of paralysis in teething children is contained in a recent number of the American Journal of the Medical Sciences, by Mr. G. Colmer. The writer, whose communication does not exceed a few lines, mentions having seen a child so affected in a village through which he passed, and states that the inhabitants informed him that several infants in the neighbourhood had suffered in a similar manner.

Dr. M'Cormack, of Belfast, has published in the Lancet for May 27, 1843, some remarks on Infantile Paraplegia. He relates two cases of the disease affecting both lower extremities in children; but the history of each is very deficient in detail. He inclines to the opinion that this impaired power over the lower extremities arises from concussion of the spinal cord, or from injury to the sciatic nerve, and does not appear to have met with any case in which either upper extremity suffered a similar loss of motor power.

It will be my aim in this paper to supply in some slight degree the absence of detail with reference to this, and other similar paralytic affections, by relating the particulars of some of the cases which have come under my own notice.

In doing this it is my intention to leave out of consideration those cases in which certain limbs or certain muscles become palsied during the progress of organic diseases of the brain or spinal cord. Palsy from such a cause is less common during childhood than in the adult, though instances of it are by no means unusual. Thus, during the past summer, a girl, aged about three years, was brought to me suffering from hemiplegia, with very marked reflex movements of the palsied limbs, induced by the spinal marrow having become affected in the progress of scrofulous disease of the vertebræ. A boy, too, eight years old,

* *Pædiatrik*, etc. 8vo. Sulzbach 1814, p. 350.

† *Ib.* p. 198.

‡ *Dublin Medical Press*, Sept. 29, 1841.

is at the present moment under my care, in whom all the indications of cerebral tubercle exist, and in whom the motor power of one side of the body is very considerably impaired. In both of these instances, as well as in many others which might be adduced, the paralysis is only a secondary incident, merely a symptom betokening the advances of a grave and incurable malady; and to enter upon their examination would be foreign to the present purpose.

It may perhaps be convenient to arrange these cases in three classes; of which—

The first will include those instances in which the paralysis was congenital.

The second, those in which it accompanied or followed convulsions, or other symptoms of cerebral disorder.

The third, those in which the paralysis occurred without any indication of cerebral disease.

1st. Cases of congenital paralysis.

Rebecca Swan, aged eight years, 19, Regent Street, Poplar, one of ten children, of whom nine are still living. One died at the age of two months, but all the others are said to be strong and healthy. Her father is healthy, but not robust. Her mother is in the last stage of consumption; and this disease is hereditary on her mother's side.

Rebecca was a delicate child from birth, and her relatives assert that from her very earliest infancy she has had imperfect use of her right side.

She is of a spare habit, and rather sickly appearance; but her manner is cheerful, and her intellect does not seem at all defective.

The palsied condition of her right side is very obvious: she limps in her walk, treads always on her toes, with her heel raised very considerably above the ground, and turns her foot inwards at every step she takes.

She can use her right arm, though but imperfectly; the fingers of the right hand are constantly flexed and drawn into the palm; and though by a great effort she can extend them, yet the moment her attention is withdrawn they return to their former flexed position.

Sensation is as perfect in the right limbs as in the left; but their wasted condition and smaller size, as compared with the left extremities, show that nutrition has been but very imperfectly carried on.

The left arm measures, from the acromion to the end of the radius, 14½ inches; right, 13 inches.

The girth of the left arm at the middle of the humerus, 5½ inches; right, 5 inches.

From the left trochanter to the heel, 24 inches; right, 22½ inches.

The right leg and thigh measured considerably less in circumference than the left; but I have not preserved an account of their exact dimensions.

A similar case, but one in which the deformity was still more marked, came under my notice some months since at the Finsbury Dispensary. The patient in this instance was a girl aged eighteen years, in whom not only were the left extremities much shorter and smaller than the right, but the left half of the face also was very much smaller than the right. The parent of the girl stated that the inequality in size of the two halves of the body had existed from earliest infancy, and had not succeeded to a fit or any other indication of acute cerebral disease. The left side was weak, and motion imperfect, but sensation seemed to be unimpaired. The patient in this case was rather deficient in intellectual endowments.

2d. Cases in which the paralysis accompanies or follows convulsions or other symptoms of cerebral disorder.

The cases included in this class are of more frequent occurrence, and of greater practical importance, than the former, since they often excite great solicitude; though they for the most part eventually do well. The morbid phenomena are very frequently connected with disturbance in the process of dentition; and it will be seen that, in the former of the two following cases, they occurred during the period of teething. In this instance, however, there were but few indications of disorder of that process; nor did the fluctuations in the child's condition, nor its ultimate recovery, appear to be in any way influenced by the eruption of teeth.

Walter Scott Taylor, aged fourteen months, living at 39, Great Hunter Street, Old Kent Road, was the delicate child of parents who had lost two children in what they called a decline. In the first week of January 1840 he had a mild attack of measles, from which he recovered without any unfavourable symptom; but his parents placed him under medical care on

January 28th, on account of rickety swellings of his joints, which however were very slight.

On January 30, at 4 P.M. he was suddenly seized with convulsive movements of the left arm; his mouth was stated to have been drawn to the left side, and his left eyelid drooped. This condition lasted for about an hour, and when it went off he seemed as well as before, and slept moderately in the night. At 8 A.M. however, on the 31st, a fit came on similar to that of the preceding night, and lasted for nearly an hour. It returned at 11 A.M. and was then accompanied with rotatory motion of the head. Before the fit came on he cried much, as if in pain, and afterwards frequently threw back his head. In the course of the day it was observed that he did not use his left arm; and on the following morning, after having passed a good night, the arm hung powerless by his side, and the hand was useless. As day advanced, he gradually regained the use of his arm; and in the afternoon, when I visited him for the first time, he could move his fingers, though the hand was weak, and he employed the right arm in preference to the left. No remains then existed of the paralysis of the face or eyelid; both pupils acted equally under the stimulus of light. The child seemed quite cheerful; the bowels acted regularly, and the tongue was clean.

I ordered no medicine for the child; but visited him again on the 7th, when I found him in much the same state as before. He could move the left arm, but not the hand; and his mother thought that he limped somewhat with the left leg, dragging it behind the other. His head was rather hot; but he seemed quite cheerful, rested well at night, and all his functions were performed naturally.

I ordered small doses of mercury and chalk every evening.

On Feb. 17, there was no increase of power in the hand; he still dragged the left leg in walking; did not close the left eye so completely as the right. He was still cheerful, but the tongue was white, and his bowels were constipated.

On the 22d, at 4 P.M. his mother noticed that he could not use his left leg. He continued unwell and fretful until he was freely purged by castor-oil, after which he recovered his usual

health. I saw him on the 25th, when he had acquired more power over the left hand, but the left leg was quite powerless, and he dragged it behind him as though it did not belong to him. He was still quite lively and cheerful; his tongue was moist and clean, but his gums were slightly swollen. I lanced the gums, continued the use of the Hydr. c. Cretâ, and ordered a liniment to the leg.

On the 28th the state of the leg was much the same, but the child had acquired more power over the hand.

The Hydr. c. Cretâ was now discontinued, and a liniment was ordered for the leg.

March 3d.—Has recovered some use of the left leg, but it still does not serve him in walking. His bowels are disposed to be costive, unless castor-oil is given daily.

From this time he continued to improve, under the use of purgatives and stimulant liniments to the leg. His recovery, however, was very gradual, and could not be considered complete until the end of April.

William Cheshire, aged 3½ years: was never a strong boy, being always what his mother calls nervous, though he had not suffered from any particular illness until Dec. 30, 1840, when he had a fit, which lasted for five minutes; during it he struggled much, and his mouth was drawn to the left side.

On Dec. 31, some one opening his bed-room door suddenly, another fit came on, which lasted for ten minutes; during the fit he struggled, squinted, and his mouth was drawn to the left side; and the squint and distortion of the face continued for some time after the fit was over.

He was brought to me on Jan. 1, 1841. He was a fair, delicate boy, with blue eyes and a strumous aspect; his manner was quite natural, and there was no heat of head. His mouth was drawn slightly to the left side; he could not close his right eye; and in frowning or crying the muscles of the left side of his face only were brought into action, the right side remaining quite motionless. Sensation was perfect on both sides of the face. His bowels were open; tongue moist, but coated with brown fur; pulse 105, with power.

I ordered him two grains of calomel every night, and a senna draught every morning.

On the 5th he had no return of the fits, but the paralysis of the face continued, and the child complained of pain behind the right ear.

Four leeches were applied behind the right ear, and gave immediate relief to the pain; the same medicines as had before been given to him were persevered in, and the child regained the use of the right side of his face so rapidly, that by the 9th of January the signs of paralysis had almost entirely disappeared. The purgative treatment was continued for a few days longer, and a stimulant embrocation was ordered for the face, and by the end of the month the child was discharged cured.

3d. Cases in which the paralysis occurred without any indication of cerebral disease.

These cases are of the most frequent occurrence; they often run a very chronic course, and sometimes appear to be incurable, though for the most part gradual recovery takes place.

In some instances, children, apparently in perfect health, are suddenly attacked by this form of paralysis, but more frequently it follows an attack of measles or scarlatina, or comes on in strumous and debilitated children, in whom it is usually associated with obstinate constipation of the bowels.

Of the sudden supervention of paralysis in a perfectly healthy child the following may serve as an instance.

Isabella Smith, aged 2 years and 9 months: was always a healthy child, and had had none of the diseases of infancy, with the exception of whooping-cough.

In the middle of June, 1841, she went to bed in perfect health, but when she arose in the morning she was quite unable to move her right leg, or to stand.

Her mother took her to a surgeon, who ordered something to rub the leg, and the child had since so far recovered as to be able, when brought to me in February 1842, to stand, and to walk, though with difficulty. In walking she turned the right foot quite out at right angles with the body, and did not raise the foot above the ground.

The right leg was half an inch smaller in girth round the calf than the left, and it felt considerably colder to the touch. The child was fat, looked healthy, her bowels were open, and all her functions were performed naturally.

I never saw this patient again.

Henry Barrett, aged 16 months, 4, Cottage Place, Granby Street, Lambeth: the healthy child of healthy parents: went to bed quite well on the evening of July 20, 1841. In the course of the night he became restless and very feverish, and in the morning his mother found that he had completely lost all power over his right leg. In other respects he continued well, except that his bowels were constipated.

He was brought to me on July 23, 1841. I found him to be a well-grown, fair child, pale, and of a weakly appearance, but presenting no marks of scrofula, nor of any serious derangement in his system.

He moved his limbs perfectly, with the exception of the right leg. On that limb being pinched, he cried, and moved his toes slightly, but was quite unable to draw back his foot or leg, or to move the thigh. I ordered him a small dose of jalap immediately, and directed it to be repeated every other morning.

July 27th.—Child's bowels were still confined, not having acted more than two or three times since last note. His health was still good, and he had gained a little more power over the limb: he could not move the leg at all, but moved the thigh slightly.

Aug. 6th.—The child had taken the powders daily since July 27th. His bowels were now regularly open, his health good, and he had acquired more power over the palsied limb. He could stand, but was unable to put the foot flat to the ground; he could move the leg a little, but did so chiefly by means of the muscles of the thigh.

He was still improving, when he was attacked by pneumonia, of which he died at the beginning of September. I could not obtain permission to examine the body.

Alfred Appleby, aged 7½ years, living at 2, Clifford Street, Walworth, the child of healthy parents, had had good health since he was four years old; before which time he had frequent attacks of croup.

He seemed in his usual health, when, on February 6, 1841, his mother noticed that he used his left limbs much less than his right.

He was brought to me on Feb. 27: he was a pale delicate boy, whose

pulse was extremely feeble, bowels rather constipated, and tongue slightly furred. In walking he dragged his left leg, and turned the foot inwards; and though he could use the left hand, yet he was unable to grasp any object as firmly, or to hold any thing as tight, as with the right hand. Sometimes, when walking or standing, his left leg gave way under him, and he fell to the ground, though not in a fit, nor with any impairment of his senses.

I ordered him purges of calomel and senna daily, which acted violently, but did not at all improve his condition. I therefore began on the 2d of March to give the vinum ferri, and discontinued the employment of purgatives. Within a week he had acquired considerably more power over the leg, but the condition of the arm was much as before. I now ordered a stimulating liniment for the arm, directed the application of a flannel roller to the limb, and continued the use of the iron. The child now improved considerably; and after persevering in this plan of treatment was discharged on April 20th, in much more robust health than before, and having perfect use of both sides of the body.

Somewhat similar to the preceding is the case of Sarah Macartney, aged 4 years, who was brought to me on July 2, 1841. She had always been a delicate child, and about eighteen months before had had a very serious attack of measles, attended with inflammation of the lungs. She was in her usual health, however, last February, when, after having been for some days very heavy in her head, her mother noticed that she had lost the use of her left leg and arm. After taking medicine, the power over the left leg returned in the course of a few weeks, but she had not regained the complete use of her left arm.

The child's appearance was extremely unhealthy, and she was suffering from strumous ophthalmia. Her pulse was frequent and feeble, her bowels are confined, and the evacuations dark; tongue pale and moist; appetite bad; thirst considerable.

She had perfect use of all her limbs, with the exception of the left arm, which she could move slightly, but could not raise it to her mouth or head, nor grasp any thing with that hand. The fingers of the left hand were flexed, and the thumb was drawn into the palm.

She was unable to extend her fingers by any effort of the will, but could straighten them with the other hand without pain or difficulty. Sensation was perfect in the affected limb.

I ordered a small dose of the iodide of iron, three times a day, with a powder composed of rhubarb and the Hydr. c. Cret. to be taken every night, and a liniment for the arm.

In a fortnight she had acquired more power over the fingers, could grasp a little with the hand, but the state of the arm was unchanged.

She was now sent into the country: at the end of a week her general health was much improved; she could straighten her fingers, and had acquired much more power over the left arm, though she was still unable to raise it to her mouth or head.

On August 13, the same plan having been persevered in, her recovery was almost complete; she was now able to use the left arm freely, and could put the left hand on the top of her head, or bring it to her mouth.

At the end of the month she was discharged quite well.

Permanent palsy of the limb appears to be the result in some cases. This seems to have occurred to William Hinton, aged 3½ years, who, though of a strumous and unhealthy appearance, was reported by his mother to have always had good health. About ten months before he came under my notice it was observed that his left leg and arm seemed weak. As his general health continued good, no remedial measures were employed, although the impairment of power over his left extremities continued. He never completely lost the use of his left leg, but after some weeks began to regain power over it, and when brought to me could use it as well as the other. The left arm, however, grew worse, until it became completely useless, the boy having no power to move it, nor could he bend his wrist, though he could move his fingers.

The deltoid and other muscles of the left arm were so much wasted that its circumference was not much more than half that of the right. The left humerus, too, hung out of the socket, so that a finger could be placed between the head of the bone and the acromion, and a piece of tape extended from the top of the acromion to the tip of the index finger of the hand, measured—

On the left side 12½ inches.

„ right „ 12 „

Sensation was perfect in the paralysed limb.

Of the subsequent history of the boy I am ignorant, since he was not brought to me again.

The cases now related may serve as specimens of the usual characters of this affection. In the majority of instances it is important rather from the anxiety it occasions the relatives than from any thing really grave in its nature.

It will be perceived, that, though perhaps most frequent in teething children, it is by no means confined to the period of dentition. It often involves both the upper and lower extremity, in which case, as in adults affected with hemiplegia, the lower always recovers much the more rapidly. The paralysis is usually incomplete, some power of moving the fingers or toes remaining, while neither the arm nor leg can be moved. Sensation, as far as one can judge, is unimpaired, and I have not in any instance observed reflex movements. Occasionally sensation is exalted; a circumstance which, when the lower limb is the seat of the affection, and the paralysis is incomplete, may lead to the apprehension of hip-joint disease. In such a case the child bears all its weight on the healthy limb, turns the foot of the affected side inwards when walking, and stands with the toes of that foot resting on the dorsum of the foot of the healthy side. Still it will usually be found that the exaggerated sensibility of the paralysed limb varies greatly at different times, while that extreme increase of suffering produced in cases of hip-joint disease by striking the head of the femur against the acetabulum by a blow upon the heel, and the fixed pain in the knee of the affected side, so characteristic of disease of the hip-joint, are absent; and these points of difference will, I should imagine, usually suffice to distinguish between the two affections.

With reference to another important point—how we may discriminate between paralysis from structural changes in the brain, and those less grave forms of which this paper treats—I would observe, that the paralysis which occurs in cases of tubercle of the brain does not usually supervene suddenly, nor

does it for the most part at *first* involve both the upper and lower extremity, but the upper is generally the first affected. In cases of tubercle of the brain, headache, and other vague indications of cerebral disease, have usually existed for a longer or shorter time, when the power over one limb is observed to be impaired. The patient at first uses that limb less willingly than the opposite one, but still moves it, though in a tremulous manner, nor is it till after some time that any thing approaching to complete paralysis comes on; and when it does it is usually associated with an involuntary tremor or twitching of the limb.

The cases with reference to which most doubt will exist are those in which the paralysis has succeeded to an attack of convulsions. Even here, however, there are circumstances which will often help us to discriminate between the graver and the less formidable malady. In tubercle of the brain it is but very seldom that any thing approaching to complete paralysis follows the first attack of convulsions, but usually, firm contraction of the fingers of one hand, or of some joint of one or other extremity, succeeds to the convulsion, and continues for some hours, or even longer, and it is only gradually, and after the recurrence of several fits, that the paralysis of the limb becomes very obvious. Cerebral tubercle, too, is almost always attended with headache, and a peculiar stupor, which usually precede, and almost invariably follow, any convulsive seizure.

The prognosis may usually be favourable, but the probably tedious convalescence should be borne in mind. The case of Hinton, however, shows the possibility of the paralysis being permanent; and Dr. Abercrombie relates an instance in which paralysis of the right leg, coming on in an infant of 18 months, continued during the subsequent life of the patient, who, when a tall and strong young woman of 20 years, still remained entirely paralytic of her right lower extremity.

It has been seen by the details of the cases how largely purgatives entered into the plan of treatment. That state of habitual constipation, however, which is often met with in weakly children, as in some of the subjects of the foregoing observations, is not best overcome by the employment of drastic

purgatives, but rather by the persevering use of gentle aperients. The cases of Appleby and Macartney both illustrate the benefits of a tonic plan: in Appleby's case very free purging had been previously used without the slightest good effect. Stimulant liniments have often appeared to be of great service; but I have had no experience of the effects of electricity, though I had purposed trying it in Hinton's case if he had continued under my care.

ABSCESS IN THE INGUINAL CANAL.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged by the insertion of the following case in your very useful journal.—I am, sir,

Your obedient servant,

HENRY EWEN,

Member of the Royal College of Surgeons.

Long Sutton, Aug. 17, 1843.

Aug. 11, 1842.—I was requested by a professional neighbour to visit Robert Fendrick, a gardener, æt. 67, who was supposed to be suffering from strangulated hernia, and to require an operation for his relief. He complained that his bowels were constipated, and that his illness commenced five days ago with sickness, but he has not vomited since the day of attack. Four days since he observed a tumor in the situation of an inguinal hernia on the left side: there is now a tumor in that situation: the integuments covering it are red, tender, and like a phlegmon: the induration of the integuments extends as far as the linea alba on the inner side, upwards, not quite half way from the spinous process of the pubes to the umbilicus; outwards and above Poupart's ligament, nearly as far as the anterior and superior spinous process of the ilium. The spermatic cord is swollen to the size of my thumb, tense and tender, and nearly blocking up the external abdominal ring. He is pale and thin, and of lax fibre; tongue white; pulse 72, soft. The symptoms could hardly be considered as those of strangulated hernia, and I stated to my friend that I thought the case merely inflammation of the contents of the inguinal canal. Twelve leeches were

ordered, to be followed by fomentations and poultices: calomel and compound rhubarb pill, with salts and magnesia in peppermint water, were prescribed to unload the bowels.

12th.—He is much relieved; the cord is less tense and tender; the bowels have been well opened. He continues the fomentations and poultices.

20th.—The tumor is moderately easy; bowels open; urine loaded with purulent deposit. He continues the fomentations and poultices, and takes an aperient occasionally. Ordered the following:—

R. Decoct. Uvae Ursi, ʒxxvss.; Liqueoris Potassæ, Tinct. Hyoscyami, aa ʒij. M. sumat coch. iij. ampl. ter quotidie.

28th.—A considerable quantity of pus has been discharged from an opening near the abdominal external ring: the urine is pale and limpid, and free from deposit.

30th.—The induration of the integuments has increased considerably; tongue clean; bowels open; urine natural; pulse 60.

September 5th.—Convalescent.

From Mr. Lawrence's remarks on the diagnosis of inguinal hernia (page 248, 5th edition), I should infer such cases as the one I have related are not of very common occurrence.

FERRI CITRAS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the accompanying memoranda suit your pages, their insertion will oblige

Your obedient servant,

G. M. MOWBRAY.

36, Paternoster Row,
Aug. 1843.

If we add citric acid in solution to iron filings, and invert the vessel so as to exclude atmospheric air, the solution will be colourless, depositing, at the same time, flakes of proto-citrate of iron. Light does not affect either the solution or the deposited flakes. By adding to 1 iron filings 7 citric acid, and 12 gallons of water, heating to the boiling point, and leaving to digest for 24 hours, a greenish-yellow solution may be obtained, sp. gr. at 55° F. 1.025, which reddens litmus. The addition of 12 gallons more water to the sediment (after removing the previous solution)

and boiling, leaving to digest for 24 hours, affords also a somewhat lighter coloured greenish yellow solution, which reddens litmus, and has a sp. gr. at 56° F. of 1008.6. A further addition of 12 gallons of water to the sediment, and boiling, affords a solution which *bleaches* litmus paper (owing to absorption of oxygen by the iron), and has a sp. gr. of 1002.5 at 60° F.

If to each or all of the above solutions, when mixed, liq. ammonia be added, a blackish precipitate is thrown down (the magnetic oxide of iron), and if the ammonia be added to such excess as to smell distinctly, and the liquor is evaporated over a water-bath, the solution gradually reddens at the edges, until, at the termination of the process, it assumes a most brilliant garnet hue, giving out, at the same time, a peculiar and somewhat acetous odour.

Collected on plates, this ferro-citrate of ammonia, or ammonio-citrate of iron, resembles an article now sold as the citrate iron (June 1842.) The first, or acid solution, sp. gr. 1025, gives a product possessing the richest tint: the after solutions require the addition of more acid, in order to increase the solubility of the subsalt in the first instance, and afterwards to take up the peroxide which forms during evaporation.

If a quantity of the nearly insoluble proto-citrate of iron be diffused in water, and exposed to the atmosphere for a considerable length of time, say from eight to twelve months, according to the

temperature of the season, the solution gradually darkens; more and more of the once colourless and almost insoluble salt dissolves, until it is entirely taken up, whilst during the same period a corresponding deposit of hydrated peroxide of iron ensues, and finally we obtain a most brilliant, deep ruby tinted solution of a persalt, possessing a peculiar odour and somewhat sweetish taste. If now we pour off this solution, and permit it to remain exposed, the whole of the iron is precipitated in the form of red (somewhat orange red), flocculi of hydrated peroxide of iron: the supernatant fluid, which is colourless, no longer contains citric acid, but retains the sweetish taste and acetous odour, reminding the operator of that peculiar smell which pervades a chamber wherein the ammonio-citrate, or ammonio-tartrate, of iron is being evaporated to dryness; and which, indeed, characterizes these remedies when they have been recently prepared. The addition of a small quantity of ammonia hastens these changes, whilst a large excess of citric acid modifies them, since the change first observed in the latter case is a film of mildew, forming in the solution and floating thereon: this, however, disappears during the progress of the changes narrated above.

The facility with which one atom of citric acid is converted by heat into either one atom of malic acid or three atoms of aconitic acid, the change being as under—

together with the fact of the similarity of the phenomena before described—in the one case occurring by evaporation in a water bath, and in the other by the action of the atmosphere at ordinary temperatures—suggests this question: Is the salt which has been sold as the citrate of iron, or ammonio-citrate, by whichever term convenience may have designated it, to be ranged among the salts termed citrates? Is not the citric acid of the normal solution, or a portion of it, decomposed? The analysis of such decomposition I must defer until a future occasion. Meanwhile its investigation will amply repay such of your readers as take an interest in tracing the conversion of the car-

bonic acid of the atmosphere by the living plant, into tartaric, citric, malic, and other acids; being precisely the reverse of such process.

RUPTURE OF THE VAGINA.

To the Editor of the Medical Gazette.

SIR,

I SEND you a case of rupture of the vagina from sphacelation, terminating fatally. Should you be of opinion that it possesses sufficient interest, you would oblige me by its insertion.

Your obedient servant,

W. H. O. SANKEY.

Margate, Aug. 28, 1843.

Mrs. M——, æt. 47, of a very relaxed and debilitated habit of body, exposed continually to malaria, having also undergone during her pregnancy, which is the 18th, much mental anxiety, bodily fatigue, and deprivation of food, was taken in labour on 8th of August, at 10 o'clock. Her previous labours had been severe; she had suffered at various times from hæmorrhage, adherent placenta, and convulsions.

For six weeks she had been unable to rise from her bed on account of the weight of the pregnant womb. The womb was pendulous, the abdominal parietes extremely flaccid and attenuated: when she sat up in bed, which she did constantly, though unable to get off it, the womb was observed to sink deeply into the pelvis: the pains about 11 o'clock came on regularly and tolerably strong. On the first examination I found the waters had broken, and the os uteri of the size of a crown-piece; vagina hot; the labia œdematous, with slight œdema about the os uteri. I introduced repeatedly pieces of unmelted lard to cool the parts, and placed a broad bandage round the abdomen, and waited patiently. The pains continued till about 12 or 1, strong and good; they then began gradually to flag, and became weaker, till about 5 o'clock: the head of the child was partially protruded through the os uteri. Hoping from the cessation of pains she might obtain some sleep, I left her. About 7 o'clock I was again summoned. She had had no pains since I had left, but was taken sick; she vomited slightly, and as she attempted to sit up in bed she experienced a burning heat in the lower part of her body, and found she had no power over one of her limbs. and the same time a bloody, grumous discharge escaped to the amount of 7 or 8 ounces, from the vagina.

I found her breathing rapidly and laboriously, with a very anxious expression of countenance; pulse very rapid and weak. I repeated small doses of cold brandy and water, and ordered the preparation of Mist. Vin. Gallici to be got ready; and sent for my friend, Mr. G. Hoffman, of this place.

The head was found in the same position as at 5 o'clock, half protruding through the os uteri.

The possibility of the rupture of the

uterus presented itself both to Mr. Hoffman and myself, yet the non-receding of the head, and the absence of all uterine pain at the moment of the seizure, militated against it. We examined carefully for rupture of the os uteri, but could find none: that partial separation of the placenta caused the discharge seemed unlikely, on account of its black grumous nature, and the extreme depression of the patient; and the great anxiety, too, remained by that diagnosis unexplained: the impossibility of uterine pains being re-established plainly indicated the necessity of delivery by artificial means. We called in the aid of a third practitioner, Mr. Price, who concurring in the opinion, and the Mist. Vin. Gall. having been exhibited, and the usual precautions as to the contents of the bladder and rectum, &c. being taken, I proceeded to deliver.

The instruments which were the readiest at hand were a pair of short and straight forceps: the head not being out of the womb, an imperfect hold only was obtained, but the head advanced easily, assisted by some uterine pains. After the head was in the vagina, it, however, receded gradually from the grasp of the instruments. In attempting to re-apply them the head glided before my hand into the womb, and even receded within the os uterus. A delay of 20 minutes occurred before the long forceps were procured: the head was then so moveable, and the womb so flaccid, notwithstanding attempts to fix it externally by pressure, that it was found that turning would be much easier to accomplish: this was accordingly done, and a blackened dead child extracted.

A rather copious discharge of dark blood followed; the placenta was in the vagina, and easily removed. Endeavouring to pass my hand into the womb to ascertain if it was duly contracted, it passed into what at first appeared to be the uncontracted womb, filled with large coagula, the parietes being so thin as to give my hand the sensation to Mr. Hoffman, who was making gentle pressure externally, as being merely covered with a glove. I felt also a large tumor, which, for a second, appeared like the head of a second child, but passing my hand down I found it to be fixed, and in fact to be the external or peritoneal surface of

the contracted womb: my hand was therefore, for a few seconds, in the peritoneal cavity: what appeared at first coagula, were the intestines. On withdrawing the hand I found the os uteri entire, the rupture having taken place on the posterior wall of the vagina.

We placed a greased plug in the vagina, secured with a T bandage, and administered cordials; but the patient sank about 2½ hours afterwards, remaining perfectly sensible to the last.

Examination, 24 hours after death.—Great emaciation; copious frothy discharge from mouth.

Abdominal parietes in the mesial line not more than a quarter of an inch in thickness. Abdominal muscles pale, and extremely emaciated, scarcely to be detected. Peritoneum highly injected*. Uterus contracted and empty: natural, except in its peritoneal coat. Vagina blackened, its walls three quarters of an inch in thickness, ruptured longitudinally to the extent of four or five inches; the whole of posterior wall sphacelated; the bladder blackened and engorged. Rectum sound.

REMARKS.—It is evident that the state of the vagina was produced previous to commencement of the labour, and as the os uteri was sound, I imagine it took place by a kind of intussusception, especially as the rectum did not participate in the sphacelation; as it would have done had it been from pressure of the head or womb. That it did not take place during the labour is evident from the same cause, and from the short duration of the labour, lasting barely seven hours. That the rupture did not take place by the instruments, which are acknowledged to have slipped, is evident to my own mind from the gradual manner in which the head escaped from their grasp; and moreover, the rupture, which was extensive, must have been detected by the other practitioners, as well as myself, who made an examination previous to sending for the long forceps; and the rupture, if made by forceps, would have been most probably in a transverse direction. The morbid state of the vagina rendered it undilatable, crisp, and easily liable to tear, and the passage of the child, which was large, caused the rending of its walls.

* The peritoneum passed over full five inches of the vagina before it was reflected on to the rectum.

The hurried and laborious breathing took place immediately after the first symptom of the rupture: was this occasioned by the shut sac of the peritoneum having burst, and therefore no longer moving as one body upwards against the diaphragm by the action of the abdominal muscles? It is evident that, where an aperture existed in the peritoneum, the contraction and expansion of the abdominal parietes would merely act in a manner to force air in and out of its cavity, and the sac would cease to act as a body on the diaphragm.

MEDICAL GAZETTE.

Friday, September 8, 1843.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

VITAL STATISTICS OF SHEFFIELD.

ONE of the most prosperous trades in Sheffield is the silver and plated manufacture. Until the last two years it has not shared the distress experienced by all engaged in making cutlery. The workmen belonging to this branch amount to 400, and form several unions, the restrictive laws of which are effective even in times of bad trade. The earnings of men vary from 18 to 42 shillings, and of women from 8 to 15 shillings a week.

The workmen in this manufacture are sober, intelligent, steady, and are, or were, in tolerable circumstances. This is attributable to various causes. First, the rule of the trades' union, which prohibits the masters from taking apprentices, has reduced the number of workmen, formerly superabundant. Secondly, the expensive materials and tools used in this trade prevent that sudden conversion of men into masters which is so common in so many other occupations. Thirdly, children are rarely employed in this trade much under fourteen years of age. Fourthly,

the workmen are not liable to be thrown out of employment by machinery. This occupation is neither particularly detrimental to health, nor conducive to longevity. In the Silversmiths' Benefit Society, the mean age attained by those who die above the age of 40 is 59.12; while among the working classes generally, of Manchester, Leeds, and Liverpool, it is 58.97; so that the advantage in favour of the silversmiths is slight indeed. In rural districts the mean age attained by persons above 40 is 68.76. What a difference!

Next come the *saw manufacturers*.

"The workmen in this branch of trade are, perhaps, in no degree inferior in intelligence, sobriety, and general good conduct, to those in the manufacture of which we have just treated. They have both equally their respective unions, which regulate wages, the introduction of apprentices, and which, in time of sickness, afford a weekly allowance."

In the branch called *par excellence* saw making, there are 208 journeymen, of whom about 20 are not in union; 130 boys—being, indeed, more than the rules of the union allow; and about one woman or girl to every eight men.

Nine-tenths of the men are in sick clubs; nineteen out of twenty can read and write; and their average wages are 28 shillings a week, the extremes being 24 shillings and 45 shillings.

The *saw grinders* are fine healthy men, who generally live in the country, and often add the cultivation of a plot of ground, or even a small farm, to their mechanical occupation. They are peculiarly liable to accidents, and of 42 saw grinders who have died since 1821, 5 were killed by the breaking of stones. Dr. Holland gives a list of 13 accidents, being a part of those which have happened to 78 living members in union. Most of them are very serious, *e. g.* "3. Drawn over the stone; severely hurt; in bed nine months."

"9. Arm severely lacerated; lame three months."

The *edge-tool makers* are well paid, but are a less intelligent class than those previously mentioned. The number of *foremen* and *strikers* is equal in this trade; the former are said to earn, on the average, £1. 14s., and the latter £1. 2s. a week.

The account is furnished by a manufacturer, and, thought no doubt accurate as far as it goes, is defective in an important point. We do not learn from it how many months in the year the men are in work. The prices have been strictly enforced, even during the last three years, but for what portion of that time have the men obtained them?

Three-fourths of the workmen in this branch are in sick clubs; but only one among five adults can read and write. Trades that require strong arms rather than acute heads will be favourable rather to sensuality than intelligence; a blacksmith drinks more than he reasons; and Dr. Holland finds that the forgers of Sheffield have big occiputs, but low, retreating foreheads.

The spring knife makers are badly paid, and badly educated. "A few superior workmen may earn from 30s. to 40s. per week. In the first manufactories of the town the average is from 16s. to 25s. But in many of the inferior manufactories, the workmen are receiving no more than 12s. or 16s."

Moreover, when Dr. Holland was writing, in June 1843, this scale of wages was very greatly reduced.

This branch is not in union; not above half of the adults can read, and not one-fourth moderately well; about two-thirds only of the adults are in sick clubs.

Two circumstances combine to depress wages in this department. The most important is the smallness of the capital required to set up as a cutler. A few pounds are sufficient. The other

one is the facility which this branch offers for the employment of children at an early age.

The *file trade*, as regards the circumstances of those employed in it, holds a middle place between the silversmiths and saw-makers, who are above, and the spring-knife cutlers, who are below them.

The branch of the file trade called *forgers* consists, like the edge-tool makers, of foremen and strikers; but the profits are more equally divided between the two classes of workmen in the present instance; a foreman averaging £1. 12s. 10d. a week, and a striker £1. 6s. 9d.

As to *file-cutters*, by reference to thirty books of file-cutters, men of *steady* habits, each having the assistance of a boy, the average per week was found to be £1. 18s. 6d. Eighty per cent. of the adults can read, and seventy can write. The proportion among the boys is rather greater; which may either show that education is making way, or that a certain number of adults forget their little scholastic learning.

The *fork-grinders* carry on the most unwholesome trade in the kingdom. Fork grinding is always performed on a dry stone, and the clouds of stony and metallic dust produced in the process clog up the respiratory organs, and cause grinders' asthma, a disease which carries off its victims in a majority of cases before the age of thirty!

The better the state of a given trade in Sheffield, says Dr. Holland, the smaller is the proportion of minors employed in it. Thus in the silver-plated branch, the minors are to the adults as 16 to 100; and among the edge-tool makers, as 12½ to 100. In the spring-knife branch the per centage is about 25; but among the fork-grinders the minors actually outnumber the adults, as there are 100 boys and only 97 men!

Of the ninety-seven, about thirty are

at this moment suffering from grinders' asthma. It is remarkable that in this destructive trade the men are ill paid, but Dr. Holland does not say what their wages are. Nor is their education superior to their condition; for of the 197 men and boys, 109 can only read, and 69 can write.

Can nothing be done for the fork-grinders? The substitution of wet for dry stones, if this is practicable, would save numerous lives, and if the task is too difficult for unaided philanthropy, legislation might lend its assistance. We should not consider the difference of a farthing in the price of a fork a fatal objection. The Sick Clubs and Friendly Societies are very numerous, and their accumulated capital amounts, in Dr. Holland's opinion, to at least £70,000. The most ancient of them, the "Old Union," has been established for more than a century.

The error has sometimes been committed at Sheffield, as elsewhere, of making the terms of a benefit society too advantageous, so that it is ruined in twenty or thirty years by the increase of sickness and deaths among its members.

Dr. Holland has a chapter on "the amount of religious instruction and education in the several townships of the Sheffield Union."

The schools, though numerous, are insufficient. The pupils amount to 22,000; but one half of these attend only the Sunday schools, and thus receive a very trifling amount of instruction. Dr. Holland says of the Sunday schools that the knowledge imparted by them is extremely superficial; and a little further on, "for the little good which they effect we are grateful, and they richly deserve encouragement;" but two pages further on, he asserts that "not one-third of the youth of Sheffield can be regarded as receiving any education at all."

More day schools are evidently wanted, and Sheffield, like the rest of the kingdom, has reason to regret the loss of the late ministerial measure on education. Dr. Holland wishes that fewer churches and more schools had been built in Sheffield, forgetting that churches are schools, and that if the old catechetical discipline were restored, they might be made very effective Sunday schools. However, we do not differ from Dr. Holland when he asks for more schools; the National Society has set on foot a fresh subscription for this purpose, and we would suggest that he might contribute the profits of his book. We will touch but on one point more—the saddest and dreariest in his book—we mean his talk about medical charitable institutions. Four years ago Dr. Holland published a pamphlet, recommending the world not to be so charitable to the sick, on which we commented with some severity.* Time, we are sorry to see, has not mellowed the Doctor's feelings on this point. He still thinks that the Sheffield Hospital was intended for a few choice cases of unutterable distress, and gives a long extract from his former Malthusian essay. He "will not insult the memories of the good" by supposing that they intended the hospital for the working classes in general; and he thinks it "not difficult to define some of the conditions which ought to exclude from a participation in the charity."

Neither single men if employed, nor married men in work with small families, nor married men with several children and high wages, nor operatives with several sons or apprentices working for them, nor servants in place, are proper objects for the Sheffield hospital.

But what is to be done with a poor single man, without friends or money,

* MEDICAL GAZETTE, May 11th & 18th, 1839.

attacked with fever or pneumonia? We know what the founders of hospitals would answer; let us hear the reply of an economist:— "If they are not too ill to be incapacitated from pursuing their vocations, it is a gross imposition to extend to them the charity, and if otherwise, they have always homes. It may perhaps be urged in objection, that they will necessarily incur debts in providing at this time medical assistance. This, so far from being an objection, is an exceedingly powerful argument for throwing them on their own resources. They will thus be taught practically the injurious effects of misconduct: the struggle to overcome the subsequent difficulties is indeed [more] calculated to awaken reflection, and suggest rules for future guidance, than any discourse, however beautiful and just its views."

But what if the needy fork-grinder is not "taught practically," but only dies? Slips through your fingers for want of charitable aid, while you are intent on giving him a splendid Malthusian lesson?

COLLEGE OF SURGEONS — NEW CHARTER.

WE made an important mistake in our notice of this last week. It appears that there is to be no exclusion of those who practise pharmacy or midwifery from the body of Fellows, the admission to which is not to be according to standing, but by examination. Those who practise pharmacy or midwifery, however, are excluded from the council.

ASSOCIATION OF MEDICAL OFFICERS OF HOSPITALS FOR THE INSANE.

At the Second Annual Meeting of this Society, held in Lancaster, June 1, 1842, and subsequent days—

It was resolved—"That the Governors of all Public Lunatic Asylums in the United Kingdom be solicited to further the objects of this Association, and that the Honorary

Secretary be deputed to explain by letter to such parties its nature and views."

This having been done to the Governors or Visitors of those Asylums *only* which the Association wished *immediately* to visit—at the Third Annual Meeting of the Society, held in London, June 1, 1843, and subsequent days—

It was resolved—"That it is the wish of the Association that the Governors, Visitors, and Officers, of each Hospital for the Insane, be forthwith made acquainted, by Circular, with the existence of the Association, and with the objects it seeks to accomplish."

Gloucester, Aug. 25, 1843.

SIR,—In obedience to the above Resolutions I beg to inform you that "The Association of Medical Officers of Hospitals for the Insane" was formed in the summer of 1841, by medical gentlemen, officers of public lunatic asylums—that it was then proposed to consist of all the medical officers of such institutions in Great Britain as *ordinary* members—and of such medical gentlemen having the private care of the insane—of such persons not medical, known to take an interest in those afflicted with insanity—and of such distinguished foreigners, as the Society shall at any time think proper to elect, as *honorary* members.

The intentions and objects with which the Association set out, were—

1. "To improve the management of lunatic asylums."

2. "To improve the management of the insane."

3. "To acquire a more extensive and a more correct knowledge of insanity."

To effect these objects the members of the Association meet, annually, at some town or place in which there is a public lunatic asylum. They solicit the permission of the Governors or Visitors to visit the asylum, and to inspect it thoroughly, and afterwards to assemble in the committee-room of the asylum to speak freely, openly, and in good faith, upon the merits or defects they may have observed in the management of the asylum or in the treatment of the patients. On the same occasions such members as think proper read essays or papers on subjects connected with insanity; and all communicate and compare their respective experience. At these meetings the governors or visitors are respectfully requested to attend.

The more effectually to compare their respective experience, the Association has adopted a register for the use of its members, whereby the leading features in the history and character of every case, placed under the care of each member, may be *uniformly* recorded. By this a great mass of similar facts will be simultaneously collected in all parts of the kingdom, and at the same time so arranged as to shew a record of insanity,

not as presented to one lunatic asylum, but as occurring throughout the kingdom. To this the Association begs respectfully to draw the attention of the governors and visitors of lunatic asylums.

The Association is collecting plans of all the asylums at present erected, and copies of such designs as from time to time may be projected. It collects also the printed reports and other published documents of different asylums.

The Association has already been permitted to prosecute its objects at the Gloucester, Nottingham, Lancaster, Middlesex, and the Surrey County Asylums, and at the Hospital of St Luke's, in London; and it has been most kindly invited to the Kent, the Wakefield, the Northampton, Belfast, and Glasgow Asylums.

As the objects of the Association are solely directed to a public good—as they are in no degree, however remote, connected with a private end—and as the Society sustains itself by the exertions and resources of the members themselves—it feels assured that it is only necessary to make these facts known to secure the countenance and encouragement of the governors or visitors of the different establishments for the reception of the insane.—I have the honour to be,

Your most obedient servant,

SAMUEL HITCH, M.D.

Hon. Sec.

ACADEMY OF SCIENCES.

The Tartar on the Teeth. By M. MANDL.

A soft substance, of a whitish or yellowish colour, is habitually deposited upon the teeth, and sometimes becomes firmly fixed to them. This substance may accumulate in greater quantities, and growing firmer by degrees may form the hard and dry concretion known under the name of tartar. It increases in bulk by the fresh layers deposited on its surface. According to an analysis made by Vauquelin and Laugier, tartar consists of 66 parts of phosphate of lime, 9 of carbonate of lime, 14 of animal matter (of a yellowish white, different from the gelatine of bones,) and 3 parts of oxide of iron and phosphate of magnesia. Other chemists have found the proportions different; sometimes the phosphate of lime was more abundant, and sometimes the animal matter (or mucus.)

Authors have been much occupied with the manner in which this substance is produced. Is it a secretion, as some have written? Is it a deposit of the earthy salts contained in the saliva, and precipitated by a chemical agent, as medical books have repeated for ages? Is it an earthy exhalation

from the capillaries of the blood; to which the mucous membrane of diseased gums is prone?

Not one of these hypotheses has been proved; not one has the sanction of direct experience. Moreover, they are all sufficiently refuted by the following investigations into the composition of tartar.

It results from the experiments of M. Mandl that tartar is nothing but a deposit of the skeletons of dead infusoria, agglutinated by dried mucus; nearly as certain earths, according to the researches of M. Ehrenberg, are composed almost entirely of fossil infusoria.

In fact, if we take some of the mucous matter which is accumulated upon and between the teeth, and dilute it with a little distilled water previously warmed, we shall immediately perceive a host of infusoria, which move about with great liveliness. Their size varies from $\frac{1}{800}$ to several hundredths of a millimetre; and their shape is the same as that of the infusoria described by authors under the name of *vibriones*.

The presence of infusoria in mucus was pointed out by Leuwenhoek; but M. Mandl sets forth in all their details, the shape, liveliness, and other qualities of these infusoria.

These animals also exist in great quantity in patients who have been several days on low diet. They also constitute the greatest part of the mucous coating of the tongue in persons whose digestion is disordered. (According to an analysis by M. Denys, the chemical characters of this coating agree with those of tartar.)

After having ascertained the presence of infusoria in the mucus of the mouth, M. Mandl tried to find out whether these animals assist in forming the tartar also. For this purpose, he softened a particle of tartar in a drop of water for twenty or thirty minutes, and after compressing it between the two pieces of glass, he distinctly saw that the tartar was composed of dead vibriones, of different sizes, but generally measuring several hundredths of a millimetre, united by an organic substance (dried mucus,) the quantity of which is variable. The tartar is often almost entirely composed of these vibriones.

Hence it follows that these vibriones are provided with a shell, or inorganic skeleton [*squelette inorganique*], since tartar is found consisting entirely of these vibriones.

This shows, too, why cleanliness, and the use of tonic or alcoholic fluids, prevent the formation of tartar by preventing the production of the infusoria.

To recapitulate, it appears:

1. That there is a great number of vibriones in the mucus which accumulates around and between the teeth.

2. That tartar arises from an accumulation of dead vibriones, and consequently cannot be considered either as a calcareous substance deposited by the saliva, or as a peculiar secretion.

This discovery of the composition of tartar is as new, with reference to Leuwenhoek's observation, as the researches of Ehrenberg touching the composition of diluvial soils were new in reference to the well-known fact of the existence of infusoria in water.—*Gazette Médicale*.

A SIMPLE MEANS TO PREVENT OR STOP NERVOUS COUGHING.

THERE is a curious and rather interesting paper with the above title in a number of the French Gazette for February, and from it we have extracted the following passages. M. Diday, the author, makes a few prefatory remarks on the power which a mere strong effort of the will often gives to resist the impulse of a strong sensation (*besoin*, the French would say), like that of sneezing or coughing; and he goes so far as to assert that "it is always possible to prevent a fit of either by an energetic and sustained effort of the will, *if this be done from the very commencement*." In old established coughs, as a matter of course, such an attempt is quite inadmissible, at least with any reasonable hopes of success. Whenever, indeed, the cough depends upon the presence of any matter to be expectorated, it is obvious that the effect cannot be checked as long as the cause remains. It is therefore almost exclusively to coughs depending upon nervous irritation that the following remarks are intended to apply.

The attempt also must be made before the annoyance has got, as it were, root in, or hold of, the system. At first, it is especially necessary that the patient acquire the habit of drawing in his breath slowly and not too deeply, and that he should avoid all hurried and irregular inspirations.

That most people have it in their power to arrest, at least to a certain extent, the frequent recurrence of fits of coughing and sneezing, is obvious from the very circumstance that these acts are not unfrequently the effect of mere—we might almost say *wilful*—imitation; as in churches, lecture-rooms, &c.; and we know that, whatever may be acquired by the will, may be as readily checked by it. Dr. Diday tells us that one of the most eminent physicians of La Pitié hospital is in the habit of bawling out, on entering any of the wards, "I will have no coughing during my visit; whoever cannot stop himself, shall be put on low diet;" and true it is that all the patients

are wonderfully still as long as his visit lasts. It is an old saying, that very few people know what they can do until they try; and every one can testify from his own experience, that when the attention is suddenly engaged elsewhere, he ceases to feel a desire to some natural act, as to sneeze, to pass urine, &c., although this desire or *besoin* had been urgent just before.

M. Diday gives the following account of his observations.

"The first idea that occurred to me on this subject was suggested by what I observed to take place during sneezing. It is well known to many people that this act may be very often prevented by rubbing the edge of the eyelids or of the lips, or the tip of the nose, with your finger, when the disposition to sneeze is felt. I have repeatedly advised this expedient to my friends and patients, and it has invariably succeeded. In one case in particular, that of a young priest, who had been for some time much annoyed by the almost invariable recurrence of fits of sneezing that were apt to come on during his performance of mass, this simple means afforded a speedy and complete relief. In the performance of certain delicate surgical operations about the face and throat, such as that for hare-lip, fissure of the palate, &c., it is a matter of the greatest consequence that the patient should avoid all movement of the parts in the neighbourhood, and nothing disarranges everything so much as a fit of coughing or sneezing.

Now as the latter of these acts—which, by the by, is nothing else but a cough of the nasal passages, and of the back of the throat—may be so easily and effectually controlled in the manner we have just mentioned, we are naturally led to expect the same in the former; and so I have found it to be the case not only in myself, but in several other persons who have tried the experiment under my direction.

By merely rubbing pretty smartly with the point of a finger the edge of the lips or of the eyelids, or of the tip of the nose, when the first intimation of the '*besoin*' to cough is felt, the act may often be entirely prevented. When this feeling returns very frequently, it will be found useful to employ the revulsive friction first on one of the parts, and then on the others in quick succession."

M. Diday says that the object in the rubbing is not to supersede the exercise of an effort of the will, but only to aid and augment its efficacy. He accounts for its effects on the principles of the excito-motory doctrines of Marshall Hall and Müller respecting the nervous system.

The impression made on the extremities of certain branches of the trifacial nerve acts as a sort of derivative, or counter-irri-

tant, to the morbid sensibility of the extremities of the glosso-pharyngeal and pneumogastric nerves. We often observe the effects of this revulsive action in a somewhat analogous case, that of nausea; for we know that the disposition of the stomach to take on an inverted action may often be checked by rinsing the throat with a mouthful of spirits. If the stomach be not too much overloaded, this simple means will not unfrequently prevent vomiting. Here, then, is an instance where, by making a peculiar lively impression on certain sensory nerves, a tendency to muscular contraction—or, to use the language of a modern school, an excito-motory action—in another part, more or less removed from it, is prevented and controlled; and yet every one knows that a different kind of impression, that of titillation, made on the same organs, is one of the surest methods of exciting this very sympathetic action. Much, therefore, evidently depends upon the kind or degree of the irritation produced. While gentle tickling promotes, firm rubbing will often serve to check, a sympathetic movement in a distant part.—*Gazette Médicale*; and *Dublin Journal of Medical Science*.

LUXATION OF THE PATELLA ON ITS AXIS,

By DR. P. GAZSAN, of Pittsburg.

JAMES, aged twenty-one years, son of Judge Porter, of Pittsburg, was thrown while wrestling, and immediately found himself unable to rise.

On seeing him about an hour after the accident, I found the patella of the right leg dislocated on its axis, i. e. it was lying on its edge, presenting the posterior face outward, and the anterior face inward, the inner edge resting in the groove between the condyles of the femur.

Flexing the thigh on the pelvis, and straightening the leg, I endeavoured to replace the bone by pressing its edges in opposite directions, but failing (after repeated trials), I requested that the patient should be brought to town (the accident happened three miles out of the city), and additional advice procured.

At about twelve o'clock the patient was brought to his father's house, where I met Dr. Addison. After repeated unsuccessful attempts at reduction it was thought well to lessen the tension of the joint by dividing the ligament of the patella. This I did, by introducing beneath the skin a narrow-bladed knife, and cutting the ligament close to the tubercle of the tibia. Again we attempted the reduction, but failed. The patella could be moved on its edge more freely than before

the cutting, but resisted all our efforts to replace it.

Dr. Speer was now joined to the consultation, and, in accordance with his suggestion, the patient was placed erect, a vein opened, and the blood allowed to flow until the approach of syncope, when the efforts at reduction were renewed; but although the patella could be moved on its edge, it could not be lifted out of the groove in which it rested. It was now agreed to let the patient rest for a few hours.

The thigh was now strongly flexed on the pelvis, and the heel elevated. Then the leg was flexed steadily and forcibly on the thigh, and suddenly straightened. At the moment of straightening the leg I pressed very strongly against the lower edge of the patella from without, with the head of a door-key well wrapped, while Dr. Addison pressed with both thumbs against the upper edge of the bone towards the external condyle. On the fourth trial this manœuvre succeeded, the bone springing into its place with a snap. A cushioned splint was placed behind the knee and secured by a bandage; an evaporating lotion was used, and the patient kept at rest. Recovery was uninterrupted, and the young man has now perfect command of the limb.—*American Journ. of Med Sciences.*

OVARIAN DISEASE.

To the Editor of the Medical Gazette.

SIR,

I MAY perhaps not be singular when I confess myself at a loss to understand the motive that has induced your correspondent, Mr. Camplin, to put himself to the trouble of addressing you on the subject of my recent case of ovarian disease. The charge which he appears desirous of preferring against me needs no other refutation than that afforded by the narration of the case; and if Mr. C. had but read with as much care as "interest," he would, I think, scarcely have attempted to play the critic on grounds alike frivolous as untenable.

It is urged that I have adopted similar treatment to that employed by Mr. Walne, and that I have made use of the expression of "apparently having profited so little by the recorded cases of Dr. Clay and Mr. Walne." It is with true regret that I find Mr. Camplin descending to that lowest grade of criticism, which seeks its support in the selection of half sentences quoted without the accompanying context. In the few remarks appended to my case, I referred the chief causes of its successful issue to three heads, under the last of which I alluded solely to the manner of operating: in that paragraph the half sentence so inge-

niously isolated by your correspondent occurs, and has reference to no feature in the case other than that of the operation itself. I would beg to remind him, that the operations practised by Mr. Walne and myself are essentially different. Two methods of operating were many years ago introduced: one in which the abdominal incision was of very considerable length; the other having the opening into the abdomen not more than "an inch and a half or two inches long,"—the former being a severe, the latter probably a more dangerous one. Desirous of combining the advantages of both, I employed an incision sufficiently large to admit of the removal of the emptied cyst, and the application of the necessary ligatures, without the employment of any force, and at same time avoiding the increased pain consequent upon a very extensive wound of the integuments. In the first-named operation the sac is removed entire; in my own case its fluid contents were previously evacuated. It must be sufficiently obvious that I have not adopted the method of operating practised by Dr. Clay and Mr. Walne; and it was only in connection with this subject that I made use of the expression which has induced your correspondent to honour me with his remarks: whilst in the following sentence I have distinctly stated that I had carefully perused Dr. Clay's and Mr. Walne's cases, and had drawn somewhat different deductions from those arrived at by their authors.

But I will even concede to your correspondent that which he has gratuitously assumed, namely, that I denied having profited by the results of Mr. Walne's late case in the treatment of my own, and he is then placed in a more untenable position than before, for Mr. Walne's patient suffered from phlegmasia dolens, and mine did not. Surely Mr. Camplin will not assert that I adopted Mr. Walne's treatment by prescribing for a disease which did not exist. But the evidence is before him; let him compare the medical treatment of both cases, and then, as one of those trifling circumstances worthy of his criticism, he may probably discover that I have carefully abstained from administering a remedy to which much importance is attached, both by Dr. Clay and Mr. Walne,—the ox-gall, which, used by those gentlemen on several occasions, was not once employed by myself.

Your correspondent has not been less unfortunate in selecting the second case of Mr. Walne, as that from which I culled my ideas of treatment. Mr. Walne's first case was already published, and in its subsequent history corresponded much more closely to my own. Could not that fact content Mr. Camplin? He has thought otherwise, and has therefore indulged in the construction

of an obscure little paragraph, by which I am informed that I received so large a number of bulletins of the condition of Mr. Walne's patient. I have no right to allude to any attendant circumstances of a case, however trivial and unimportant they may be, if not previously published; I may, however, briefly state that all that Mr. Camplin can mean is, that at about the time of Mr. Walne's operation I happened to be in attendance upon a lady, one of whose medical attendants had frequent opportunities of watching Mr. Walne's patient, and that I thus occasionally heard of the progress of the case.

It has not been without hesitation that I have replied to the letter of Mr. Camplin, and I cannot but feel that something like an apology should be offered to Mr. Walne for the very frequent reference made to his cases. Such apology is due from your correspondent; and in conclusion I would beg him (and the caution seems necessary) not to again misunderstand me. I trust I shall not fall into the equal absurdity of refusing to learn from recorded experience, or accusing others of having done so. I have derived both pleasure and instruction from the perusal of the writings of Mr. Walne, and shall be always glad to profit by the experience of one who so advantageously employs it; and let me add, if Mr. Camplin will kindly inform me where I can meet with any addition he has ever made to medical science, I shall be happy to profit by that also.

Allow me to remain, sir,

Your obedient servant,

FREDERICK BIRD, M.D.

38, Craven Street, Sept. 2, 1843.

MEDICAL ATTENDANTS ON UNIONS AND PARISHES.

To the Editor of the Medical Gazette.

SIR,

As it is of great importance that medical men should be aware of the nature of the qualifications required to enable them to hold situations in Unions, Parishes, &c., under the English Poor Law Act, it would, I feel assured, be conferring a favour on the profession your giving publicity to the following statement:—

By the General Medical Order of the Poor Law Commissioners, of date March 12, 1842, the guardians were instructed that no medical person, not possessing purely English qualifications in medicine and surgery, was legally qualified for holding offices in the Unions, &c. In consequence of remonstrances made against this order to the Secretary of State for the Home Department, by various Scotch and Irish medical bodies, the commissioners were instructed

by him to take a law opinion from Her Majesty's Attorney-General as to the state of the law on the matter. The Attorney General, and Mr. Martin, (another Counsel who was consulted,) have stated it to be their opinion "that as far as surgery is concerned, those persons who have a *surgical* diploma, or degree, from a Royal College or University in Scotland or Ireland are (in point of law) as competent to be appointed and to act as medical officers, under the statute referred to, as the persons who have the diploma of the Royal College of Surgeons in London.

It is important to medical men to be informed, that, in consequence of this opinion, the Poor Law Commissioners have intimated their intention "to admit persons having a surgical diploma or degree from a Royal College or University in Scotland or Ireland, to the same rights under the Poor Law Amendment Act, as members of the Royal College of Surgeons of London, and to make such modifications in their general medical order of the 12th April [March?] 1842, as may be necessary for giving effect to the above recited opinion of the Attorney-General."

If not too long for insertion, it would be highly satisfactory to medical men to find published in full in your widely circulated Journal the letter of the Poor Law Commissioners of date 21 August, 1843, and the opinion of the Attorney General, dated August, 8th, 1843, which was circulated along with it.—I am, sir,

Your obedient servant,

MEDICUS.

Edinburgh, August 2, 1843.

STRICTURE OF THE RECTUM.

To the Editor of the Medical Gazette.

SIR,

A VERY melancholy case occurred at this place about ten days ago. A lady of rank was supposed to have stricture in the rectum. Her surgeon, after several attempts at different times, at length succeeded, as he thought, in passing the bougie through the obstruction, but instead of this he fairly ran the instrument through the gut, and death followed in about 24 hours!!!

The body was opened, and, as some predicted, no stricture (or any trace of disease) was discovered. This sad event has, as you may imagine, led to much discussion among medical men. Some maintain that there is no such thing as *simple stricture* of the rectum—that it is never seen amongst the poor (only among the rich, who can afford to pay for it), that it is never found on dissection, and that they doubt the accuracy of the statements they find in books, without impugning the veracity of the writers.

On the other hand, a few maintain that they have met with the disease, and cured it too. Now it would be a great satisfaction to know the opinion of your great London surgeons on this point. If there is such a disease, some of them must have met with it in their extensive practice, and it must have been often seen in the dead-rooms of the different hospitals.

The rectum was greatly *patronised* in this city some years ago, and it is still a favourite with one or two surgeons, who doubtless find it a fruitful source of income.

I am, sir,
Your obedient servant,
A SUBSCRIBER.

Bath, Aug. 25, 1843.
[The above is authenticated.]

SYDENHAM'S WORKS.

To the Editor of the Medical Gazette.

SIR,
I BEG to call your attention to an advertisement on the sheet of your excellent journal, by the honorary secretary of the Sydenham Society, of the 25th of August, announcing editions of works shortly to appear, the first of which seems to be in Latin.

"1st. A complete edition of Sydenham's Works in Latin, by Dr. Greenhill, of Oxford."

With all due deference and respect to the proceedings of the Council of the Sydenham Society, I beg to remind them that, should this edition be published in Latin, as announced, without an English translation, it will not be read or appreciated by far the greater portion of the more practical members of the profession, from want of time and classical knowledge. An English translation would be far preferable to a Latin edition, and would better answer the good intentions of the society. With every desire for its substitution myself, I am, sir,

Your obedient servant,
A MEMBER OF THE SYDENHAM SOCIETY.

Heywood, Lancashire,
Sept. 2, 1842.

RECEIVED FOR REVIEW.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XLIII.

On Crural Phlebitis.

WHEN inflammation commences in the uterine branches of the internal iliac or hypogastric veins, it sometimes extends into the common, external iliac, and femoral veins, and thus gives rise to the swelling of the lower extremities, and to all the other local and constitutional symptoms of phlegmasia dolens, oedema lacteum, oedeme des nouvelles accouchées, dépôts laiteux, les infiltrations laiteuses des extrémités inférieures, hysteralgia lactea, or metastasis lactis. In the works of Hippocrates, Rodericus a Castro, and Wiseman, there are obscure notices of this disease. Mauriceau was the first author who pointed out distinctly its most characteristic symptoms. I have seen, he says, several women after being safely delivered, who have had their whole legs and thighs, from the groin to the side of the foot, sometimes on one side, at other times on both, remarkably swollen and oedematous. This accident, he says, often occurs after a sciatic pain caused by a reflux upon the parts of certain humours which ought to be evacuated by the lochia. "Cet accident survient souvent ensuite d'une douleur sciaticque causée par un reflux, qui se fait sur ces parties, des humeurs qui devoit être évacuées par les vuidanges, dont le gros nerf de la cuisse s'abreuve quelquefois tellement, qu'il en peut rester à la femme une claudication dans la suite, comme il est arrivée à une de mes tantes, qui quoiqu'elle fut très bien faite, and fort droite auparavant, est restée tout-a-

fait boiteuse d'une jambe depuis trente-huit ans par un semblable accident, ensuit d'une de ses couches." Mauriceau does not state that he ever saw the disease prove fatal, but he knew that it was dangerous when the pain and swelling of the limbs were great, accompanied with fever, difficulty of respiration, and much tension and soreness of the hypogastrium. When the swelling was slight and unaccompanied by fever, he knew that the affection was without danger, and would soon disappear by the use of diuretics. A far more full and exact description was given of the symptoms of crural phlebitis by Puzos, in two Memoirs, entitled *Sur les Dépôts Laiteux*, appellés communement *Lait Repandu*, in 1759. He states that it is a painful and protracted, and sometimes a fatal disease, and that it occurs most frequently about the twelfth day after delivery, though sometimes as late as the sixth week. He also observed that one limb only is at first affected, and that the pain and swelling commence in the groin and superior part of the thigh, and descend along the course of the crural vessels to the ham, and thence along the calf of the leg to the foot. He observed likewise that the disease sometimes attacked the other limb, and that it presented the same appearances as the first affected. The extent of the evil, he remarks, is readily recognised by a painful cord formed by the infiltration of the cellular tissue which accompanies the crural vessels. "Quand le dépôt laiteux se fait sur les extrémités inférieures (p. 345), il n'en attaque qu'une à la fois. Souvent le mal guerit d'un côté, pour passer ensuite à l'autre. La douleur et l'enflure commencent toujours dans l'aîne, and par le haut de la cuisse: le mal descend ensuite tout le long du cordon des vaisseaux; c'est à dire, qu'il s'étend de haut en bas; il gagne le jarret, le gras de la jambe, and vient se terminer au pied." At page 350 he says, again, "C'est dans l'aîne, et dans la parte supérieure de la cuisse, que le dépôt commence à donner des signes

de sa presence par la douleur que l'accouchée y ressent, et la douleur suit ordinairement le trajet des gros vaisseaux qui descendent le long de la cuisse; elle est même plus vive dans tout ce trajet. On reconnoit l'étendue du mal par une espèce de corde douloureuse que forme l'infiltration du tissu cellulaire qui accompagne ces vaisseaux; et l'enflure se joint presque toujours à la douleur." In the treatment of the disease, which Puzos considered to depend on metastasis of milk, he recommends repeated venesection, cathartics, and sudorifics, and various local applications, as fomentations and embrocations. The daughter in law of M. Clement, one of the most distinguished accoucheurs at the time, but an enemy to blood-letting in this disease, was attacked with pain in the thigh on the fifteenth day after a natural labour; violent fever and great swelling of the thigh speedily followed, and she died from the *dépôt lacteux*, as it was called, on the twentieth day after her confinement, and the fifth day of the disease. Puzos admits that this was not the only case he had seen which had terminated fatally, and that copious blood-letting was not an infallible remedy. "J'ai eu le malheur de perdre plus d'une malade, malgré toutes les saignées que j'avois pu faire: non que les saignées eussent été contraires; mais elles avoient été insuffisantes pour ces cas las, parceque le mal étoit plus puissant que le remède, and qu'il n'y en avoit pas d'autre."

Levret's description of crural phlebitis (1761), coincides in every respect with that of Puzos, and he refers the disease to the crural vessels, in so direct a manner, that it is wonderful some opportunity did not occur to enable him to discover its precise nature. When the disease attacks one side, a swelling more or less considerable, he observes, is felt in the iliac fossa. The cord of crural vessels is also painful through a great part of its course.

In a manuscript copy of Dr. William Hunter's Lectures, taken in 1775, no account is given of the disease; but from the following note written by Mr. Cruickshanks to Mr. Trye, at the time he was engaged in the publication of his work on the subject, it is evident that Dr. Hunter had seen cases of crural phlebitis, and was convinced that the opinions of Puzos and Levret respecting the nature of the disease had no solid foundation. "They have imputed the swelled leg, which happens after lying-in, to a *dépôt de lait*, but it is not; to something wrong in the constitution. The patient is first seized with pain in the groin; the pulse becomes smart, and the part becomes tender; the pain and tenderness get gradually lower down, and the muscles are stiffened into hard bumps, and an oedema frequently succeeds the inflammatory swelling. It is ge-

nerally called a cold, but it is not. In some it is over in a short time, in others it will last some months; it generally does well." In 1784, Mr. White, of Manchester, published an "Inquiry into the nature and cause of the swelling in one or both of the lower extremities, which sometimes happens to lying-in women;" and he suggested or adopted the opinion, that the disease depends on obstruction, detention, and accumulation of lymph in the limb, or on some other morbid condition of the lymphatic vessels and glands of the affected parts. He considered it to arise from some local accident during labour, and to be a purely local disease. Mr. White saw fourteen cases either during or subsequent to the attack; but as none of them proved fatal, an opportunity was not afforded him to determine the truth of his hypothesis by an examination of the actual condition of the different textures of the affected extremities. An Essay on the swelling of the lower extremities incident to lying-in women, was published in 1792, by Mr. Trye, of Gloucester, in which he referred the symptoms to rupture of the lymphatics as they cross the brim of the pelvis under Poupert's ligament. Six cases came under the observation of Mr. Trye, and in all recovery likewise took place. He clearly perceived, although he was unable to explain the fact, that an intimate relation subsists between uterine inflammation or puerperal fever, and the swelled leg of lying-in women. Dr. Ferriar soon after maintained, without furnishing the slightest evidence in support of his opinion, that there is a general inflammatory state of the absorbents in this disease. Dr. Hull, of Manchester, published, in 1800, an essay on crural phlebitis, which he called phlegmasia dolens, in which he showed that it was impossible to account for the phenomena on the supposition that the lymphatics were affected independently of a considerable primary affection of the sanguiferous system of the limb. He considered the proximate cause to consist in an inflammatory affection, producing suddenly a considerable effusion of serum and coagulating lymph, from the exhalants into the cellular membrane of the limb. All the textures, muscles, cellular membrane, lymphatics, nerves, glands, and blood-vessels, he supposed to become affected. The primary seat of the inflammation he believed to be in the muscles, cellular membrane, and inferior surface of the cutis; but it was a mere supposition. Dr. Hull thus describes the symptoms of the disease:—"It has in many instances attacked women who were recovering from puerperal fever, and in some cases has supervened or succeeded to thoracic inflammation. It not uncommonly begins with coldness and rigors. These are succeeded by heat, thirst, and other symp-

toms of pyrexia; and then pain, stiffness, and other symptoms of topical inflammation supervene. Sometimes the local affection is from the first accompanied with, but is not preceded by, febrile symptoms. Upon other occasions the topical affection is neither preceded by puerperal fever nor rigors, &c.; but soon after it has taken place, the pulse becomes more frequent, the heat of the body is increased, and the patient is affected with thirst and headache, &c. The pyrexia is very various in degree in different patients, and sometimes assumes an irregular remittent or intermittent type. "The complaint generally takes place on one side only at first, and the part where it commences is various; but it most commonly begins in the lumbar, hypogastric, or inguinal region, on one side; or in the hip or top of the thigh, and corresponding labium pudendi. In this case the patient first perceives a sense of pain, weight, and stiffness, in some of the above-mentioned parts, which are increased by every attempt to move the pelvis or lower limb. If the part be carefully examined, it generally is found rather fuller or hotter than natural, and tender to the touch, but not discoloured. The pain increases, always becomes very severe, and in some cases is of the most excruciating kind. It extends along the thigh; and when it has subsisted for some time, longer or shorter in different patients, the top of the thigh and the labium pudendi become greatly swelled, and the pain is then sometimes alleviated, and unaccompanied with a greater sense of distension. The pain next extends down to the knee, and is generally the most severe on the inside and back of the thigh, in the direction of the internal, cutaneous, and crural nerves. When it has continued for some time the whole of the thigh becomes swelled, and the pain is somewhat relieved. The pain then extends down the leg to the foot, and is commonly most severe in the direction of the posterior tibial nerve. After some time the parts last attacked begin to swell, and the pain abates in violence, but is still very considerable, especially on any attempt to move the limb. The extremity being now swelled throughout its whole extent, appears perfectly or nearly uniform; and it is not perceptibly lessened by an horizontal position, like an oedematous limb. It is of the natural colour, or even whiter; is hotter than natural, excessively tense, and exquisitely tender when touched. When pressed by the finger in different parts, it is found to be elastic, little if any impression remaining, and that only for a very short time." After describing the manner in which the constitutional and local symptoms subside, Dr. Hull further observes, that "hitherto the disease has been described as

affecting only one of the inferior extremities, and as terminating by resolution, or the effusion of a fluid that is removed by the absorbents; but, unfortunately, it sometimes happens that, after it abates in one limb, the other is attacked in a similar way. It also happens, in some cases, that the swelling is not terminated by resolution; for sometimes a suppuration takes place in one or both legs, and ulcers are formed, which are difficult to heal. In a few cases gangrene has supervened. In some instances the patient has been destroyed by the violence of the disease, before either suppuration or gangrene has happened."

It is a very remarkable circumstance in the history of crural phlebitis, that above a century and a half should have elapsed from the time when it was first clearly pointed out by Mauriceau, and the seat of the disease distinctly referred, at a later period, to the crural vessels by Puzos and Levret, before an opportunity was presented or embraced of ascertaining by dissection the precise nature of the disease. There had indeed been opportunities to determine the accuracy of the different hypotheses which had been advanced, but these had been neglected; and the seat of the disease in the crural veins, and its commencement in the uterus, were imperfectly understood before the year 1829.

In January 1823, M. Bouillaud related in the 2d vol. of the *Archives Générales de Médecine*, p. 188, several cases and dissections, in which the crural veins were obliterated in women who had suffered from a swelling of the lower extremities after delivery; and he distinctly stated that he considered obstruction of the veins to be the cause, not only of the oedema of the lower extremities in lying-in women, but of many partial dropsies. He has adduced various facts and observations in support of the opinion, that in many cases venous obstruction, and not general debility, is a common cause of dropsy. A woman, set. 20, was admitted into the hospital Cochin, on the 19th July, 1822, affected with tubercles of the lungs, and oedema of both lower extremities. She died in 45 days, and on opening the body a cancerous tumor was found in the pelvis, which involved the uterus, rectum, and the cellular tissue, and glands around. The hypogastric and iliac veins, which traversed this enormous mass, were obliterated by an old red fibrinous coagulum; the obliteration extended downward along the whole course of the crural veins, and upward into the vena cava, to the level of the right kidney.

Anne Vilard, set. 55, entered the same hospital on the 19th of November, 1822. She died 59 days after, from chronic peritonitis, cancer of the ovaria, and an encysted abscess in the left hemisphere of the brain.

The two inferior extremities were infiltrated. On examination after death, the crural, external, and common iliac veins, were obliterated, and rendered impervious by the presence of solid fibrinous coagula.

A man, æt. 60, was admitted on the 16th of April, 1822, with pleurisy and chronic peritonitis. The lower extremities were swollen, and the scrotum and trunk of the body soon also became infiltrated. The dropsy of the trunk disappeared, and the abdomen was seen covered with large veins. The patient died in 75 days, and on opening the body, the right kidney was found greatly enlarged, and affected with encephaloid cancer. The tumor lay over the vena cava, was filled up with a fibrous, friable, pul-taceous matter; the emulgent veins, the veins of the pelvis, and those of the inferior extremities, were equally obliterated by old coagula.

Virginie Aubert, æt. 21, much affected with ataxic, adynamic fever, of three weeks duration, entered on the 8th of November, 1822. The left lower extremity was at this time infiltrated and painful. She died in nine days, and on examining the body, the veins of the swollen limb were found obliterated by a long, solid, red fibrinous coagulum, which extended into the vena cava. The veins on the opposite side contained fluid blood.—The two following cases are examples of genuine crural phlebitis, or phlegmasia dolens, in puerperal women, and they are the first cases, I believe, that were ever published, in which the crural veins were examined after death. Elizabeth Perfu, æt. 38, was received into the Cochin Hospital on the 27th of April, 1822, two months after her delivery. She had tubercles of the lungs, and infiltration of the left inferior extremity. The body was in a state of great marasmus. The veins of the affected extremity were found after death plugged up with a very old, red-coloured, easily broken down, fibrinous coagulum, which extended into the common iliac vein, where its consistence diminished. The vena cava, and veins of the other extremities, contained more or less fluid blood.

Marguerite Colliere, æt. 30, was delivered by the forceps in the Maternité, about the end of January, 1822. She entered the same hospital on the 20th of March following, having the left lower extremity greatly swollen. She died on the seventh day after. On opening the body, an enormous abscess was found in the pelvis, which appeared to have commenced on the left side of the cavity, before and within the psoas muscle. All the surrounding parts were extensively disorganised, and softened like lard. The veins of the swollen extremity, without excepting the great saphena, were obliterated by a solid, fibrinous, friable coagulum.

“It is known,” adds M. Bouillaud, “that infiltration of one or both of the lower extremities is not unfrequently observed in women recently delivered, and that in the bodies of those who die, the crural veins are obliterated; compression and inflammation are the causes to which he attributes this. On sait qu’il n’est pas rare de voir l’infiltration s’emparer de l’un ou des deux membres abdominaux chez les nouvelles accouchées. Eh bien ! on trouve sur les cadavres de celles qui succombent, des obliterations des veines crurales. Les 5^e et 6^e observations que j’ai rapportées en fournissent des exemples. MM. Chaussier, Meckel, Travers, en ont recueilli de semblables.”

An Essay on the proximate cause of the disease called Phlegmasia Dolens, by Dr. David D. Davis, was read to the Medical and Chirurgical Society, May 6th, 1823, and subsequently published in the 12th vol. of the Med. Chir. Transactions. The following is the first case related.

“Caroline Dunn, æt. 21, of a weak constitution, was delivered of a male child on the 7th of February, 1817, after a severe labour of 27 hours’ duration. Some loss of blood was sustained both before and after the birth of the child. On account of the latter hæmorrhage, the placenta was removed artificially by the introduction of the hand into the uterus. On the following day the pulse was full, and regular at 90; the tongue was white, but moist, and there was a slight thirst. Pressure upon the abdomen occasioned no pain, but a soreness was felt in the vagina. During the days immediately succeeding, the symptoms were moderate.” On the 13th, the case was reported as follows. Slight fever; pulse quick and full; bowels costive; tongue white and dry; labia pudendi inflamed, swelled, and œdematous; some headache; respiration difficult; appetite bad; a copious yellow discharge from the vagina, having the consistence of cream, but without foetor.

17th.—The report was, better generally; discharge much decreased; inflammation subsided; bowels well relieved; pulse regular at 86; tongue natural in its appearance; thirst still great.

21st.—Much better; sleep good; sat up out of bed for four hours.

22d.—Better still; complained of slight pain, like cramp, as the patient herself expressed it, in the left leg.

26th.—Worse; left leg and thigh much swollen; pain in the inguinal region; skin hot; no signs externally of inflammation; no pitting on pressure; bowels costive; slight cough; respiration difficult; pulse very quick and small; headache.

Feb. 28th to March 2d.—No better; leg pitted on pressure; countenance depressed; languor; giddiness at intervals; pulse 80;

freedom from pain; no appetite; bowels twice relieved.

3d.—Total insensibility; limb equally swollen; countenance sunk; pale, and emaciated.

4th.—Died at noon this day. Mr. Lawrence examined the body on the 6th of March, 1817, and gave the following description of the morbid appearances. "The left lower extremity presented an uniform oedematous enlargement without any external discolouration, from the hip to the foot. This was found on further examination to proceed from the ordinary anasarcaous effusion into the cellular substance. The inguinal glands were a little enlarged, as they usually are in a dropsical limb, but pale coloured, and free from the slightest sign of inflammation. The femoral vein from the ham upwards, the external iliac, and the common iliac veins, as far as the junction of the latter with the corresponding trunk of the right side, were distended and firmly plugged with what appeared externally a coagulum of blood. The femoral portion of the vein, slightly thickened in its coats, and of a deep red colour, was filled with a firm bloody coagulum closely adhering to the sides of the tube, so that it could not be drawn out. As the red colour of the vein might have been caused by the red clot every where in close contact with it, it cannot be deemed a proof of inflammation. The trunk of the profunda was distended in the same way as that of the femoral vein; but the saphena and its branches were empty and healthy. The substance filling the external iliac, and common iliac portions of the vein, was like the laminated coagulum of an aneurismal sac, at least with a very slight mixture of red particles. The tube was completely obstructed by this matter, more intimately connected to its surface than in the femoral vein; adhering, indeed, as firmly as the coagulum does to any part of an old aneurismal sac. But in its centre there was a cavity containing about a tea-spoonful of a thick fluid of the consistence of pus, of a light brownish red tint, and pultaceous appearance. The uterus, which had contracted to the usual degree at such a distance of time from delivery, its appendages and blood-vessels, and the vagina, were in a perfectly natural state. There was not the least appearance of vascular congestion about the organ, nor the slightest distension of any of its vessels. Its whole substance was on the contrary pale, and the vessels every where contracted and empty. The state of the abdominal cavity and its contents was perfectly natural. That the substance occupying the upper part of the venous trunk, and the fluid in its central cavity, had been deposited there during life from inflammation of the vessel, does not admit of doubt." "I am

also," observes Mr. Lawrence, "decidedly of opinion, in consequence of its firmness, and close adhesion to the vein, that the red coagulum in the femoral vein was the result of a similar affection extending along the tube; and that the passage of blood through it in the whole tract submitted to examination must have been completely obstructed before death."

I have examined the preparation of the diseased veins, and there can be no doubt that the appearances here described were produced by inflammation of their lining membrane. If you look at the coloured engraving which accompanies the paper, and observe the thickened state of their coats, and the coagulum adhering to their inner surface, you will entertain no doubt of this. The greater part of the coagulum in the femoral vein is blood; it does not adhere to the lining membrane, but a coagulum similar to that in the common and external iliac is never seen but as the consequence of inflammation. No light is thrown by this dissection on the origin of the disease, and you might be led to infer from the observation of Mr. Lawrence, that the uterus and its appendages, and blood-vessels, were healthy; that the inflammation did not commence in the uterine branches of the hypogastric vein, or internal iliac; but it does not appear that the course of this vein was traced to its ramifications in the uterus, and unless the attention had been directed in a particular manner to the internal iliac vein, its morbid state might easily have escaped detection. Dr. Davis has also related the following case.

A lady died suddenly in the midst of apparent health on the 20th of September, 1819, in the sixth week after her second labour. The day after her delivery she was seized with violent peritoneal inflammation, the acute symptoms of which were subdued by antiphlogistic treatment. The febrile excitement was nevertheless not completely subdued, and ten days after she complained of a deep-seated pain in the groin, and along the tract of the great vessels of the thigh. The limb was observed to be swelled and exquisitely painful. By leeching and blistering, the new inflammation was speedily reduced, and in about a week from its commencement the swelling had entirely subsided, and the patient had recovered the full power of contracting and extending the extremity without suffering pain. From this period she recovered rapidly and satisfactorily. Her death took place instantaneously, whilst in the act of changing the recumbent for the sitting position, soon after dinner, and in a moment of slight excitement. The left external iliac vein, including about half an inch of the upper portion of its corresponding femoral vein, were found strongly attached by adhesions of its cellular

coat to the parts around. Its parietes still retained a morbid thickness, and its internal tunic was studded in several places with deposits of adherent lymph. The portion most remarkable for this incrustation, and otherwise most diseased, was the part of the vein immediately under Poupart's ligament. The tube of the vessel was still manifestly pervious, though it had suffered a diminution of capacity amounting to perhaps one half of its natural diameter. The inguinal glands were also diseased. The right iliac vein was also in a perfectly healthy state. These appearances have also been represented in this coloured engraving, and there can be no doubt that they are the result of inflammation.

A case of fatal phlegmasia dolens, which occurred to Mr. Oldknow, has also been recorded by Mr. Davis as follows. "Jane Elliott was delivered in September, 1820, having an easy and natural labour. Until the 20th day after the delivery she was doing well; on that day she was seized with a violent purging, for which astringents were given with success; but the pulse continued quick, and she had considerable fever; on the 30th day the purging returned, and the left lower extremity became swollen and painful, with considerable increase of fever. She died on the 34th day." On examining the swollen limb the day after her death, "I found the femoral vein," says Mr. Oldknow, "one-third down the thigh, and all the iliac veins much enlarged, and containing adherent layers of coagulated blood, similar to that found in aneurismal sacs, together with a sort of grumous fluid of a brown colour, more or less mixed with air, and almost obliterating the venous canals. The same appearances, but in a much less degree, extended along the vena cava as far as the entrance of the renal veins. The coats of the veins were highly inflamed, and intimately attached to the surrounding parts. The absorbent vessels and glands were slightly enlarged as high as the lumbar regions, but no otherwise affected. The uterus had regained nearly its natural size." The appearances here described have also been represented in this coloured engraving, and there can be no doubt that the veins were inflamed. A fourth case has been related by Dr. Davis. "Mrs. L——, a lady of a delicate constitution, and of a very irritable habit, was delivered of her fifth child on the 2d day of July, 1821. She had been subject to feverish affections in several of her former confinements. On this occasion she was doing well until the 7th day after her delivery, when she was taken out of bed and placed upon a sofa, between the fire and a large loosely hung window. In this situation she was seized with a violent rigor. During the gradual

development of the succeeding hot fit she experienced a pain of the left side of the chest, which increased rapidly in intensity. She was freely bled before I saw her, without experiencing adequate relief. She was afterwards bled, leeches, and blistered. The pain of the chest was then in a great measure subdued; but this flattering advantage was not accompanied by any material reduction of the attendant fever. The pulse, on the contrary, continued quick, and the general distress and restlessness were so little mitigated as to call for much sympathy, and to excite serious alarm. In the evening of the same day, unequivocal symptoms of phlegmasia dolens declared themselves. The patient died on the 23d of the month. The pleura costalis on the left side was found inflamed. All the surfaces and viscera of the abdomen were apparently in a perfectly sound state. The left lower extremity, from the hip to the toe, was considerably but not greatly enlarged, and there was an evident fulness of the labium pudendi of the same side. The iliac veins of both sides were unusually turgid with blood; but presenting no other external manifestation of disease. They were entirely free from attachments to the contiguous parts. The inguinal glands were certainly not diseased, nor even visibly enlarged. On making a careful incision into the left internal iliac, it was first found to contain a coagulum of blood of firm consistence; but not at that part adherent to the internal surface of the vein. Upon opening, however, the common iliac portion of the vessel, adhesion of the same column of coagulum had obviously taken place; an appearance which is now distinctly to be seen in the preparation. The left internal iliac was greatly inflamed, and its diameter was so much contracted by the morbid thickening of its parietes, that it was rendered almost impervious. The right iliac vein, including both its common and external portions, was distended with a similar coagulum; or rather the same coagulum was prolonged over the angle of their common junction with the vena cava, from one iliac to the other." These appearances have also been represented in this coloured engraving. From these cases Dr. Davis inferred that the proximate cause of phlegmasia dolens is a violent destructive inflammation of the iliac veins and their contributory branches, including in some cases the inferior portion of the vena cava. "The principal veins of the pelvis are necessarily exposed to great pressure," he says, "from the uterus during the latter months of gestation. A well-known effect of this pressure is a varicose dilatation of the superficial veins, together with oedema of the lower extremities: a state of the limbs indicative, in the opinion of practical writers, of a predisposition to phlegmasia dolens."

"Phlegmasia dolens," he adds, "is a disease which almost always occurs in an excited state of the organs of circulation, and when that is not the case it is known to take place during a period of predisponency to inflammatory action of the great blood-vessels within the pelvis, and their immediate ramifications. Hence its occurrence after labours and miscarriages, before the perfect re-establishment of the balance of the circulation; and at those time more particularly after profuse hæmorrhages, or during phlegmasia of other parts; or from the application of occasional causes of whatever kind which may have the effect of exciting a febrile disturbance in the system. All the veins liable to much pressure, or to enlargement of diameter during pregnancy, appear to be more or less predisposed to inflammation upon the sudden removal of those agencies by the consummation of the act of parturition. Hence the predisposition to hysteritis and peritonitis during the first week after labour, and to the swelled leg, and to mammary abscesses, at a more advanced period."

For six years after the publication of these cases by M. Bouillaud and Dr. Davis, there was perhaps no subject on which a greater difference of opinion prevailed than on the pathology of phlegmasia dolens; and many remained in doubt whether these cases should be considered as examples of genuine phlegmasia dolens, or be viewed as essentially different diseases, and analogous in their nature to those formidable attacks of phlebitis which sometimes succeed to venesection and wounds. In opposition to their views, it was forcibly urged, that if phlegmasia dolens depended on inflammation of the iliac and femoral veins, the majority of those affected with the disease would die; whereas death does not take place in one case in a hundred where that disease is distinctly marked. Even that distinguished anatomist and pathologist, Mr. Lawrence, who had examined the first fatal case which occurred to Dr. Davis, and whose history of the morbid appearances threw more light on the nature of the affection than all the hypotheses that had previously been advanced—which were mere speculations, unsupported by facts—declared in the Medical and Chirurgical Society, as late as 1828, that he was fully convinced, from what had subsequently fallen under his observation, that Dr. Davis's views were incorrect, and that phlegmasia dolens did not arise from inflammation of the iliac and femoral veins.

In the next lecture I shall relate to you the cases, and exhibit the various preparations and drawings, which appear to me to demonstrate, not only that inflammation of the iliac and femoral veins gives rise to all the phenomena of phlegmasia, but that, in

puerperal women, it originates in the uterine branches of the hypogastric veins, and subsequently extends from them into the iliac and femoral trunks of the affected side.

SPIDERS DISCHARGED FROM THE EYE*.

HYSTERIC MONOMANIA.

By A. LOPEZ, M.D. Mobile, Ala.

I WAS requested, on the 5th of February, 1840, to visit a young lady, from whose mother I received the following statement:—The patient had left the city of Charleston, S. C. (at which place I then was), to visit a friend who resided in the country. On the night of the 29th of January, while conversing in bed, she was sensible that some object had fallen from the ceiling of the apartment, upon her cheek, just below the inferior lid. This caused her to apply the hand briskly and forcibly in order to brush off what she supposed to be some one of the many insects so common in country houses, upon which the friend with whom she slept observed, that, as the room was much infested with spiders, it was probable that the object which had fallen was one of them. In the course of the night she was awakened by a feeling of intense pain in her left eye, which continued at intervals until morning, when, upon examination, the eye was discovered to be highly inflamed and lachrymose. Ordinary domestic means were applied, and during the morning, feeling an intense degree of itching and irritation, she rubbed the lids together upon the ball and removed two fragments which were readily recognised as the dismembered parts of a spider. Her alarm in consequence became very great, and was much heightened when the same thing was repeated in the afternoon. She left for home and arrived in Charleston on the 2d of February. During the voyage her mind was much perturbed and under considerable excitement from the event, and when I paid my first visit on the 5th, the date mentioned in the early part of my statement, the following was her condition: the right eye unaffected; the left turgid, inflamed, and weeping; and there had been removed from it, that morning, a spider, imbedded in a mucous covering. It was entire with the exception of two legs. The two preceding days before I had seen her, three others had been removed; and were now exhibited to me. I immediately submitted the eye to as close an examination as the irritable condition of

* From the American Journal of the Medical Sciences—July 1843.

the parts permitted, without being enabled to discover the minutest portion of any foreign substance. In order, however, to combat the pain and inflammation, I ordered leeches, saline-antimonial medicines, and evaporating lotions. I thenceforward visited her daily until the 19th, and at every visit I removed either an entire or dismembered spider from the same eye. Before proceeding it will be well to mention that during the interval between the 5th and 19th, I invited, to an examination of the case, Professors Geddings and Dickson, and Doctors Bellinger and Wurdeman. Dr. Dickson on one or two occasions also removed these objects from the patient's eye. I made, assisted by Professor Geddings, the most minute scrutiny with a view of discovering—first, whether there could possibly exist a nidus within the orbit for these animals; secondly, whether a sac containing their ova was there concealed; and, thirdly, if any communication between the eye and nose could account for their appearance. For these purposes, the superior and inferior palpebræ were everted with great care, traversed thoroughly with a blunt probe, and afterwards I threw injections around the internal lining, but all to no avail. The anterior and posterior nares were closely examined by strong light, both of the sun and candle, yet we could not perceive the slightest trace of any means by which either ova, insect, or nidus, could be retained.

The sensations always precursory to their removal were: a sense of burning in the ball, a pricking of the superior lid, proceeding more or less severely around the orbit, until it assumed a fixed pain within the lower lid, upon the eversion of which, by myself, if present, or her mother, in my absence, the spider, always dead, would be discovered enshrouded in its mucous bed, and removed by means of the finger or probe. I now resume the order of their discharge. From the 19th they were removed from both eyes, and so continued until the 23d, when again they became confined to the left, and afterwards from each eye alternately until the 5th of March, when a truce was had until the 10th. During this interval, the eyes resumed their normal condition, but again on the 10th the inflammation was renewed and the discharge of spiders recommenced, the right eye being now chiefly the depository. Up to the date, during which time my visits were unremittingly made, none other than general observations were kept, but, the spider-making power appearing so inexhaustible, a more circumstantial diary was thought necessary.

March 10th.—Two spiders.

11th.—Two. Pain over right orbital region, passing gradually over the frontal

sinus to the left. Sharp pricking pains upon pressure.

12th.—Previous to my visit, one from the left eye, which was much less inflamed than the right.

13th.—Eyes much improved in appearance. One discharged since my last visit, and another just previous to my departure this morning. As this discharge served greatly to perplex the views at which I shall arrive before I conclude this paper, it may not be irrelevant to notice it. I have mentioned the scrupulousness with which the eye and its appendages were examined, in order to elicit, if possible, any clue by which to unravel this enigma, and the fruitlessness of those exertions. It appears, then, that on the day of this visit (the 13th) a spider was removed before my arrival. A servant was despatched for it to a neighbour's whither it had been sent for examination. Some time elapsed before her return, during which time I sat in such a relative position to the patient as to preclude all possibility of deception, and I had this day, as was my wont at every visit, made a careful examination of the eye without discovering a vestige of any kind of substance. Upon the return of the servant I arose to depart, at which moment the patient complained of pain, and, in a few seconds, by turning down the lid, I removed another spider.

15th.—Eyes extremely healthy and clear. On the 13th, just after my visit, the mother removed three spiders, two entire and one broken; also a putrid substance, the precise nature of which I could not define. No others discharged to date.

17th.—None since the 15th. Right eye more affected; upper lid much irritated and swollen. Left eye healthy.

18th.—Right eye still inflamed—discharged a portion of web from the inner canthus.

19th.—Eyes the same; another piece of web.

20th.—Eyes perfectly natural. After my departure on the 19th, there was removed a sacculus containing ova.

27th.—None since the 20th until to-day. The left eye being inflamed and painful she was advised by a friend to insert an eye-stone, which, at its exit, protruded one spider of the long-legged kind, entire.

April 6th.—None since the 27th ultimo. Eyes healthy, and generally improved in their appearance.

13th.—None since the 6th. Eyes healthy; has used them since my last visit, in sewing and reading without inconvenience.

May 14th.—None since the 13th of April. Eyes healthy until a few days past; to-day they are weak, lachrymose, and slightly injected. They however improved under remedial measures, and the case terminated.

The total number of spiders removed from the commencement were between forty and fifty. During the progress of this very singular case, the treatment was regulated according to the greater or less degree of local or general disturbance. The patient was restored to good health, and continued so uninterruptedly to the date of my leaving Carolina, in November 1840.

I have presented the facts as succinctly as possible, and here, perhaps, in the opinion of many, it should rest; but other considerations may offer themselves to warrant a further notice. They are these: 1st, a case so anomalous and of so unusual occurrence, could not well exist, without necessarily exciting an intense degree of public curiosity, and, in fact, becoming, as it did, a subject of general notoriety and discussion in the various public presses of the union, all of which, however, were strictly unprofessional, as this is the first entire and correct statement yet made on the subject by myself. 2dly, the character and respectability of the patient as well as her mother, being familiarly known to me for many years, preclude the remotest suspicion of any desire to impose, or to acquire a spurious notoriety on the part of the daughter, or of the countenance of fraud by the mother. 3dly, the pathological history of the patient, which I will proceed to give, and which has induced me to distinguish this case as one unequivocally of Hysteric Monomania.

In adopting this rationale I am of opinion that I conform more strictly to the category within whose scope are embraced so many equally singular and otherwise inexplicable perversions of the nervous system, and under the influence of which the most remarkable anomalies have been produced. I, moreover, am disposed to regard it rather as a melancholy, though interesting feature of disease, than a subject of levity to be classed among the nine-day wonders of every day report. The patient from her childhood exhibited a due inheritance of that temperament, which became more strongly developed at that age, which, in females so strikingly calls into action the consentaneous play of every nervous affinity. The establishment of the catamenial period corresponded with this complication. Her natural disposition was variable, at times cheerful, sometimes gloomy, but more commonly timid and reserved.

In 1839 I attended her for an attack of chorea, during which many peculiarities were observable, and a few months preceding the invasion of the case now under consideration she was under my care for a neuralgic affection, terminating in a tremulousness of her upper extremities corresponding with what Good in his *Neurotica* recognises as

"*synclonus tremor*," except that here the morbid action is exhibited on attempt at voluntary motion, whereas in this case it was independent of such causes. In the presence of these facts, to wit, the entire confidence entertained not only by myself but all others, in the strict veracity and irreproachable integrity of the parties; the predisposing and salient qualities in the idiosyncrasy of the patient, and the indisputable, though too frequently unexplained effects resulting from a morbid condition of the nervous system,—effects impressing their astounding influences not only upon the physical but also upon the psychological nature of man,—can we, without becoming amenable to the charge of an indifference incompatible with the proper spirit of inquiry which is so peculiarly the province of medical philosophy, refrain from devoting a little time to the investigation of this case.

Previously to any considerations touching the mental agency involved in this history, I will refer in abstract to a few instances, which, if not even in strict analogy, are nevertheless not devoid of interest, either as objects of science or curiosity.

1. In the "*Mémoires de la Société Médicale*," (Année 5me, p. 181,) M. Silvy relates a case in which an immense number of pins and needles were swallowed, and their exit from parts remarkably singular. These were doubtless swallowed under an erratic condition of the mind.

2. In the *Med.-Chir. Rev.* vol. ii. No. 22, Oct. 1825, p. 559, will be found the extraordinary "*Copenhagen Needle Case*," in which it is stated that a young woman from Aug. 1807 to Dec. 1823, discharged from nearly every part of her body 400 needles. This case is reported conjointly by Professor Heckoldt and Dr. Otto. In 1825 she was living and in good health in Frederick's Hospital, at Copenhagen. No account is given by which we are to infer that so immense an amount of needles were accidentally introduced, and the presumption is legitimate that they were either swallowed or thrust in under a state of mind beyond the patient's control. These are instances which would seem to owe their existence to influences such as constitute the pathological features of the case under review. They are only a few from the many with which medical history abounds. Nor are these records silent with regard to insects and larvæ being discharged from the human body, and from places so unusual as to excite surprise; and while I refer to a few of the most prominent, I do not conceive their characters parallel with my case, because in the former there are palpable grounds for explanation, whereas, in the latter, there is one of two modes alone, by which to obtain a solution,—either gross

fraud and premeditated concert, or a morbid condition dependent upon extreme exaltation of the nervous system. I will, nevertheless, briefly condense a few of the cases referred to.

In 1828, M. Cloquet reported to the Philomathic Society of Paris, the case of a rag-gatherer who in a state of intoxication laid himself down to sleep near some dead horses. He slept for twenty-four hours. On awakening he felt as if he were swelled out with much unusual pain. On his return home, a number of blisters arose about his head, and worms crawled out of his nose and ears, and other natural openings of his body. He went to the Hospital St. Louis. More came from his head when the swellings were lanced. His skin produced them every instant. The nurse collected three plates full. The conjecture was that the flies from the dead horses laid their eggs in the pores of the man's skin during sleep, as well as in the natural openings of his body, and that warmth hatched the eggs which produced the worms."—*American Journal of Medical Science*, No. 3, May 1828, p. 228.

Animals are frequently found in situations of the human body, for whose location it would be difficult to account. The doctrines of equivocal and spontaneous generation have been taxed through all the bearings, and still leave us as much benighted as ever. I will merely refer to the several authorities, and give their cases in brief. Worms in active motion under the conjunctiva. Blot, of Martinique, removed by incision two from a similar position in the eye of a negress. They were thread shaped, 38 millimetres long, with a black protuberance adapted for suction. The worm lay on the outside of the eye, and sometimes turned around a portion of the cornea, causing stinging pains and nervous symptoms from fear. The patient, an African, was unable to give any account of herself, or the liability of her country people to this disease.

Bajou, of Cayenne, in 1768, observed a worm in serpentine motion in the eye of a negress; upon incision being made it removed, but was secured by forceps and dislodged. He saw another case in 1771. (*Am. Journ. Med. Sci.*, May 1840, p. 194.) The *LOND. MED. GAZ.* Aug. 1833, records a case of a little girl, ætat. 6, under whose conjunctiva, and resting upon the sclerotica, there was found a *cysticercus cellulosa* perfect in all its parts.

Some years since the *Baltimore Sun* related the case of an insect resembling a snake in the eye of a horse. It grew in two months from a half inch to three and a half or four inches in length. It moved with great rapidity, and incessantly.

Dr. Yule, in the *Edinburgh Philosophical*

Journal, July 1825, p. 72, records cases of insects in the human stomach:—One, of a countryman, from whose stomach, after several weeks of intense suffering, there was ejected a large hairy caterpillar, supposed to be of the common dragon fly. The opinion is, that it must have lived several weeks in the stomach, and grown to its full size.

Dr. Reeve mentions the fact of larvæ inhabiting the human stomach. He cites a case, where the larvæ of the *musca domestica*, or common house fly, were voided by a girl.—*New England Med. and Surg. Journal*, Jan. 1821.

Kirby and Spence relate a case where several beetles were vomited by a boy.

In the *Amer. Journ. Med. Sci.*, No. xlii. Feb. 1838, p. 473, will be found a case of a beetle discharged from the urinary bladder.

It now remains to attempt some explanation as to the means by which the spiders obtained their "local habitation" in the eyes of my patient. As might be supposed, conjectures were not idle, and the reasons assigned assumed their complexion in proportion as the credulity or scepticism of individuals prevailed. Those who yielded to the first, of course resorted to the intervention of miraculous agency, while the latter class believed it to be an artful endeavour to impose upon the community. I need not reiterate how unjust and unphilosophical such suspicions must appear under the historical features of this case. The only attempt to explain it by a natural and direct probable cause, was published by a Mr. Meddler, of Erie, Pennsylvania. In a letter addressed to the postmaster of Charleston, he gives the natural history and habits of the wood spider, which, he says, unlike the rest of that class of insects who propagate their young from eggs, "bring them forth in perfect form," and the female carries them about, attached to the extremity of the tail. Mr. Meddler thinks, therefore, that it was one of this class which fell upon the young lady's cheek, and that the effort to brush it off separated the young from the point of attachment, upon which they took different directions, some into the eyes and others into the nostrils, whence they "could easily pass" to the eyes, and become killed there by the touch. He also thinks that the spiders discharged from the eyes "were at different stages of maturity, and not of different species."

Now, Mr. Meddler errs in every particular. The wood spiders "bring forth their young in perfect form." We have shown that one of the articles removed on the 20th March, was a sacculus containing ova. Again, his idea of their passage into the eye at the moment of accident is disproved, because I have stated the extreme care with

which I repeatedly examined that organ and all its appendages; and surely if the extraordinary number discharged from first to last had been lodged therein, they could not have escaped observation. They were not in the nostril, for I have also said that due exploration was there made: moreover, the communication between the nose and eyes, even in a healthy condition, could not possibly have admitted the passage of bodies as large as many of these spiders were, much less under the high state of inflammation and swelling in which they were almost constantly found. Lastly, Mr. Meddler, deriving his history of the case solely from newspaper reports, originating with persons unacquainted with its character and progress, errs in thinking that the spiders were only "at different stages of maturity," and not of different species. The spiders removed from the eye were subjected to close microscopic examination by myself, assisted by several professional gentlemen accustomed to scientific investigations, among whom was the Rev. Dr. Bachman, whose reputation precludes all doubt, and we discovered at least three different species, distinguished by the anatomical classification of Latreille, Walkenar, and Hentz. But even supposing them to have been lodged "in perfect form," the fact that they were subjected to a residence in depraved secretions unfit to preserve the lives of insects, forbids the belief that they could have reached the different stages of size and maturity which they presented; much less so, then, could we suppose them to have been hatched by incubation either in the eyes or nostrils. I am, then, constrained to discard from my mind the presumption that they were lodged and perfected previously to their discharge, or that they were placed there by the patient in a healthy condition of feeling and with a desire to impose.

The only suggestion left for my adoption is this,—that from all the preceding history of my patient, there existed a want of nervous integrity, so operating upon the mind as to produce the form of disease which I have distinguished in my text as hysteric monomania; and I am induced to think that the various types of mental irregularities, which an unbalanced nervous system is so familiarly known to produce, sustain the belief. It is needless on this occasion to investigate the diversified operations of the human mind in its physical and pathological relations, or to refer to the multiform phases it is capable of assuming under the excitement to which it is subjected by the agents which are perpetually at work upon its impressionable nature; suffice it to say, that the history of the different forms of insanity, from the highest degree of concentrated fury

to the most subtle shade of the mind's day-dream, present arguments and examples sufficiently numerous to render my view of this case at least plausible.

At the incipency of the case, I do not for an instant doubt the presence of those fragments of spiders, and perhaps one or two entire; but my opinion is, that subsequently, terror, superinduced upon the idiosyncrasy described, dethroned the judgment; hallucination usurped its seat; a morbid concatenation was excited, and the patient under the control of this influence was urged irresistibly to introduce them from day to day, until the morbid series was exhausted. I cannot express myself more forcibly than by adopting the language of M. Ollivier, addressed to the court at Paris, in behalf of a young girl arraigned for the murder of an infant. She confessed to have given it ten pins to swallow from time to time. M. Ollivier said, "he was inclined to attribute the present act to one of those unaccountable perverse impulses which are not unfrequent in certain females, more especially about their menstrual periods." (*Lancette Française*, 1839.) M. Dupuytren says, "I have seen at the Hôtel-Dieu a great number of women and children, who had been affected with the strange mania of swallowing pins and needles." He then gives the case in detail, and concludes by saying, "on examining the body after death, several hundred pins and needles were found scattered through the viscera, muscles, cellular substance, &c."

I will, lastly, merely refer to that extraordinary form of insanity described in the *Journal de Progrès*, for 1828, under the title of Periodical Vino-Mania. It is reported by M. Pierquin who says, "The disorder commenced fifteen years ago in the shape of an irresistible impulse to swallow wine day and night without the possibility of satiety. The paroxysm lasts from two to three months, with an interval of equal duration, when it returns again without any prodrome that might indicate its approach."

I here close this case, extraordinary in its character under any aspect, and if my view of it be a correct one, it will afford another to the many which are to be found in nearly every work professing to analyze the yet inscrutable character of the human mind.

Mobile, Ala., April 26, 1843.

N.B.—The spiders are in my possession, and were exhibited with a statement to the Medical Society of this city.

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

(For the London Medical Gazette.)

I.—Obliteration of the cavity of the Tunica Vaginalis Testis in middle and aged persons.

DURING the last eight or ten years, I have remarked, in the dissecting-rooms I conduct, four or five cases of obliteration of the cavity of the tunica vaginalis testis, unconnected, so far as we could ascertain, with any operation or accident. In these persons the cavity was generally entirely obliterated; but without any other morbid appearance either in the testicle or in the cord. The tunica vaginalis itself could be forced from off the testicle by dissection; and near the parietal portion it resembled common cellular tissue, but shewed no traces whatever of its having ever been inflamed.

In mentioning these cases during my lectures on the anatomy of textures, I have generally taken occasion to say, that I agreed with Baron Portal, and some others, in the theory, that adhesions of serous membranes, so extensive as entirely to obliterate their cavities, may take place altogether independent of inflammation; and that I felt assured that I had seen this twice happen to the serous cavity of the pericardium. In quoting Portal's opinion as coinciding with my own as to the real nature of such adhesions, I do so from memory, having failed in recollecting the particular part in the Baron's voluminous works in which he mentions this doctrine.

II.—On a Congenital Deformity of the Head and Neck of the Femur.

In 1827, I published in the Transactions of the Medico-Chirurgical Society of Edinburgh, the brief history of a case in which, as it appeared to me, there had existed from infancy, perhaps even congenitally, a shortening of the neck of the thigh bone, with *sessile* head, and a general shortening of the whole extremity: as a consequence of

this change upon the femur, the head of the bone was depressed as low at least as the level of the trochanter major. The particulars of the case, in so far as they require to be detailed here, were simply these. A child about two years of age, and of a suspected scrofulous constitution, died in consequence of an extensive inflammation of the right pleuræ, producing empyema. But although the child was suspected to be of a scrofulous habit, we found nothing in any of the textures confirming this opinion, excepting a slight tubercular appearance in the left lung.

Whilst examining the body of this child in order to ascertain the cause of death (which we have seen to depend on the state of the left pleura), I observed that one of the limbs was obviously shorter than the other, and suspecting that there existed some disease in the hip-joint, leave was got from the parents to examine the joint; they assuring me, however, at the same time, that the child had never walked lame. On cutting into the joint every texture was found to be healthy, shewing no appearance whatever of diseased structure; but the neck of the femur had almost entirely disappeared, and the head of the bone, *sessile*, was on a level with the trochanter major. The specimen bore a very great resemblance to those described by Mr. Benjamin Bell, Sir A. Cooper, and others, under the name of interstitial absorption of the neck of the femur, and which had been so often mistaken for fracture of the *cervix femoris*, followed by osseous union.

Of the nature of this change upon the neck and head of the femur there have been held several opinions: some, as Beclard, considering the change to be the effects of age; others ascribing it to chronic rheumatism; and some, as Mr. Gulliver (in an excellent memoir published in the Edinburgh Medical and Surgical Journal, for July 1836), viewing it as a change in the structure of the bone, to be traced, in some instances at least, to a direct injury inflicted on the joint by a fall. The object of the present brief notice is not, however, to discuss the causes which may give rise to a shortening of the neck of the thigh-bone with occasional alteration of its cartilages, which causes may even be more

various and obscure than is at present supposed, but to submit to the medical world a second case, in which, as it seems to me, the shortening of the neck of the femur, and greatly altered form of the head of the bone, was a *congenital malformation* altogether independent of any accident, or of any diseased condition of the bone, or its investing cartilage.

A strong muscular young person, who had died of acute pericarditis, was brought into the dissecting-room. The body, remarkably well formed in other respects, shewed this peculiarity, that the left lower extremity was obviously about half an inch shorter than the right. The limb could be moved freely in most directions, and had evidently been used equally with the other during life; but it could not be abducted so freely as the right leg, and when flexed, so as to allow the dissector to dissect and examine the perineum, the heel interfered considerably with the view of the left side of the perineum; the foot, in fact, projecting in front of this region in such a way as to conceal it to a great extent.*

On observing these facts, I drew the inference, that the hip-joint could not be altogether sound, and that the neck of the femur, more especially, could not possibly be so long as that of the opposite side. A careful dissection of the joint shewed that every structure was healthy, but that the head and neck of the femur presented the appearance delineated in the figure: the

head was sessile, and had descended to a level with the trochanter; the cervix femoris was greatly shortened, but in all other respects the bone and joint generally were perfectly healthy: the opposite femur had the usual form in persons of this age.

Some may be disposed to think that there are no proofs adduced here of this being a congenital malformation, and I admit that after perusing Mr. Gulliver's accurately detailed cases of a similar change in the form of the femur seemingly produced by violence, the proofs I have to offer in favour of my own opinion are far from being convincing; but still, on reviewing the whole case, and the appearances on dissection, comparing it with that of the child of two years old, and of Sandifort (referred to by Mr. Gulliver), I feel much inclined to adhere to my first opinion, viz. that occasionally there is met with a congenital malformation of the femur in one or other limb, such as I have described.

It ought to have been added, that the left os innominatum partook of the change, being obviously weaker in its pubic portion than the corresponding bone of the opposite side.

I find that I ought to have added to the above brief notice, the condition of the skeleton of this person generally, and the texture of the left femur. Now in regard to the first, it appeared healthy throughout; and in respect to the second, it was found that all trace of epiphysis in the femur had disappeared: the intimate texture was white, firm, and, as appeared to me, remarkably dense and solid.

Observations on the muscle of the lachrymal sac, or tensor tarsi.

My attention to this muscle, as a part distinct from the orbicularis palpebrarum, was, with most anatomists I presume, first directed by Dr. Horner, of Philadelphia, about the year 1821. On re-examining the muscle at that time, it appeared to me—1st, that many would be disposed to view the tensor tarsi merely as a more or less detached portion of the sphincter. 2dly, What was most evident to myself, its anatomy had not been given correctly by Dr. Horner. From that time to the present I have often had occasion to repeat these remarks, but did not deem

* In other words, when placed in the usual position for performing the operation for lithotomy, the left foot lay in front of the perineum in such a way as to conceal the left side of the region from the dissector.

the matter worthy further notice. Lately, however, I observe that a very distinguished oculist and surgeon, Dr. W. Mackenzie, of Glasgow, has reviewed the matter in an historical point of view, contesting the discovery of the muscle with Dr. Horner, and restoring it to Du Verney, to whom the merit of having first described it evidently belongs. This called my attention again to the muscle; and as both the descriptions of Du Verney and of Dr. Horner are inaccurate, conveying to the student of anatomy and physiology a false notion of the shape, extent, uses, and connection of the muscle with the orbicularis, I have thought it worth while to submit the following brief observations.

In 1805, Rosenmüller gave a drawing of the muscle, and a method of dissecting it. There can be no objection made to his method of display, but the drawing is very imperfect. He recommends the eyelids to be cut from the edge of the orbits, and laid down over the nose; and of course towards the opposite side: the membrana nictitans comes in view, which is then to be dissected off; below it will be found a quantity of fat, cellular substance, and nervous filaments, with a firm though delicate fascia of cellular membrane covering the surface of the muscle. On removing this with the scalpel, a muscle of the size stated by Rosenmüller comes into view; it arises as if fleshy, and at once from the back of the os unguis, or where that bone meets the orbital plate of the ethmoid, and proceeding forward and outward (but forward and inward as looked at during the dissection), soon divides into two portions, proceeding to the inner surface of the tarsal cartilages. Now instead of stopping at the puncta lachrymalia, as described by Rosenmüller, and as is represented in his drawings, and as is described, I presume, by most anatomists of the day, the bifurcated muscle runs on quite to the opposite extremity of the eyelids, thus doubling that part of the sphincter coming from the upper and lower part of the tendo oculi, and forming in itself the more immediate and most powerful part of the sphincter of the eyelids. This at least is what I have often seen.

By this arrangement the sphere of action of the muscle, when fully deve-

loped, is much more extended than is generally supposed. It supports the eyelids, draws them forcibly towards the inner canthus, and in the most efficient way, being bound down by cellular substance to the lachrymal sac, retains the eyelids in apposition to the eyeball, which no part of the orbicularis, as it is now arranged, could have done. Relaxation of the eyelids may depend, I imagine, on a relaxed condition of this muscle; and that peculiar and contracted condition of the eyelids, which every surgeon must have observed in some persons subject to ophthalmia with inversion of the eyelids, in all probability may depend occasionally on a spasmodic state of this muscle.

I ought to have added, that there is a very good description of the tensor tarsi in the French translation of Meckel's Anatomy.

ON VIVISECTION.

By ROBERT HULL, M.D.

(For the London Medical Gazette.)

I FIND a recent author, who is in every respect to be treated with attention—from his honourable personal character and his didactic position—making the following excuse for the infernal practice of vivisection; *videlicet*—

“The surgeon's hand becomes tutored to act with steadiness, while he is under the influence of the natural abhorrence of giving pain to the subject of experiment, and he himself is thus schooled for the severer ordeal of operating on the human frame.”

Now against such a reason for vivisection, I deem it a duty to enter a most solemn protest.

If young men are to learn steadiness of hand, whilst torturing animals, that they may be “schooled” to steadiness when they have to inflict pain on human patients, they become not surgeons but carnifices.

Is it meant that the tyro should vanquish his natural terror at pain-giving? or that, the terror remaining, the hand should get steady in spite of it? In either sense, *this* advocacy of vivisection is as unreasonable as it is unfeeling.

As to a victory over the natural ab-

horrence, the surgeon ought never to lose his sympathies; it is the feeling horror at the infliction of pain that induces him to master the science of anatomy, that he may cut his living subject as precisely and as quickly as he can. No superfluous incision; no protracted agony! His very sympathy with the *pained* victim tends to give him steadiness and dispatch. The softer his heart, the rapider his hand.

The most slow, nay bungling operators, that I have ever witnessed, have been cold-hearted, unfeeling men. They have carved and sliced the living organs, as they would the nonsentient corpse. Is not our natural abhorrence from giving pain implanted for reasonable purposes? Intended to make us treat others as ourselves would like to be treated? The more the operator *feels*, the more science, dexterity, dispatch, he will bring to the case of his fellow man.

"Natural," indeed, is our abhorrence, and this very circumstance might induce a tormentor to desist, and examine the propriety of his conduct. Considering this instinctive horror at mutilation as implanted by the great spirit of the universe for wise purposes, he might ask himself, when meditating torture, whether, in the particular instance, *sobriety* of views, a judicious selection of his miserable victim, an *imperative* demand on science, justify his process? No torture, save what is *needful*, can be approved by the great *Father* of his sensitive creatures. Is this or that particular experiment *needful*? If not, the manipulator is guilty of barbarity, of murder-like conduct. If needful, who is he that says so? The apprentice? The student? The young surgeon? The *unread* man? Prove, sirs, the *necessity*, before you dare to torture a being quite as deserving protection and happiness as yourselves!

If it be meant to say that no attempt should be made to eradicate our native tenderness; but that the sentiments subsisting, the mere hand should be made steady on the brute sufferer; such a disciple had better not aim at surgery; having commenced, he had best leave the profession. Nature has never intended him for it! Nature intends that steadiness of hand should result from clearness of head and benevo-

lence of heart; that we might master the studies, before we commenced the practice. His heart informs the surgeon of the great misery he *must* inflict; his head instructs him not to make it greater than needful; and in exact proportion as he is fitted by his anatomical skill, will he approach his patient with steadiness of hand. Conscious skill is the true source of steadiness; not the mere acquirement of a *habit* of bearing with callosity the cries of the wounded. If he cannot boast *this* steadiness, and still must cut, let him take to sculpture! In this art his slowest incisions will bring him nearest to humanity. The marble will do him credit; and he *may* come to be classed with Pygmalion, Canova, and Chantrey. To me it is not unquestionably established that any of the great discoveries in surgery have been *essentially* connected with vivisection: that the results could not have been worked out by other and innocent processes. But, admitting that the grand discoveries by unquestionable philosophers could never have been effected without animal agony, I protest most vehemently against the mutilation of God's *feeling* creatures by boys, by students, by unphilosophical hands.

The Earl of Carnarvon, in a speech at the last general meeting of the Royal Society for the Prevention of Cruelty to Animals, gave utterance to sentiments which do him infinite honour—which add immense splendour and richness to his coronet and ermine. Let the chirurgic operator peruse this speech, and subscribe to that society! Let him see how the world at large is opening its eyes to the practices of the cruel experimenters; nor fancy any longer that the frightful howlings of their pitiful victims are muffled within the walls of the anatomical slaughter-house! "I have," says this noble nobleman, "high professional authority for believing, that in an immense majority of instances those inhuman operations are performed for the sole purpose of illustrating what has already been established, or in an idle attempt to obtain results, which the extreme anguish and disturbances of system created in the unhappy victim by these operations, prevent men from attaining.

I do not wish to harrow up your feelings, or to work on them more than is necessary to impress you with the ne-

cessity of ultimately looking to legislative remedies for the correction of these monstrous abuses. Nor is it only for the sake of the victims that the legislature should interfere; they are bound to rescue the youth of England, who are intended for the profession of surgery, from such contaminating scenes; so horrible, that no religious parent could bear to see his child exposed to them.

I will read you a letter which comes from a distinguished gentleman of Germany. It refers to a work published a few months ago, alluding to a case of the kind I have just recorded, and which was justly stigmatised in one of our reviews as hellish."

[Here the letter was read, expressing abhorrence of vivisection, as pursued in England, and of the facts detailed respecting Sir Astley Cooper, in the *Life* recently published; concluding with Abernethy's opinion, that no medical man, who could be guilty of such practices to animals, was fit to attend a family.]

"Most fully do I coincide," said the feeling nobleman; most deeply do I coincide with him: and in language stronger than any which has been used, I fain would clothe my expressions. But what language can find a stronger term than "hellish;" and this is the language of the *Quarterly Review*; that glorious publication, which has always advocated the proprieties and virtues; which has thus openly declared itself against vivisection; and which cannot fail, supported as it is by writers of manly hearts and clear heads, to exhibit the zoicides to British scorn and horror.

The horrid practice of vivisection, according to one philosopher, is more important than common mortals can imagine.

"Shall it be said that the objects of physiological science are not worth the sacrifice of a few animals? Men are constantly forming the most erroneous estimates. Of what importance is it now whether Antony or Augustus filled the imperial chair? What will it matter, a few centuries hence, whether England or France swept the ocean with her fleets? But mankind will always be interested in the great truths deducible from physiologic experiments." Oh yes! The names of fiendish

vivisectors will be applauded when those of Antony and Augustus, Nelson and Wellington, are pronounced no more:—*but not till then.*

The vivisectors have never made out an undeniable justification of their revolting practices. Until they do, and on them lies the burthen, they have, whether or not they feel it, the settled dislike of mankind; nobody permitting to them the unproved boast—

ἐκ τῶν γὰρ αἰσχυρῶν ἐσθλὰ μηχανώμεθα.

Norwich, Sept. 1843.

DR. WIGAN ON TINEA CAPITIS.

To the Editor of the Medical Gazette.

SIR,

HAVING recently been in correspondence with Dr. Wigan on the subject of that obnoxious and very intractable disease, tinea capitis, he has favoured me with the following statement of the method he pursues.

Desirous that a mode of treatment professing to be uniformly successful, should be extensively tested, I have obtained his sanction to publishing his letter. Should it attract attention, he will, I have no doubt, furnish a fuller detail; but his present impression seems to be, that no one can obtain notice unless he possess a public appointment.—I am, sir,

Your obedient servant,

THOMAS WILLIS, M.D.

20, Old Steine, Brighton.
August 30, 1843.

Dear Sir,—To give a full answer to your queries as to my treatment of tinea capitis, would require a pamphlet instead of a letter—at least, if I were to enter into all the minute characteristics by which the disease is distinguished, the degree and mode of its propagation, and the combinations by which it is often mystified.

I waive, therefore, all these considerations for the present, and suppose the disease to be clearly recognised. When this is the case, I do not hesitate to say that there is no other mode of treatment which can be compared with mine for certainty, rapidity, and absence of collateral or consequent inconveniences, and I have seen, I believe, all modes, as well of the Continent, as

of Great Britain and Ireland. If any faith is to be placed in firm convictions, I am exempt from prejudice, but as this is every man's opinion of himself, I only put it forth (*quantum valeat*) as presumptive evidence that my mind was not lightly made up.

My plan, although never published (in the usual sense of the term), was made known by me many years ago to some hundreds of medical men in London and its environs; but I really believe that the absolute terms in which I spoke of instantly curing a disease which has for ages been the *opprobrium medicorum*, indisposed the great majority to put faith in my statements, and to give the plan a trial; because it sounded so like quackery.

My mode is this—

Unless the quantity of hair on the head is exceedingly small and offers no obstacle to the complete examination of the skin, I insist on the head being shaved very carefully, twice.

The reason is obvious: with a moderate quantity of hair you may be curing the parts which first attract notice, while others which have been infected are gradually progressing to a visible disease, and the cure is thus indefinitely prolonged. I do not, however, object to a little circlet of hair round the face, if there be no sign of disease apparent in it, and if it be carefully washed with hot common vinegar. This is a concession to parental vanity which may be safely made, and without which sometimes it would be impossible to obtain confidence.

My remedy is Beaufoy's *concentrated acetic acid*—pyroligneous acid, as it is still called—though no longer made from wood.

As a preliminary, however, I use the acid diluted with three times its weight of water. I call this the detector acid.

On its application a number of spots which looked perfectly healthy become red patches. They are indications that infection had been taken, but had not gone through its stages, which period I believe (after great experience), to be eight days. This assertion is not lightly hazarded.

Having by this reconnaissance ascertained the numbers and position of your enemy, your course is clear. One vigorous assault, and there is an end of

the matter. With a piece of fine sponge either tied to the end of a stick or held in a pair of silver sugar-tongs, I imbue each spot thoroughly with the concentrated acid for the space of three or four minutes, and the business is finished.

The only reason why it is necessary to see the patient again, is, that as a crust is generally formed, and an appearance of "worsening" takes place, the friends require to have their confidence renewed from time to time by explanation and encouragement. I have often applied the acid more than once, but it was always (I firmly believe) unnecessary, when the preliminaries above stated had been gone through properly upon the *shaved* and *tested* head.

The crust gradually grows up with the hair, which soon sprouts again if the eruption be recent, and as soon as a pair of fine scissors can be inserted underneath, it should be removed; but this should not be done prematurely, lest a sore place be produced.

When first proposed, a good deal of correspondence took place respecting the plan with those who had tried it without success. I found, however, that in *every case* they had either used a much weaker acid (it is sold of all strengths), or that they had continued the use of it long after the disease was cured, and thus produced that not very rare result, "*disease of the Doctor*." In the latter cases it was only necessary to discontinue the acid, and wash the head with warm water.

It is so difficult in the present day to attract notice to any plan of treatment, the result of common sense and experience, unless accompanied by a plausible theory, that I quite despair of obtaining attention, were I to publish my sentiments on this subject. I introduced nearly twenty years ago a German invention (if so simple a contrivance deserves the name), by which a man with broken leg is enabled the same day that it has been put into order to move in and out of bed without any assistance, and without the slightest risk of displacement. It is not adopted by any but those who have seen it in use; and to this day patients are allowed to linger weeks or months in the rheumatic gout, with frequent metastasis to heart, loss of its elasticity,

hypertrophy, water in the chest or pericardium, to terminate in a painful death, who might *not* have been cured in twenty-four hours by a remedy simple, safe, and *certain*, which I published ten years ago, and from the use of which no ill consequences have ever resulted.

Had I done nothing more for my fellow-creatures than this, I have not lived in vain. I consider that my mode of treating rheumatic gout, introduced after a long, careful, and discriminating attention, much thought, and cautious experiment, is as great a benefaction to society (compared with the smaller numbers of the sufferers) as vaccination itself.

This boast, which would have been indecorous and ridiculous while I was in practice, may be pardoned now.

No man can obtain attention in the present day unless he possess a public appointment, or be connected with a Medical School.—I am, my dear sir,

Yours very truly,

A. L. WIGAN.

The complications of tinea capitis with other diseases of the scalp produce a few and slight modifications of the treatment, especially the common eruption, porrigo favosa; but even this is often a very simple eruption, and will get well without aid.

ON

BRONCHIAL BLENORRHOEA, &c.

CONSIDERED IN CONNECTION WITH
RHEUMATISM.

By R. R. CHEYNE, SURGEON.

(For the London Medical Gazette.)

The metastasis of diseased actions is one of the most curious and interesting subjects that can occupy the attention of the practitioner of medicine, whether we view it by reference either to the treatment or to the pathology of disease. The primary seat of these phenomena may be noted in general terms, attributed to the operation of the various functions of the nerves, and to the sympathy, supposed to exist, between similar and different organs and tissues, but yet it must be admitted that the nerves which regulate such actions

from the most usual source of disease are in general the same.

Gout and rheumatism seem to be remarkably prone to transfer the morbid action in which they consist to the fibrous and mucous tissues, and the diagnostic powers we possess are often called forth to enable us to discover the real disease under the strange mask it assumes. Rheumatic affections of the fibrous tissues, such as those of the periosteum, pericardium, pleura, diaphragm, dura mater, and serous coat of the eye, are, it is well known, exceedingly common, both as primary affections and as the result of metastasis; and it is a well-recognized principle in practice that they require a mixed treatment, viz. that of rheumatism, combined with the antiphlogistic, when inflammation exists, which it must be borne in mind is here much altered in character by the rheumatic diathesis. My own opinion is, that the term inflammatory is often very vaguely applied to many of these affections, and that infinite mischief may be done in omitting to follow the indications afforded by their specific nature.

The latter remark will bear still more forcibly upon that peculiar irritation of one or more of the several tracts of mucous membrane which from time to time is set up, whilst the system is struggling (if I may use the expression) to throw off an attack of rheumatism or gout. The result of this struggle may be, in one case, the development of bronchitis; in another, of dyspepsia or diarrhoea; and in a third, of irritation of the genito-urinary mucous membrane. But, whatever the form of the secondary disorder, it must, if possible, be traced to its cause, otherwise the treatment we adopt cannot fail to be empirical and inefficient. It is not, however, always easy to unravel the intricacies of these perplexing cases, and it is fortunate that nature now and then gives us a broad hint, which serves to guide us out of the path of error, and directs us how to prescribe for our patient with the greatest precision and success.

The above remarks may properly introduce the subject of this paper.

My observation has been for some time directed upon a well-marked form of what may be called bronchial

Blenorrhœa, which is clearly dependent upon the metastasis of rheumatism, or, at least, upon the rheumatic diathesis, and which is as clearly unconnected with bronchitis. As this affection, as far as I know, has not been described, I will sketch a case which, in most respects, may be considered a type of the whole class; and, at the same time, I will point out the remedies which, in my hands, have been strikingly and uniformly beneficial.

CASE.—Mr. B., æt. about 60, a strong healthy man, whose occupation exposed him, for many hours daily, to a very high temperature, and subjected him constantly to profuse perspirations, became in June last affected with troublesome cough, without expectoration or dyspnœa. His pulse was natural, and skin cool; his appetite was deficient; he became weak and out of spirits, perspired profusely at night, and passed little urine, which was loaded with the lithates. At the end of a week he began to expectorate large quantities of muco-purulent fluid, without relief to his cough; he got weaker, and lost flesh; so much so, that his friends feared consumption, to which view of the case, however, auscultation gave the negative, inasmuch as, at first, no morbid condition whatever could be detected, and it was only when free secretion was taking place that rhonchi could be heard shifting about in every ramification of the air-tubes. Besides, percussion elicited a clear sound over the whole of the chest. Now, the treatment of this patient, during a fortnight, consisted in the application of a blister, the use of mild doses of mercury and ipecacuanha until the gums were slightly touched, and of occasional opiates at night to relieve the cough; at the same time the diet was strictly regulated. This plan, which was steadily pursued, failed in controlling the symptoms. My patient was then sent a few miles into the country, where I continued to visit him daily; and (as the enormous expectoration was producing great debility, and there was a total freedom from fever), I changed the treatment, and prescribed quinine with iron, and a liberal diet. Nevertheless, the disease still defied the remedies, after three weeks' duration. I must confess I was now puzzled, until one morning I found my patient complaining of an attack of severe pain in

the ankle-joint, which was not accompanied by either swelling or redness; and, in addition, I then learnt that he had been for a year or two occasionally subject to pain and slight puffy swelling of the right knee-joint, though never to the degree of confining him to his house. He now, also, recalled to mind, that he had felt great weakness in the knee, but not in the ankle, just before his present illness. These invaluable hints of the true origin of the complaint I was not slow to act upon. I at once ordered for him a pill composed of two grains of the acetous extract of colchicum, and three grains of the compound extract of colocynth, to be taken at night, as an aperient; and, in the course of twenty-four hours, a mixture containing of Iodide of Potassium ℥j., of liquor Potassæ, and Tincture of Henbane aa. ʒj. in Mist. Camph. ʒvj. He was also directed to place his feet every night and morning in a hot mustard and water bath.

In so short a period as three days, under these remedies, the bronchial blenorhœa was reduced to half its former quantity, and at the end of a week it had ceased altogether. Soon afterwards his cough left him; and his health and strength were rapidly restored.

Two facts may, I think, be fairly deduced from the history of this case; viz. first, that a peculiar irritation of the bronchial mucous membrane, with profuse secretion, constituting a distinct kind of bronchial blenorhœa, may be induced by the rheumatic diathesis; and secondly, that iodide of potassium (as in the above formula) is, undoubtedly, a medicine of astonishing power over this state of the mucous membrane. I may add, that colchicum, in my hands, has frequently proved to be of greatly inferior efficacy.

I can, certainly, come to no other conclusion but that the description I have given of the above disease cannot, with any regard to accuracy, be identified with that of any form of bronchitis, unless the latter term be used, without the least reference to the actual symptoms.

Having thus endeavoured to shew, by analysis, the existence of a rheumatic form of bronchial blenorhœa, I will now, in order to make the evidence as conclusive as I can, examine the subject, by a method

like that of sythesis, in briefly alluding to a class of morbid phenomena, often excited in another tract of mucous membrane; viz. the genito-urinary, which phenomena clearly evince the close connection that obtains between either irritation, or simple discharge from that membrane, and the development of rheumatism, in individuals who possess the rheumatic diathesis. For example, gonorrhœa, urethral blenorhœa, and even the irritation and discharge sometimes brought on by the passage of a bougie (as I have again, and again witnessed), may be excitants of rheumatism. Leucorrhœa, also, is often attended by the same complication, especially in the form of neuralgia, to which young women are extremely predisposed. Lastly, I may observe, that, for the supervention of rheumatism, it is by no means necessary that this irritation, and increased secretion, be of a specific nature, as in gonorrhœa. It was with reference to what has been named gonorrhœal rheumatism, that Swediaur*, who first noticed it, asks the question, whether in such cases, gonorrhœa is not rather arthritic than syphilitic; and I am, myself, almost disposed to agree with Richter†, and others, who attribute some forms of these discharges to transferred rheumatic action.

43, Berners Street.
Sept. 7, 1843.

TUMOR OF THE PHARYNX,

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the brief outlines of the following case sufficiently interesting, their insertion in your valuable journal will much oblige

Your obedient servant,
CHARLES DEAZELEY.

Late Demonstrator of Anatomy,
Westminster Hospital.

Mrs. H——, the wife of a military officer, having suffered for a long period from a dull aching pain in the head, extending down the neck to the chest, and often producing fainting and insensibility, requested me to examine her throat, as she said it was

becoming so narrow that she could neither breathe nor swallow without extreme pain and difficulty.

On examination, I found a tumor about the size of a small strawberry, which it somewhat resembled in appearance, growing from the back of the pharynx, about opposite the third cervical vertebra, and to a great extent diminishing the passage for the food to the stomach. When seized by the forceps, it felt firmly attached and unyielding, leading me to suppose that it originated from, or adhered to, the body of one of the vertebræ; it was evidently not a polypus, from the hardness of its structure, and the force required to move it with the forceps. I applied the lunar caustic to its surface for a few days, under the use of which it appeared rather to increase, and certainly to become much more painful. I then resolved to remove it *cum ferro*. Having the head made steady by the aid of an assistant, and depressing the tongue by means of a broad spatula, I was enabled to see the tumor distinctly, and with one sweep of a long bistoury to remove it completely from its attachment, which was done as nearly as possible to its connexion with the vertebra. It required considerable force to cut through the base, which communicated to the touch a sensation similar to that experienced when cutting through bone in a state of caries. The tumor, however, was not of the latter description, but rather of a fibro-cartilaginous nature, with gritty particles of ossific matter developed in its interior. The operation caused but little hæmorrhage, and the application of the *argenti nitras* occasionally for a few days subdued the irritation and produced complete cicatrization. More than six months have now elapsed since the operation, and there is not the slightest appearance of the tumor returning. It is worthy of remark that prior to the removal of the tumor the lady suffered very often from fainting fits, for which every medicine prescribed was only of temporary benefit; but since, the fits or headache have not returned, and she enjoys excellent health, often facetiously amusing her friends by relating the anecdote of a doctor having cut her throat to save her life.

I think it very probable that the swooning and headache, which were

* *Traité des Mal. Syphilitiques*, tom. ii. ch. vii.
† *Chir. Bibl.* b. iv. p. 508.

always worse after eating, may have arisen from the pressure of the tumor, in the efforts to swallow, on the numerous filaments of the sympathetic nerve with which it must have come in contact. It is true, the difficult respiration might account for the other symptoms, and *vice versa*. Certain it is, however, that since the tumor has been removed the paroxysms have ceased.

MEDICAL GAZETTE.

Friday, September 15, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

A LATE INQUEST IN THE NORTH.

WE have been favoured with copies of the Carlisle Patriot and the Carlisle Journal of the 2d instant, both giving an account of an inquest held just before their publication, at Beaumont, near Carlisle. So great an interest has been excited by this inquiry that the Patriot devotes eight columns to its report, and the Journal five. This interest is of a medico-political stamp. It appears that a feud has long raged among the practitioners of Carlisle, and the grave of James Clark is the battlefield of the contending factions.

The mere dry facts, or skeleton of the case, are as follows.

James Clark, a countryman, æt. 50, was admitted an out-patient of the Carlisle Infirmary in October 1842. On the 14th of December, he was made an in-patient, and was discharged January 11th, 1843. He then returned to Beaumont, his usual residence, where he remained without advice till the month of April. He was then attended by some practitioners from Carlisle (not those of the Infirmary) grew worse and worse, and died August 25th. He was buried on the 27th; on the 28th his grave was just opened, so that the jury might take a

glance at his body, for form's sake; and the inquest was held on the 28th and 31st. The jury found that the deceased had laboured under rheumatism and disease of the hip-joint; that he had died of the latter; and that he had been properly treated.

So much for the broad features of the history, which we give to serve as a general guide to what follows; the interest of the case depends, of course, on the minuter and more controverted facts.

James Clark, when admitted as an out-patient, was labouring under rheumatism and disease of the hip-joint. But though *morbis coxarius* was set down by Dr. Barnes, his physician, as one of his diseases, its symptoms do not appear to have been very prominent; had they been so, indeed, it is reasonable to suppose that the patient would have been placed under the care of the surgeon of the hospital, rather than the physician. During Clark's attendance as an out-patient, he was bled, cupped, blistered, and rubbed with tartar emetic ointment, and took a dose of Epsom salts and one of Dover's powder. A mixture of spirits of turpentine was also given internally. During this period of eight weeks the patient used to go from Beaumont to Carlisle once a week in a cart, and return the same day. Had his disease been in an advanced stage this would have been impossible.

He was now admitted into the Infirmary, where he remained four weeks.

The ticket placed at the patient's bed-head, on which the prescriptions were entered, has not been preserved; but the Physician's Register, kept by the House-Surgeon, contains the following abstract of it.

"1843, No. 8. James Clark, aged 50, married; residence, Beaumont; occupation, labourer; date of admission, Dec. 14, 1842; date of discharge, Jan. 11, 1843; disease, rheumatism,

&c.; relieved; treatment, quinine, cupping; subscriber's name, Mr. Thurnam."

Besides the treatment mentioned in this abstract, Clark took calomel and Dover's powder, and the house-surgeon thinks he also had blisters.

While Clark was in the Infirmary, repose was not insisted upon. Dr. Barnes desired him to keep his bed a good deal; but as he said that the heat of the bed increased his pain, he was allowed to sit up. As Dr. Barnes found neither enlargement of the hip-joint, nor matter in its cavity, nor ulceration of the cartilages, he allowed the patient to walk about. Clark liked to walk about, though it gave him pain to do so. Was this permission to walk warrantable? *Judicent peritiores*. The witnesses against the Infirmary doctors lay much stress on perfect rest as the most essential part of the treatment of *morbis coxarius*. The authorities are, no doubt, with them; yet there are exceptions to this great rule. Thus, when delivering the treatment of inflammation of the synovial membranes of joints, Sir Benjamin Brodie says, "The chronic inflammation is relieved more slowly. In the first instance the joint should be kept in a state of perfect quietude."

But soon after we read, that "when the inflammation is in great measure relieved, a moderate degree of exercise of the joint is beneficial rather than otherwise*."

Whether the disease, in Clark, had reached this favourable turning-point, may, of course, be a matter of doubt. Another question which, if solved, would throw light on this difficulty, is the one, was Clark relieved when discharged from the Infirmary on the 11th of January? Had the four weeks' walking in the wards of the Carlisle Infirmary made him better or worse?

There is plenty of evidence to show that he was better, some to show that he was just the same, none to say that he was worse.

All the formal or official evidence goes to prove that he was better. The Physician's Register, as we have seen, says "relieved." Mr. Page, surgeon to the Infirmary, deposes that Clark, on his discharge, said to the Committee that he was much better. Mrs. Masterman, matron of the Infirmary, says, "he thanked me for my attention, and very grateful he was. He expressed himself as better. I think he was better. When he first came, he required help to get up the steps; when he went out, he had only the aid of his sticks. He was less lame than when he entered. I used to say to him he altered as the weather altered."

Grace Reay, who was a nurse in the Infirmary when Clark was an in-patient, deposes, that when he left he told her he was much better than when he came.

John Davidson, a pensioner, and an intimate acquaintance of Clark, used to conduct him to the infirmary as an out-patient, helped him up the stairs when he was taken into the house, and received him when he came out. Clark told Davidson that he was much better when he left the infirmary than when he went in. "He was not so much better as he would like."

John Graham deposes, that when Clark came out of the Infirmary he said he was easier.

The Rev. Robert Robinson, the clergyman of the parish, deposes that thanks were returned in the church for the relief obtained by James Clark in the Cumberland Infirmary. Moreover, Clark attended church once or twice after being at the Infirmary, and told Mr. Robinson that he thought himself a little better.

The parish clerk deposes that he got the paper (of thanks) which he gave to

* *Pathological and Surgical Observations on the Diseases of the Joints*, 2d edit. pp. 35 and 37.

Mr. Robinson, either from Clark or his wife.

Per contra there are four witnesses. The first is the widow of the deceased, who deposes that when he left the Infirmary he did not feel himself any better; and that he informed her that he had told Dr. Barnes that he did not think he had got any benefit, and might as well go home as not.

Secondly, James Sewell, of Beaumont, farmer, deposes that he saw Clark shortly after his return from the infirmary, and he was much the same as when he went. "Some of our folk told me (I was not there myself) that James Clark had returned thanks in the church to Almighty God for being relieved at the infirmary; and I was uncommonly hurt at this, because he was not a bit better."

When this honest husbandman was told that returning thanks was only a form, he replied: "let us be duin with forms and ceremonies, and give us the reality o't thing." He adds, in his evidence, that Clark "was not a stroke better when he returned from the infirmary."

It is impossible not to sympathize with this sturdy Cumbrian farmer in his contempt for shams and flams; let us hope that the coming age may be blessed with many such reformers!

Thirdly, Thomas Todhunter, who lives in the village of Beaumont, and was a near neighbour of Clark's, saw him on the night of his return from the infirmary, and he was no better than when he went.

Lastly, John Hodgson, surgeon, of Carlisle, was told by the deceased that the doctors of the infirmary had done him no good.

How shall we balance this conflicting evidence? Probably, James Clark, when he left the infirmary, was substantially in the same condition as when he entered it; yet for a day or two he might enjoy sufficient ease to

give him the hope of recovery. In a genial or polite moment he might return thanks to his doctors; in his candid hours (no longer a hero to his *valet de chambre*) he might confess that he had not improved, and might exclaim, as he did, while an out-patient, to frank farmer Sewell, that "there was no betterness for him in this world."

The remainder of the history we must dispatch briefly.

We do not hear anything farther of the progress of the case until Easter Sunday, when he was seen by Mr. Hodgson.

On that day Clark hobbled after him on two sticks, said he was rapidly getting worse, and that he would be glad if Mr. Hodgson or any of his medical friends could do anything for him.

On the 27th of April, Clark was visited by Dr. Jackson and Mr. Elliott, of Carlisle, and he was seen again by Mr. Hodgson in the beginning of May. "He was in bed: there was a large abscess discharging from the front of the thigh—the limb was shortened an inch and a half. There was great pain on the slightest motion. Matter was spreading among the muscles of the thigh, so that when the lower part of the thigh was pressed, matter came out at the anterior and upper part of the thigh."

About this time a seton was put in his groin, and pus was freely evacuated. "Many gallons of matter ran from the wound," says his wife; meaning, of course, during the seventeen weeks that the patient was confined to his bed. After his discharge from the infirmary, he was not seen by any of the medical officers of the institution, excepting on the day of his death, by the house-surgeon.

It would be difficult to affirm that the treatment of Clark in the infirmary was the most vigorous that the case admitted, *especially now that we know its subsequent progress.* It would be

still more difficult to conclude that the treatment was very bad, considering the age of the patient, and want of prominence in the symptoms; and also recollecting that he went out at least as well as he came in; but it would be most difficult, and almost impossible, to believe that this inquest could have taken place, had it not been for the internecine war waged by the medical men of Carlisle. Whether it befits practitioner to pick holes so eagerly in the coat of his brother practitioner, we leave to the good sense and good feeling of our readers.

THE CARLISLE CONTROVERSY.

SINCE writing the above, we have received the Carlisle papers of Saturday, the 9th inst. We subjoin a couple of extracts; and, to make the matter clearer to our readers, we add the following elucidations.

The Infirmary at Carlisle was founded about two years ago, and at the present moment contains twenty patients. Dr. Barnes is the physician, Mr. Page the surgeon, and Mr. Burch the house-surgeon. In the present controversy, and, we believe, in the feuds which preceded it, the Carlisle Patriot has taken the side of the medical officers of the Infirmary, while the Carlisle Journal has espoused the cause of the critical lookers-on.

Mr. Steel, editor of the Carlisle Journal, is a governor of the Infirmary, and a chief promoter of the attack on the present officers.

The Patriot, on the other hand, calls the discontented practitioners "Medical Trades Unionists," and can see errors in them alone. The supposed facts, therefore, of the two journals, and the arguments built upon them, must be taken with some grains of allowance.

The first two extracts are from a letter by Mr. Steel to the Bishop of Carlisle.

From the Carlisle Journal of Sept. 9th.

"And first as to the inquest. It has been said that it was "an investigation without a parallel in this or any other country." If this had been an assertion founded in ignorance, the writer might have some claim upon our pity; but when put forth as a wilful perversion of well-known facts, loathing and contempt are the only feelings excited by it. Inquests on persons suspected to have "died of the doctor" are of common, almost every-day occurrence, as must be well known to every reader of the daily journals or works of medical jurisprudence. Then Mr. Nanson, who appeared before the coroner as the advocate of the governors—though what advocacy *they* required I am at a loss to conceive—appeared to think he had made a great point when Dr. Jackson and Mr. Elliott candidly admitted that *they* had called upon the coroner to hold the inquest; and I am aware that attempts have been made to treat this act of theirs as little less than a crime. My Lord, they who thus speak have surely forgotten all that has passed, or are wilfully blind to what has been passing under their noses. If Dr. Jackson and Mr. Elliot had not taken steps to call for an inquest, they must have been content to sit down under the stigma of having been accessory to the death of James Clark. At the public meeting of the governors of the Infirmary, held on the 1st of August, at which your Lordship so ably presided, Dr. Barnes made this statement:—

" 'It might well be said he (Clark) was relieved. When he came to the Infirmary he could not walk, but when he left it he could walk well. *He had since that been operated upon by other medical gentlemen*: when he left the Infirmary he was rapidly recovering, and walking about; but SINCE OTHER MEDICAL GENTLEMEN ATTENDED HIM, he was now in bed and in great danger.' "

From the Carlisle Journal of Sept. 9th.

"Three medical men connected with the infirmary were examined. Dr. Barnes, the physician, says Clark was labouring under rheumatism and disease of the hip-joint. Mr. Page, the surgeon, swears it was debility, rheumatism, and disease of the hip-joint. Mr. Burch, the house surgeon, looked upon it as rheumatism alone—he so records it on the only records kept, and

it appears never to have struck him that Dr. Barnes was treating the patient for anything else.—This is confirmed by the nurse, who says she applied blisters to the man's *knee* by Mr. Burch's direction. Mr. Page's evidence, to be sure, can go for very little, for he seems to be wonderfully oblivious of everything connected with the case. He might have seen him, or he might not have seen him—it is probable he saw him—it is probable he treated him—but he has no entry of him in his book. My Lord, is this the practice of the Infirmary, which gives the Committee "full confidence" in the "ability and attention" of their medical officers? A patient enters labouring under the most dangerous of all surgical diseases—and his case is never entered in the surgeon's book!

The patient says he was first seen by Mr. Page, who ordered him a blister on the *knee*, thus showing that he entirely mistook the nature of his complaint—and then turned him over to Dr. Barnes, the physician—thus affording another proof that he had either not examined the man as he ought, or that he was unable to distinguish between the cause of disease and its symptoms. Your Lordship will doubtless think this still more strange, after hearing Mr. Page declare that he (a young gentleman with a year and a half's practice) had seen "hundreds of cases of hip-joint disease"—a degree of good fortune to a practitioner which, I shall venture to say, was never enjoyed by Sir Benjamin Brodie himself, in all his long experience*. But the truth is, my Lord, Mr. Page's evidence proves nothing—except that he turned his patient over to his colleague as a *medical* case, and that his colleague immediately entered the man as labouring under a *surgical* disease!" "When I left I said to Dr. Barnes I think I'll go out, for I am getting no better, and if I was at home I could toddle about there. He said, well, if you think you are no better you may go. My leg was then as bad as ever. I thanked the gentlemen (committee) for their kindness. I got a paper from the committee to return thanks in church for being cured."

Mr. Gilkerson. — "I was in the

church, and heard the words 'thank either for being cured or relieved, I am not sure which.'

Patient.—"Miss Margaret Blamire called to see me after church-time, and remarked that it was odd I should return thanks for being cured, when I was no better."

Mr. Gilkerson.—"He was worse, and everybody remarked it."

From the Carlisle Patriot of Sept. 9th.

"We do not consider a general newspaper the proper medium for discussing a medical question, or we could multiply our quotations from authors of great authority to show, that, at the very least, 'doctors differ,'—but, in point of fact, we believe it will be generally understood from the evidence, that Clarke had for many years been labouring under chronic inflammation of the fibrous structures around the joint; for that there was no disease in the joint itself while the patient was in the Infirmary, is proved by Dr. Barnes and Mr. Burch, who rotated or moved the limb in every direction; and a part so labouring under chronic disease was more liable to active inflammation, which a fall or other accidental cause might set up, and which might, if unattended to, go on to the destruction of the joint. But be this as it may, we wish to press upon the attention of our readers a fact which we consider decisive as to whether Clarke's case was best understood by the officers of the Infirmary, or by Dr. Jackson and Mr. Elliott—and it is this, that the treatment adopted by Dr. Barnes aimed at *relieving* the patient, and it succeeded in accomplishing that result; but the treatment adopted by Dr. Jackson and Mr. Elliott, which also aimed at relieving the patient, did not succeed in affording him any relief, as it is distinctly stated in evidence that poor Clarke said that he never knew what pain was until subjected to the treatment they adopted.

But there remains another interpolation in the *Journal's* report, of still greater importance. With a desperate determination to save the 'Medical Trades' Unionists from the odium to which they had subjected themselves, the reporter for the *Journal* has appended to the verdict of the jury a statement that "the jury were unanimously of opinion, that the treatment of Dr. Jackson and Mr. Elliott was

* Why should Mr. Steel limit Mr. Page's experience to the year and a half that he has been surgeon to the Infirmary? He must allow him the cases which occurred at the hospitals where he learned surgery.—*Ed. Med. Gazette.*

correct, and all that could be done for him under the circumstances." This admits of but one sort of contradiction. It is a deliberate and desperate falsehood. No such statement was made in the court; and we have ascertained, on inquiry, that no such opinion was ever expressed, or meant, or intended to be expressed by the jury."

INFLUENCE OF THE SEASONS.

THE results to which the foregoing facts and reasonings lead may be briefly stated as follows:—

1. The amount of sickness in the central districts of London during the year 1842 varied directly as the temperature, being a maximum in August, the hottest month of the year, and a minimum in January, the coldest month.

2. The diseases which determined the order of sickness were febrile and catarrhal affections, the contagious exanthemata, and the disorders of the digestive organs; to which may be added, the mixed group, consisting of gout, scrofula, &c.

3. The diseases of the organs of respiration followed the inverse order of those already mentioned, and were inversely as the temperature, being most numerous in the colder, and fewest in the hotter months.

4. The temperature did not appear to exercise a marked influence on the other classes of disease: with the exception, perhaps, of those which form a measure of the activity of the sexual passion, which were in excess during the hottest months of the year—a fact which corresponds with, and corroborates, our experience of the influence of the seasons on crimes against the person, &c.

5. The hygrometric state of the air appeared to have little effect on disease, and if it produced any effect it was on the diseases of the organs of respiration, which were in excess during the months in which the quantity of moisture in the air was the greatest; but these were also the coldest months.

6. The mortality for the metropolis during the year 1842 was greatest in the first quarter, and least in the second, and was inversely as the sickness, except that the mortality of the third quarter exceeded that of the fourth.

7. The diseases which chiefly influenced the order of the quarters in respect of mortality, were those of the chest; to which may be added, as following the same order, the decay of nature in the aged. It is well known that the most common cause of death in the aged is an affection of the lungs, called "bronchitis senilis."

8. The order of the seasons in respect of sickness and mortality differs year by year, and does not admit of being reduced to any precise rule.

9. As a general rule, but one admitting of many exceptions, it may be stated, that the amount of sickness tends to vary directly, and the amount of mortality inversely as the temperature.

These results must be received with some reserve, as they are founded on a comparatively small number of facts; but they are probably not very far from the truth. At any rate they may prove suggestive of future inquiries, founded upon a broader basis. At present the materials for a comprehensive theory of the influence of the seasons and weather upon sickness and mortality are wanting, and are not likely to be supplied till the example set by one or two public hospitals and dispensaries shall have provoked imitation. In the meantime the present attempt, if it accomplish no other purpose, may serve as an example of the mode by which such inquiries must be conducted.

In the course of this inquiry it is scarcely possible that some hypothesis should not have suggested itself as the most likely to prove true; and it may not be amiss to bring this attempt to a conclusion, by stating in few words that which I have been led to form.

The causes of sickness are twofold, consisting of atmospheric changes which may be submitted to measurement, and of certain more subtle changes in the composition of the air, which at present can neither be analysed nor estimated. To the former class belong the temperature, moisture, and pressure of the air; to the latter those emanations from the earth, or from human beings themselves, which give rise to the majority of epidemic, endemic, and contagious diseases. As the number of cases of sickness produced by these latter causes is generally considerable, the influence of the pressure, temperature, and hygrometric state of the air, will not be observed in those years in which these causes are in operation; but in the absence of epidemics, the temperature will be found to be the most influential cause of sickness. When the temperature of the summer is high, there will be such an amount of sickness in the summer months as to cause a large return of sickness for the entire year; so, on the other hand, a severe winter will swell the total sickness of the year, by producing a great excess of affections of the organs of respiration. A summer or winter of unusual length, beginning early and ending late, will also cause an increase of sickness on the entire year; but the nature of the sickness will be different as the temperature is higher or lower than usual. The order of the seasons in re-

spect of sickness will also be mainly determined by the degree in which the temperature of these seasons exceeds, or falls short of, the average temperature.

The mortality, in like manner, in non-epidemic years will be chiefly dependent upon the temperature, varying in the several seasons inversely as the temperature, except in those years in which the summer is unusually warm, when the mortality of the summer may even exceed that of the winter season. In other instances, the mortality of the summer months will rank next to that of the winter or autumn.—*Dr. Guy, in Quarterly Journal of the Statistical Society.*

ON THE PREPARATION OF HYDRIODIC ACID.

IN consequence of a remark made at a recent meeting of the Pharmaceutical Society, recommending the use of hydriodic acid in the manufacture of iodide of potassium, we have been applied to by two or three correspondents for a description of the best and easiest method by which this acid can be obtained. A correspondent, who writes from Birmingham, seems to consider the process an intricate and difficult one; but in this opinion we do not coincide, at least with reference to the liquid acid, which of course would be used in the case alluded to. The process recommended in most chemical books consists in mixing iodine with water, placed in any suitable vessel, and passing a stream of sulphuretted hydrogen through the liquid, until the whole of the iodine has disappeared. The sulphuretted hydrogen (H S) on coming in contact with the iodine, is decomposed, the hydrogen quitting the sulphur, which is precipitated, and combining with the iodine to form hydriodic acid (H I), which is held in solution. On heating the liquid to expel free sulphuretted hydrogen, and separating the sulphur by filtration, a colourless solution of pure hydriodic acid is obtained. There is, surely, nothing complicated in this process; it is a case of simple substitution.

In conducting the operation, there are two or three practical points to be attended to, on which the success and facility with which it is conducted will greatly depend. The iodine should be reduced to fine powder, by rubbing it down in a mortar, and in doing this it will be well to add a small quantity of the water with which it is to be mixed. The iodine (half an ounce) and water (eight ounces) are now to be placed in an open vessel, such as a beaker glass, or a cylindrical pint-measure glass, and a glass rod of suitable size provided, for the

purpose of agitating the mixture during the transmission of the gas through it.

It is necessary to have an abundant supply of the sulphuretted hydrogen gas, and the following is the best means of obtaining it:— In the first place, provide a gas generating bottle; a six or eight ounce wide-mouthed bottle, to which is fitted a cork with a bent tube of sufficient length to reach the bottom of the vessel containing the iodine, will answer the purpose. Into this bottle put an ounce or two of sulphuret of iron, in pieces about the size of a pea. The best sulphuret of iron is made by heating a bar of iron at a blacksmith's forge, to a white or welding heat, and while the iron is at this temperature, holding a stick of roll sulphur against the end of it, over a pail of cold water. The sulphuret and warm water enter into combination, and the resulting sulphuret flows in a state of fusion into the water. This sulphuret is an indispensable item in every practical laboratory, and some of it, as above directed, should be kept in a gas-generating bottle, ready for use. On pouring a few ounces of diluted sulphuric acid into the bottle, a copious evolution of sulphuretted hydrogen takes place, which is to be conducted to the bottom of the vessel containing the iodine and water, by means of the bent tube. As the gas is thus made to pass through the mixture, the iodine should be stirred up with the glass rod from the bottom. Notwithstanding this precaution, however, it will be found difficult to keep the iodine diffused through the liquor, for the sulphur, as it separates, forms a spongy mass, in which the iodine becomes enveloped, and shielded from the action of the gas. This constitutes a practical difficulty, and indeed the only one which occurs in the operation, as it becomes necessary to continue the transmission of the gas for a much longer time than would otherwise be the case.

It is very easy to obviate this difficulty, in making the hydriodic acid for the purpose we are contemplating, namely, the employment of it in the manufacture of iodide of potassium. Instead of mixing the iodine with the water, in which case the greater part of it remains undissolved, the four drachms of iodine should be mixed with six drachms of iodide of potassium, or a sufficient quantity of the solution of iodide of potassium under operation, so as to form a clear solution. On sending the sulphuretted hydrogen gas through this solution, the decomposition is effected in a very short time, and without the slightest difficulty, the acidification of the iodine being completed in about two minutes.

The completion of the process is ascertained by the entire discolouration of the

liquid; and this being effected, the gas-delivering tube is to be removed, and the acid being poured away from the remaining sulphuret of iron contained in the bottle, the latter will be for use on a subsequent occasion. We now have a solution of hydriodic acid mixed with iodide of potassium; and this may be used for neutralizing the alkalinity of the iodide of potassium liquor; while any remaining portion, not required for this purpose, should be saturated with potash, and then added to the other liquor.—*Pharmaceutical Journal*.

OPERATIONS FOR FISSURE OF THE SOFT AND HARD PALATE.

BY J. MASON WARREN, M.D.

THE form of operation which I have practised will be best illustrated by the relation of the first case in which it was put into execution.

The patient was a young man, 25 years old, with a congenital fissure of the soft and hard palate, the bones being separated quite up to the alveolar processes, with a deviation to the left side. On looking into the mouth, the whole posterior fauces were exposed, with the openings of the eustachian tubes and the bottom of the nasal cavity of the left side distinctly visible. The speech of the patient was rendered so indistinct by this misfortune, that it was with the greatest difficulty that he could make himself understood. Deglutition had always been imperfectly performed, liquids, particularly, being swallowed with much difficulty, and often regurgitated through the nose. At the first glance the soft parts were scarcely perceptible, being almost concealed in the sides of the throat from the action of the muscles. On being seized by a forceps they could be partially drawn out, though with great resistance. So far as any of the old methods were applicable to the relief of this extensive fissure, the patient was beyond surgical aid. I determined, however, to put in practice the operation which had before appeared to me practicable.

The patient was placed in a strong light, his mouth widely opened, and the head well supported by an assistant: with a long double-edged knife, curved on its flat side, I now carefully dissected up the membrane covering the hard palate, pursuing the dissection quite back to the root of the alveolar processes. By this process, which was not effected without considerable difficulty, the membrane seemed gradually to unfold itself, and could be easily drawn across the very

wide fissure. A narrow slip was now removed from the edges of the soft palate, and with it the two halves of the uvula. By this means a continuous flap was obtained, beginning at the roots of the teeth and extending backwards to the edges of the velum palati. Finally, six sutures were introduced, on tying of which the whole fissure was obliterated. The patient was directed to maintain the most perfect quiet, and to abstain from making the slightest efforts to swallow even the mucus which collected in the throat, which was to be carefully sponged out as occasion required.

The following day he was doing well. He complained of some pain or rather sensation of excessive emptiness of the bowels, which was relieved by the use of a hot spirituous fomentation. On the third day, a slight hacking cough commenced, owing to the collection of thick ropy mucus in the throat and air-passages. The cough was temporarily relieved by an injection of a pint of oatmeal gruel into the rectum; during the night, however, it again increased so much as to tear away the upper and lower ligatures. I now allowed him to take liquid nourishment, which at once quieted the irritation in the throat. The other four ligatures were removed on the following days; the last being left until the sixth after the operation. This patient returned home into the country at the end of three weeks, a firm fleshy palate being formed behind, and half the fissure in the bony palate obliterated.

In the following spring I again operated on the remaining fissure in the hard palate, and succeeded in closing about half the extent of it; the tissues yielding with some difficulty, owing to the inflammation caused by the former operation. The small aperture which remained I directed to be closed by a gold plate. His speech was very much improved at once, as well as the powers of deglutition, and he will no doubt, ultimately, as the soft parts become more flexible, to a great degree recover the natural intonations of the voice.

Since performing this operation, I have had occasion to repeat it in thirteen different cases, which with one exception have terminated successfully, either in the closure of the whole fissure, or of both hard and soft palate, or so far that the aperture which remained in the bones could be easily closed by an obturator fitted to the adjoining teeth. Some of these cases have been exceedingly interesting.—*New England Quarterly Journal of Medicine and Surgery*; and *Dublin Journal*.

A CAUTION RESPECTING NITRIC ACID.

We not unfrequently see prescriptions in which five or six minims of nitric acid are ordered for a dose, diffused in an ounce or an ounce and a half of fluid. This is a strong dose when the acid is of sp. gr. 1.4, as was the case with the acid generally used until lately. But since the publication of the remarks of Mr. Phillips on the subject, which drew attention to the fact that the acid ordered in the Pharmacopœia is of sp. gr. 1.504, the manufacturers have supplied the article according to the correct standard; and the circumstance not having been sufficiently made known in the medical profession, patients have sometimes suffered from the inconvenience of taking a dose considerably stronger than was intended. In such cases we conceive it to be the duty of the pharmaceutical chemist to impart that information to the prescriber which shall enable him to regulate the dose accordingly.

The maximum dose of acidum nitricum dilutum is stated in the Pharmacopœia to be forty minims (equal to four minims of the strong acid); and we have no hesitation in stating that this quantity is quite sufficient, *unless largely diluted*, to act injuriously on the enamel of the teeth. On reference to some other authorities, we see the dose of strong nitric acid stated as "from five to ten minims;" and on this account might have felt a delicacy in animadverting on the subject, if we had not repeatedly heard serious complaints from patients. An instance lately occurred in which six minims were taken in an ounce of fluid, three times a day. In the course of two or three days the teeth were found to be seriously injured, to the great annoyance of the medical attendant, who was not aware that he had ordered more than might be taken with perfect safety. In all cases in which it is desirable to administer large doses of this powerful acid, care should be taken to dilute it sufficiently, and the patient should be directed to rinse the mouth with water, or a solution of carbonate of potash, immediately after having taken each dose. These precautions should never be neglected, by those who consider the preservation of a good set of teeth of any importance.

We may also observe, that the strong nitric acid should never be used in dispensing in small quantities, as it is impossible to measure a few minims with so much accuracy as a proportionate quantity of the diluted acid.

Nitric acid of sp. gr. 1.504, always contains a considerable portion of nitrous acid, which gives it a pale yellow colour. The

action of light and air occasions the liberation of oxygen, and the consequent conversion of a further portion of nitric into nitrous acid. According to M. Millon this is the case, more or less, with commercial nitric acid of all densities, but more particularly when highly concentrated; consequently, the Acidum Nitricum P.L. is not a convenient preparation for general use, and should be kept in the dark, and not unnecessarily exposed to the action of the air by the frequent removal of the stopper.—*Pharmaceutical Journal*.

FLUID EXTRACT OF SENNA.

By PROFESSOR CHRISTISON.

TAKE fifteen pounds avoirdupois of Tinnevelly senna, and exhaust it with boiling water by displacement: about four times its weight of water is sufficient. Concentrate the infusion in vacuo to ten pounds; dissolve in the product six pounds of treacle previously concentrated over the vapour-bath, till a little of it becomes nearly dry on cooling; add twenty-four fluid ounces of rectified spirit (dens. .835); and, if necessary, add water to make fifteen (16 oz.) pints—the object being that the preparation shall be of such strength that every fluid ounce shall correspond to one avoirdupois ounce of senna. Mr. Duncan, of Edinburgh, generally makes eighty pounds of senna into this extract in one operation. The numbers given are those by which he worked in the first instance. The dose is two drachms for an adult; it very rarely causes griping. It tastes precisely like treacle, and the absence of disagreeable taste is owing to the fact that pure senna has but a feeble mawkish taste, which treacle easily covers.—*Pharmaceutical Journal*.

ON ROARING IN THE HORSE.

I FIND in my own practice, says Mr. Webb, and in that of others, so few cases of roaring successfully treated that, perhaps, it will not be deemed presumption on my part if I send the account of one in which I have been fortunate.

The patient, a thorough-bred chestnut stallion, was considered to be entirely useless, on account of his being a confirmed roarer. The sound was occasionally so loud that his master was ashamed to be seen driving him, and requested me to do what I could with him.

Upon careful examination of him, the seat of disease seemed to be confined to the larynx. The treatment which I adopted was

to have the compound iodine ointment well rubbed into the throttle during three months.

I am glad to say that the roaring has entirely ceased. He is used in harness, and to ride; and not the least noise can be heard.—*Veterinarian*.

NEW HERNIA KNIFE.

DR. T. CAMBELL STEWART has described in a late number of the "American Journal," a new form of knife for the purpose of dividing the stricture in cases of strangulated hernia, and said not to be open to the sources of danger attending upon the employment of the instruments commonly in use; he particularly advocates its use in cases of inguinal and crural hernia. The knife consists of a small convex blade concealed in a hollow canula, presenting at half an inch from its extremity a notch of about two lines in length, and one line deep, for receiving the membranes which constitute the structure; the opening is closed at the top by a steel blade, presenting at one end a small shoulder, and at the other a wire spring concealed in the handle. The knife, small and convex, is strengthened by a shoulder on either side, projecting a little higher than itself, and protecting its edge from contact with the canula.

The instrument is directed to be used in the following manner:—

So soon as the sac constituting the hernia shall have been laid bare and opened, the canula containing the knife is to be introduced flat, between the intestine and the stricture; so soon as it has entered, the instrument is turned, so as to bring its upper surface in contact with the part to be divided, and then pushing gently and cautiously onwards: after penetrating a short distance, its further progress is arrested by a small shoulder, the blade of which, however, being terminated by the spring, yields to continued pressure so far, and so far only, as may be necessary to admit the constricting membranes. These being now engaged in the excavation, the knife is made to move forwards and backwards by pushing and withdrawing a button placed beneath the handle, with the index finger of the right hand, so as to incise as much of the membranes as may be thought necessary to permit the reduction of the hernia. The structure may be thus divided, above, below, or on either side of the intestine.

SCENES ON THE NIGER.

WE were soon at Bullock's island, and about nine we reached its upper extremity. The island seemed to be swamped throughout. An egret and a few other birds were the

only living things appearing on it. A short way above this a human body was seen floating downwards with the stream; on coming near to it, we found the face downward, the nates and abdomen distended, the viscera of the latter protruding; the hands and feet seemed blanched; the back appeared as if it had been scorched. A band ornamented with beads crossed the loins, and a cincture round the head was similarly adorned. At twelve, the Albert entered a passage between the left bank and a group of islands in the middle of the river. This delightful passage was about four or five miles long, and varied in breadth from fifty to sixty yards, and its banks were richly clothed. The stately bombax from its enormous trunk reared its wide-spreading branches in the midst of cassia, and other shrubs and trees of endless variety of tint and shade. The amount of cultivation of yams, bananas, and plantains, indicated more extensive habitation than we had yet seen, with the exception of Aboh.—*Dr. Macwilliam's Medical History of the Expedition to the Niger*.

TREATMENT OF HEMICRANIA & TIC DOULOUREUX

BY CAUTERIZING THE PALATE.

By M. DUCROS, of Marseilles.

IN the most intense hemicrania, and in the most obstinate *tic douloureux*, whether fronto-facial or temporo-facial, the pain disappears instantaneously on the application of ammonia at 25°, to the palatine arch, by means of a [camel's-hair] brush; the brush being allowed to remain on the part, till a copious flow of tears has been excited. I have tried this for the last three months in a very great number of cases, and the pain has always ceased. If the pain returns, a fresh application again produces a cessation of the neuralgia.—*Gazette Médicale*.

ANALYTICAL TABLES

OF THE CASES OF DISEASES TREATED AT
THE INFIRMARY OF THE PARISH OF ST.
MARYLEBONE FOR THE YEAR 1841.

THE chief object held in view in the arrangement of the following tables has been to show the influence of age, of sex, and of season, upon disease, as occurring amongst the pauper population of this section of the metropolis, during one year.

The first table includes the total number of the cases treated, with the exception of

* i. e. A solution of ammonia, showing 25° on Raume's hydrometer, = a specific gravity of .906. The Liquor Ammonia fort. of the London College is of the sp. gr. .882.—*Translator's Note*.

about 900, of such a nature as would only be admitted to the infirmary of a workhouse, or establishment similarly constituted. This table contains also the age, the sex, and the results of disease, at the four periods of life.

The second table shows in a more condensed form, the prevalence, and the mortality, of each class of disease, according to sex, and the period of life.

The third table comprises the whole of the cases contained in the preceding, and the rate of mortality, at the different quarters of the year.

The fourth table contains the gross number of patients admitted into the lying-in ward and into the infirmary in each quarter; the average number under treatment and average duration of their residence in the house; distinguishing them into medical and surgical.

An abstract of the expenditure of the establishment has been added, with the average number of patients of all classes in-door and out.

In the first table it may be observed, that the females far outnumber the male. This fact has been remarked in former years; as also that the mortality among the females is inferior to that of the former, being 1 in 6, the latter 1 in 5.3.

When we look at the different classes of disease, singular facts are presented; in those of the digestive organs, there is a preponderance of one-third on the part of females. This disproportion depended mainly on the more frequent occurrence of inflammatory affections of those organs in the female than the male, the number and the mortality of those affections being more than twice greater in the former than the latter. The tendency to diarrhoea was nearly equal in both classes, but the mortality was greatest in the males.

In the diseases of the respiratory organs the numbers were nearly alike in both sexes, but the mortality was greatest among males, being about 43½ per cent., and in females 37 per cent. The present tables confirm the incorrectness of that opinion which assigns a greater mortality from pulmonary consumption to women than to men.

Dropsy was most frequent amongst females.

The diseases of the vascular system fell more heavily on the females than the males. To some extent this is owing to derangement in menstruation; and so far as concerns the heart, the preponderance is owing to affections of that organ being less frequently complicated with disease of the respiratory organs in woman than in man.

Nothing particular is to be remarked of diseases of the genito-urinary organs. Venereal cases, however, have been much more numerous among females than males.

Diseases of the nervous system have fallen most heavily on females, which may be accounted for, from hysteria having been exclusively confined to them, and also the greater frequency of insanity among them in this house. The rate of mortality, however, is nearly equal in both sexes, from the more frequent occurrence of apoplexy and *delirium tremens* in males.

Diseases of the locomotive organs and cellular tissue, are, as might have been expected, more frequent in males than females.

Fever seems to affect both sexes almost indifferently; but in those of an eruptive kind, the mortality has been greatest in the female, and chiefly confined to the first period of life. So much for the comparative frequency of different diseases, and the mortality in both sexes.

An analysis of the second table shows us that diseases of the digestive organs chiefly prevail between twenty and forty-five years of age, the mortality being greater as life advances.

In the diseases of the respiratory organs the prevalence was greatest after 45, but the mortality was enormous in infancy. This fact is so striking, that, if returns from other institutions correspond with the present, it will call loudly for the necessity of excluding young children from crowded establishments in large towns.

Diseases of the vascular system prevailed most in adult and advanced life, and were most fatal at the latter period.

Diseases of the nervous system were most numerous between twenty and forty-five, but the greatest mortality occurred after that period.

There were but few cases of disease in the locomotive organs and cellular tissue, until after the first period of life, when they became pretty equally distributed over the three last periods.

The peculiarities respecting fevers have already been pointed out.

The effects of season upon particular diseases, as is shown in the third table, are very remarkable. Those of the digestive organs are most numerous, but least fatal, during the summer months. Those of the respiratory organs most frequent in winter.

Diseases of the vascular system were most numerous in the first quarter; the mortality was greatest in the first and last quarters; syphilitic cases were most numerous in the last quarter. This may partly be owing to the inclemency of the weather forcing a greater number to seek an asylum at that season.

Common fever was most frequent and fatal during the first quarter, and least so in the last quarter.—*Edin. Med. and Surgical Journal.*

STRICTURE OF THE RECTUM.

To the Editor of the Medical Gazette.

SIR,
Your last number contains a letter from a correspondent in relation to stricture of the rectum, which letter you, judiciously consulting the reputation of its author, have imparted to your readers anonymously.
I do not address you for the purpose of supporting or protecting the professional character of the individual who is stated to have committed the unfortunately fatal error, although I take pleasure in asserting, that having known him almost from his infancy, I may, without fear of contradiction, affirm that the profession does not contain a man of better education, more sterling integrity, or general practical information.
Your correspondent writes, in allusion to the existence of stricture of the rectum, "Now, it would be a great satisfaction to know the opinion of your great London surgeons on this point. If there is such a disease, some of them must have met with it in their extensive practice, and it must have been often seen in the dead-rooms of the different hospitals. The rectum was greatly patronised in this city some years ago, and it is still a favourite with one or two surgeons, who doubtless find it a fruitful source of income." Being a London surgeon, but without the wish or intention of assuming to myself the term "great," I would answer his inquiries so far only as may be requisite for the furtherance of science, and the amelioration of human suffering, by assuring the profession that simple stricture of the rectum does exist, and is commonly met with among the poor,—a fact of which your correspondent may be convinced by investigating the practice of this charity, which is open gratuitously to the medical public, while in the museum thereto attached are many preparations of the disease, varying in its position from the sigmoid flexure of the colon to the anal extremity of the rectum.
I am, sir,
Your obedient servant,
FREDERICK SALMON.
12, Old Broad Street, Sept. 13, 1843.

MEDICAL ATTENDANCE ON THE POOR.

THE Poor-Law Commissioners have signified their intention of hereafter admitting those gentlemen who hold a Scotch or Irish diploma in surgery, to the same rights under the Poor-Law Amendment Act, as members of the College of Surgeons in London. For this purpose they are to make the necessary alterations in their order of the 12th of March, 1842.

WOUND OF THE AORTA AND PERICARDIUM.

THE following case is interesting in a medico-legal point of view :—A Spanish refugee was struck by one of his companions with a knife in the back. The blade broke at a little distance from the skin. The patient walked to the hospital, where he died two hours after. At the *post-mortem* examination, it was found that the knife had penetrated between the seventh and eighth dorsal spines, that it had cut or broken a portion of one of these processes, crossed obliquely the vertebral canal, traversed the body of the vertebra from below, and a little to the right side of the centre, and then wounded the aorta below its arch. The pericardium was divided to the extent of five millimetres; it contained three grammes of blood. The pleuræ, but more especially the left, were filled with a considerable quantity. The spinal cord was not affected.—*Bull. de Ther.*, June 1842; and *Dublin Journal of Medical Science*.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XLIV.

*On the Origin, Symptoms, and Treatment
of Crural Phlebitis.*

No unequivocal example of phlegmasia dolens was recorded in the medical literature of this country, where the actual condition of the affected parts was ascertained by dissection, from the year 1823 to 1829, when the history of the following case was published in the fifteenth volume of the *Medico-Chirurgical Transactions*. Several eminent physicians and surgeons examined the patient during the progress of the affection, who was under the care of Dr. Nathaniel Grant, Thayer Street, and none of them expressed a doubt as to the disease being genuine phlegmasia dolens. The hard painful femoral vein in the groin was supposed by some to be an inflamed absorbent vessel, but the dissection proved this opinion to be incorrect.

I. Mrs. Jones, æt. 31; delivered on March 10, 1827. On the 14th she began to experience a sense of pain in the left groin and calf of the leg, with numbness in the whole left inferior extremity, but nothing unusual was perceived in the appearance of the limb, except a slight tumefaction of the inguinal glands, where pressure occasioned great uneasiness. She had rigors; the tongue was furred, and there was much thirst; bowels open; pulse 80; the flow of milk and lochia natural. 16th (the sixth day after parturition), the pain of the left thigh and leg continued with increased severity, particularly from the groin to the knee, along the inner surface of the limb, where a swelling of a glistening white appearance was observed;

the pulse still 80; and the general functions but little deranged. 19th. The pain had diminished, but the swelling had greatly increased, and extended to the leg and foot, which were both very tense, and did not pit upon pressure; there was no discolouration of the skin; the pain of the limb was relieved by placing it in a state of moderate flexion. 21st. The pain in the groin had abated, and the swelling appeared to decrease. 24th. Pain of the limb aggravated particularly on moving it; pulse more accelerated; skin hot and moist; she was extremely irritable and desponding. 25th (the fifteenth day after delivery), when I first saw her, the whole extremity was much swollen, the intumescence being greatest in the ham and calf of the leg. The integuments wore a uniform smooth shining appearance, having a cream-like colour, and every where pitting on pressure, but more readily in some situations than in others; the temperature to the touch did not differ from that of the other limb, though she complained of a disagreeable sensation of heat throughout its whole extent, and much pain was experienced in the upper and inner part of the thigh on moving it. Immediately below Poupart's ligament, in the situation of the femoral vein, a thick hard cord, about the size of the little finger, was distinctly felt. This cord, which rolled under the fingers, and was exquisitely sensible when pressed, could be distinctly traced three or four inches down the thigh in the course of the femoral vessels, and great pain was experienced on pressure as low down as the middle of the thigh, in the same direction. The pulsations of the femoral artery were felt in the usual situation below Poupart's ligament: pressure over this vessel excited little or no uneasiness. Pulse 90, and sharp; tongue much furred; thirst urgent; bowels confined; the lochia had nearly disappeared; leeches were applied to the left groin and upper and inner part of the thigh; these were followed by cold evaporating lotions to the affected parts, and

mild cathartics and anodynes were administered internally. 30th. The acute pain on pressure and motion of the limb had subsided, and the extremity was universally oedematous. For two months after this period the limb remained so feeble as to disable her from walking, and continued larger than the other. Eleven months after the attack the general health of the patient was completely restored, and she again became pregnant. Because she recovered perfectly from the attack of phlegmasia dolens, I was not unfrequently afterwards reminded by one of the physicians who had seen her of the mistake he believed I had committed in supposing that the hard painful cord in the groin was the inflamed femoral vein, and not an inflamed absorbent. On the 5th of November, 1828, she was delivered of a still-born child, and died soon after from uterine hæmorrhage. On dissection the whole of the left inferior extremity was considerably larger than the right, but no serous fluid escaped from the incisions made through the integuments, beneath which a thick layer of peculiarly dense granular adipose matter was observed. The common and internal iliac and femoral veins and arteries, inclosed in their sheath, were removed from the body for examination. The common iliac, with its subdivisions, and the upper part of the femoral veins, so resembled a ligamentous cord, that on opening the sheath, the vessel was not, until dissected out, distinguishable from the cellular substance surrounding it. On laying open the middle portion of the vein, a firm thin layer of ash-coloured lymph was found in some places adhering close to and uniting its sides, and in others clogging it up, but not distending it. On tracing upwards the obliterated vein, that portion which lies above Poupart's ligament was observed to become gradually smaller, so that, in the situation of the common iliac, it was lost in the surrounding cellular membrane, and no traces of its entrance into the vena cava were discernible. The vena cava itself was in its natural state. The entrance of the internal iliac was completely closed, and in the small portion of it which I had the opportunity of examining the inner surface was coated with an adventitious membrane. The lower end of the removed vein was permeable, but its coats were much more dense than natural, and the inner surface was lined with a strong membrane, which diminished considerably its calibre, and here and there fine bands of the same membrane ran from one side of the vessel to the other. The outer coat had formed strong adhesions with the artery and the common sheath; the inguinal glands adhered firmly to the veins, but were otherwise in a healthy condition. No appearance of recent disease existed, and the density and firmness of the morbid tex-

tures evidently showed that the whole was the result of inflammation, which had occurred at a remote period. An accurate coloured drawing of the appearances was made immediately after the removal of the vessels from the body, which I shall now hand round, with the preparation of the morbid parts, and which I entreat you to examine rigorously. At the period when this occurred I was wholly unacquainted with the important pathological fact, that the inflammation of the iliac and femoral veins in phlegmasia dolens commences in the uterus, and I could obtain no satisfactory explanation of the cause why the disease did not occur during pregnancy, which it must have done had it been owing to pressure of the gravid uterus on the vessels: and why a certain period should always elapse after delivery before the disease commences. Neither in this nor in the following case, which has also been recorded in the fifteenth volume of the *Medico-Chirurgical Transactions*, were the internal iliac veins examined with a view to discover the commencement of the disease in the uterus, because at this time no suspicion existed that it originated in the uterine veins, and that crural was the result of uterine phlebitis.

II. Mrs. Edwards, æt. 35, No. 54, King Street. 16th of April, 1829, was delivered of her second child, three weeks ago, after a natural labour, and on the 9th inst. was attacked suddenly with a pain in the calf of the right leg, and loss of power in the whole right inferior extremity. On the 13th, a considerable swelling, without discolouration, had taken place from the ham to the foot, and great tenderness was experienced along the inner surface of the thigh to the groin. The extremity is now universally swollen, painful, and deprived of all power of motion. The temperature along the inner surface of the limb is increased; the integuments are pale and glistening, and do not pit upon pressure. There is no pain in the hypogastrium, but pressure along the course of the crural vessels excites great suffering, and the vein from the groin to the middle of the thigh is indurated, enlarged, and exquisitely sensible. There is also great sensibility in the ham, and along the inner surface of the leg to the ankle, where some branches of the superficial veins are hard and painful on pressure. Pulse 80; tongue much loaded; thirst; bowels open. There was no rigor, or symptom of pyrexia, at the invasion of the disease. She states, that the veins of the right extremity were more distended during pregnancy than those of the left. Twelve years ago, after the birth of her first child, the patient and her relatives report, that she experienced an attack similar to the present, in the same limb, and that it remained in a weak condition for several

months afterwards, but ultimately recovered its natural size and power. April 18th.—The tension and increased heat along the inner surface of the limb are somewhat diminished, but the pain continues in the course of the vessels. May 1st.—Affection declining. The femoral vein cannot now be felt, but there is still a sense of tenderness in its course down the thigh. No pitting on pressure. She has suffered, during three or four days, considerable uneasiness between the umbilicus and pubes, as well as in the loins, and has had rigors, with quick pulse, loaded tongue, and thirst. The abdomen is soft, but tender on pressure around the umbilicus. 9th.—The swelling of the limb is nearly gone, as is the tenderness in the course of the femoral vessels. For several days past, she has experienced attacks of acute pain in the umbilical region, loins, and back, which have assumed a regular intermittent form. Every afternoon there has been a violent rigor, of an hour's duration, followed by increased heat and profuse perspiration. In the course of the last and preceding nights, there was slight delirium. The skin is now hot and dry; the pulse 125; the tongue brown and parched; bowels open. The abdomen is neither tense nor swollen. On pressing around the umbilicus, she complains of a deep-seated feeling of soreness. A strong vibratory motion, corresponding with the pulsations of the heart, is perceived in the epigastrium. 21st.—The febrile attacks gradually declined in severity, and she appeared to recover, until yesterday, when she had a long and violent fit of cold shivering. The countenance is now expressive of great anxiety, and the pulse extremely quick and feeble. There remains no visible trace of the affection of the lower extremity. 23d.—Has been vomiting ever since yesterday, at intervals of half an hour. Complains of great pain in the left side, increased upon taking a deep inspiration. The pulsation in the epigastrium diminished, although it is still clearly perceived: pulse 120, and soft.

24th.—Symptoms continue without alleviation. Has had a severe shivering fit of long duration. Skin hot and dry; pulse 140; tongue brown and parched; diarrhoea. The pulsation in the epigastrium has entirely disappeared; the pain in the left side of the thorax is diminished; but the respiration is hurried, and there is frequent cough. Great prostration of strength. Surface of the body has assumed a peculiar sallow tinge. She has been delirious in the night, but is now perfectly conscious when roused. The conjunctiva of the right eye has suddenly become of a deep red colour, and so much swollen, that the eyelids cannot be closed. The cornea is dull, she makes little complaint of pain in the eye, and there is no intolerance of light. The vomiting has ceased. 25th,—

Has again had repeated attacks of vomiting. Debility rapidly increasing; respiration hurried; incessant hacking cough; pulse 140, extremely feeble; surface of the body cold and clammy; the tongue and teeth covered with dark sordes; diarrhoea. The left eye has also become red and swollen, without much increased sensibility. 26th.—Great debility; when undisturbed she is delirious, but is conscious when roused, and complains of pain in the left side of the chest. Pulse above 140. Tongue black and dry. Conjunctiva of the left eye also affected with swelling and intense redness. The cornea is dull, and shreds of lymph appear to have been effused over the left iris. 28th.—Had so violent a rigor in the afternoon that the bed shook under her. She is now completely insensible. The eyes are red and swollen, and there is a copious secretion of an opaque fluid from their surface and from the eye-lids, which cannot be closed. The respiration hurried. Pulse 140. 31st.—Has recovered her consciousness, and drank cider and porter with great eagerness. Pulse rapid and feeble. Eyes so much swollen that they seem pushed forward from their orbits. Vision entirely lost; but hearing and the other senses remain. 2d June.—Great debility. A red puffy swelling has suddenly appeared over the right elbow-joint. Tongue dry and black; diarrhoea; frequent, or rather constant wandering, except when spoken to, when she answers questions distinctly, and complains only of pain in the chest, with difficult respiration and cough. 10th.—Little change has taken place in the symptoms; but she has become much weaker. The vision is lost, but the hearing is perfect, and she makes no complaint of pain in any part of the body, 15th June.—Died this morning.

Morbid appearances on examining the body of Sarah Edwards on the 16th of June.—Present, Drs. Sims and Locock.

Thorax.—In its left cavity were contained upwards of two pints of a thin purulent fluid, and extensive recent adhesions existed between the pleura covering the lower margin of the superior lobe, and the pleura costalis. The surface of the inferior lobe was coated with a thick layer of flocculent coagulated lymph, as was a corresponding part of the pleura costalis. The substance of this lobe was of a dark colour, approaching to black, and soft in texture, so as to be readily broken down with the fingers. In its centre about an ounce of thick cream-coloured pus was found deposited in the dark-coloured and softened lung. This was not contained in any cyst or membrane, but infiltrated into the pulmonary tissue.

In the right cavity of the chest recent adhesions also existed at the inferior part. A

considerable portion of the right inferior lobe was entirely changed from the healthy structure, being converted into a dense, solid, dark red coloured mass. On the anterior surface of this lobe the pleura was elevated as if by a hard irregular tumor; but when cut into, no pus escaped from this part, and it presented only the appearance of the surrounding portions of lung with a greater degree of condensation.

Vena cava inferior: Coats of the vessel considerably thickened, and the internal were visible, of a scarlet colour; its whole cavity occupied by a coagulum, distending it to its utmost extent, and terminating in a loose pointed extremity about an inch below the entrance of the vena cava hepatica. The coagulum, covered with a membranous-like investiture of a bright red colour, throughout firmly, and in many places inseparably, adherent to the inner lining of the vein. The substance within it varied in consistence and colour: in some parts it presented the appearance of coagulable lymph; in others it was a pultaceous, dull yellow mass, made up apparently of pus and lymph blended together. The exterior of the firmer portions were separated into layers, which gradually disappeared as they approached the centre. The mouths of all the veins emptying themselves into the cava were sealed up, the emulgents excepted, the coagulum near the entrance of these vessels hanging loosely within the cava.

Left common iliac and its branches: Its interior plugged up with a continuation of the coagulum from the cava, and differing in no respect from it either as to consistence, colour, or the firmness of its adhesions to the inner tunic of the vein; it was continued beyond the entrance of the internal iliac (which it completely closed), and terminated in a pointed extremity about the middle of the external iliac; neither the remainder of this vessel nor the femoral vein exhibited any morbid changes. The internal iliac was much contracted, and lined with a thick adventitious membrane.

Right common iliac and its branches: This vessel was contracted to more than one-half its natural size; it was firm to the touch, and of a greyish blue colour; to its internal coat adhered an adventitious membrane of the same colour, containing within it a firm coagulum, made up of thin layers of dense lymph. The internal iliac was rendered quite impervious by dense dark-coloured bluish membranes, and, at its entrance into the common iliac, was converted into a solid cord. The contracted external iliac contained within it a soft yellowish coagulum, similar to the one in the cava; its coats were three or four times their natural thickness, and lined with dark-coloured membranous layers. The *femoral vein*, from Poupart's ligament to the middle of the thigh, was diminished

in size, and almost inseparable from the artery. Its tunics were thickened, and its interior coated with a dense membrane surrounding a solid purple coagulum strongly adherent to it. The superficial and deep femoral veins were in a similar condition, and the saphena major and minor differed from the femoral veins only in the size of the coagulum they contained, which was slender, and had formed no adhesions with the layers of lymph lining their cavity. The cellular membrane and other textures of the limb were in a perfectly healthy condition, and in size and appearance there was externally no visible difference between the two extremities. The morbid alterations of structure now described can still be distinctly seen in the preparation of the diseased veins, and have been represented with great accuracy in this beautiful drawing, made by Mr. Perry, from the parts immediately after their removal from the body. These I shall likewise hand round, that you may have an opportunity of comparing them with this description, and verifying its accuracy.

In this case, the connection between inflammation of the vena cava and of the iliac and femoral veins, and the destructive inflammation of the eyes in puerperal women, was so obvious, that it could not be overlooked, and I supposed had long been admitted as an undoubted fact. In the article *Puerperal Fevers*, by Dr. Locock, published in the first volume of Dr. Tweedie's *System of Practical Medicine* (1840), p. 361, there is the following statement:—"The remarkable destructive inflammation of the eye, which has been already mentioned, rare as it is, can hardly, perhaps, be placed as a symptom peculiar to this form of puerperal fever, but we have witnessed four instances of it, and in each there were purulent deposits in various parts of the body. In the five cases related by Dr. Marshall Hall, which also occurred after delivery, the same fact is noticed; there is the same rapid pulse, with constitutional disturbance, lasting for many days before the inflammation of the eye was discovered. In Dr. Hall's cases the left eye was uniformly the one inflamed, and it is curious that such was the fact in the four which have come under our own knowledge. In only one of Dr. Hall's cases was any decided abdominal pain and tenderness noticed, whereas three out of the four of our cases had such symptoms. In none could any post-mortem inspection be obtained. Dr. Robert Lee (*Cyc. Pract. Med. art. Puerperal Fever*) has alluded to two cases under his care where this destructive inflammation of the eye occurred in both eyes. He is inclined to believe that this remarkable affection is the attendant upon 'the morbid condition of the veins of the uterus,' the purulent or other depraved secretions entering the system, and

acting as a poison on the whole mass of blood. In Dr. Hall's cases and our own no examination took place to elucidate this theory, and *Dr. Lee does not quote any dissections to confirm it.*"

The following statement, contained in the same article, is so completely at variance with all my experience respecting uterine inflammation in puerperal women, that it would have been much more satisfactory had the author mentioned where and when the cases occurred, and by whom the most careful but unsuccessful search was made for morbid alterations of structure in the veins, the absorbents, the muscular structure, and the lining membrane of the uterus, and of the adjacent parts. "In Gooch's Treatise on Peritoneal Fevers, already quoted, several cases are recorded in which death ensued after certain symptoms, and in which no morbid appearances were discovered on dissection. Dr. Lee would reply to this that the examination was not pushed far enough, and that a more close inspection must have discovered some of the changes he has described. But after Dr. Lee's researches into these subjects were known, several cases similar to those related by Gooch occurring in our own practice, and in that of others, convinced us that in these something might therefore be found. The most careful search was made for morbid alterations of structure in the veins, the absorbents, the muscular structure, and the lining membrane of the uterus and of the adjacent parts, and nothing could be found to explain the cause of death."

III. Mrs. Foster, æt. 25, No. 27, Little Windmill Street, out-patient of the British Lying-in Hospital. May 8, 1829. Previous to her confinement, six weeks ago, she had been affected for several months with pain in the chest, difficulty of respiration, cough, with copious expectoration of a matter tinged with blood, profuse perspirations in the night, and had become greatly emaciated. During the last fourteen days she has been suffering from attacks of pain in the bowels, and diarrhoea. On the 4th instant she experienced a sense of soreness in the left groin, which gradually extended along the inner surface of the thigh to the ham, and from thence along the posterior surface of the leg to the foot. She stated, that for two or three days before the occurrence of pain in the groin she had felt great uneasiness in the region of the uterus, that this suddenly quitted the hypogastrium and passed into the groin, and that from thence it extended downward along the inner surface of the thigh and leg. The limb became swollen twenty-four hours after the invasion of the pain. The whole left inferior extremity is now affected with a hot, painful, colourless swelling, no where pitting on pressure except over the foot. The thigh is double the size

of the other, and any attempt to move the limb produces excruciating pain along the inner surface of the thigh; and the pain excited by pressure along the tract of the femoral vein is so acute that the condition of this vessel cannot be ascertained. Several branches of the saphena major above the knee are distended and hard; pulse 120; respiration quick and laborious; tongue peculiarly red and glossy; diarrhoea continues. 10th. Pulmonary affection aggravated. The limb continues extremely painful, and is still more swollen. The groin is so tender that she cannot endure the slightest pressure over it. The same is the case with the inner surface of the thigh. The branches of the saphena vein are still hard and painful. 11th. The femoral vein, under Poupart's ligament, can now be felt indurated and enlarged, and it is exquisitely painful when pressed, as is the inner surface of the thigh, the ham, and the calf of the leg. There is comparatively little tenderness along the outer surface of the limb; pulse 120; skin hot. 17th. Diarrhoea, emaciation, colliquative sweats, and difficulty of respiration, increasing. The left inferior extremity is still much swollen, but there is less pain at the groin and in the course of the femoral vessels. The foot and ankle pit on pressure. 26th. Calf of the leg still swollen and painful. June 19th. The pulmonary affection aggravated, and she is now reduced to a state of extreme debility. The limb is still considerably swollen, and is universally oedematous. 24th. Died this morning from the disease of the chest. *Dissection*—present Dr. Sims and Mr. Prout. *Thorax*: Extensive adhesions between the pleuræ on both sides. Scarcely a portion of lung could be observed which did not contain tubercles in various stages of their growth. The right and left superior lobes contained several large tuberculous excavations. The vena cava and right common external iliac veins were in a sound state. The left common external and internal iliac veins were all impervious, and had undergone various alterations of structure. The common iliac, at its termination, was reduced to a slender tube, about a line in diameter, which was lined with a bluish slate-coloured adventitious membrane. The remainder of the common and the external iliac veins were coated also with a dark-coloured membrane, and their centre filled with a brownish ochrey-coloured tenacious substance, rather more consistent than the crassamentum of the blood. The left hypogastric or internal iliac vein was in the same condition, but in some places reduced to a cord-like substance, and its cavity throughout completely obliterated. The branches of this vein taking their origin in the uterus, and usually termed the uterine plexus, were found completely plugged up

with firm reddish coagula of lymph. From the commencement of the branches of this plexus of the hypogastric vein to the termination of this vein in the iliac, the whole had become thickened, contracted, and plugged up with coagula and adventitious membranes of a dark blue colour. The same changes had taken place in the uterine plexus and trunk of the right hypogastric vein, from the uterus to its unusual termination in the left common iliac vein. The coats of the left femoral vein were thickened, and closely adherent to the artery and surrounding cellular substance; its whole interior lined with an adventitious membrane, and distended with a reddish-coloured coagulum. The same morbid changes presented themselves in the deep and superficial branches as far as they were examined down the thigh. If you examine this drawing made of the

parts by Mr. Perry, immediately after their removal from the body, and this preparation of them, you will require no further evidence to convince you that the inflammation of the left iliac and femoral veins which produced phlegmasia dolens in the left lower extremity, commenced in the uterine branches of the hypogastric vein. The following case, which has likewise been published in Vol. XV. of the *Medico-Chirurgical Transactions*, with a coloured engraving, demonstrates this fact in the most conclusive manner.

IV. Mrs. Mason, æt. 42, No. 3, Little Vine Street, August 29th, 1829, four weeks ago, was delivered of twins, and before the

expulsion of the placenta had nearly perished from uterine hæmorrhage. Considerable tenderness of the uterus succeeded and remained until the 27th instant, when, without any apparent cause, she had a violent fit of cold shivering, followed by febrile symptoms, and pain in the right iliac region and groin. Yesterday morning the pain increased in severity, and extended down the inner surface of the thigh towards the ham, and in the evening the whole thigh and leg was perceived to be considerably swollen. At present the whole right interior extremity is affected with a general intumescence, and is completely deprived of all power of motion. The temperature of the limb, particularly along the inner surface, is much higher than that of the other, but the integuments retain their natural colour, and do not pit on pressure. The femoral vein, for several inches under Poupart's ligament, is very distinctly felt enlarged, and is very painful when pressed. Out of the course of the crural vessels little uneasiness is produced by pressure. In the right side of the hypogastrium there is also great tenderness; pulse 120; tongue furred. She appears pale and depressed, and complains of deep-seated acute pain in the lower part of the spine when she attempts to move. August 31st.—The pain continues in the groin, and along the inner surface of the thigh. The glands in the groin are painful and tumid. The limb is considerably swollen, and the temperature is increased. Febrile symptoms continue. Sept. 8th.—There is less pain in the limb, but the femoral vein can still be felt large and hard, and is painful on pressure. The foot and leg pit. She has suffered much from rigors, and has had repeated attacks of diarrhoea; pulse quick, with great prostration of strength. 14th.—The limb is now oedematous, and nearly free from pain. She has complained of tenderness in the left groin and thigh, but nothing unusual can be perceived in the seat of the pain. During the last four days she has had repeated attacks of cold shivering, and has suffered severely from diarrhoea, and deep-seated pain in the lower part of the back; pulse 130, and feeble; tongue white. From the 13th to the 22d, when she died, she was occasionally delirious, and made no complaint of pain except in the back; pulse 140; tongue dry and furred. Frequent attacks of diarrhoea and severe rigors. Both inferior extremities were oedematous. *Dissection:* present Mr. Prout. The veins presented nearly similar appearances to those observed in the preceding cases, and the drawing and preparation will convey a more correct idea of the changes they had undergone, than any verbal description. The divisions of the vena cava were in this instance both affected. On the left side, the cavities of the iliac and femoral veins were filled with a dark purple

coagulum, their coats being not much thicker than natural; whilst, on the right side, the coats of these veins were dense and ligamentous, and the cavities blocked up by adventitious membranes, or lymph of a dull yellow colour. The lower part of the vena cava, for the space of two inches, as well as the right common iliac, was obstructed by a tough membrane of lymph surrounding a soft semifluid yellowish matter. The right, common, external, and internal veins were imbedded in a mass of suppurating glands, the purulent fluid of which had escaped into the adjacent cellular membrane, and forced its way downwards in the course of the psoas muscle, as low as Poupart's ligament. The right hypogastric vein was reduced to a small impervious cord, and its membranes distended with coagula of lymph of a bright red colour. The right femoral and its branches were in like manner impervious, their coats being greatly thickened, and their interior occupied by coagula. The cavities of the left common external iliac and hypogastric veins contained soft coagula, disposed in layers, which adhered to the inner tunic of the vessel. The trunk of the left hypogastric vein was contracted, its coats somewhat thickened, as well as its branches filled with red-coloured, worm-like, coagula. The spermatic veins were healthy. The lower extremities were both infiltrated with serum.

V. A lady, 26 years of age, was delivered on the 19th of June, 1831. The labour was protracted, and the placenta, after having been retained in the uterus six hours, was removed artificially by the practitioner with some difficulty. In the course of a few days after, great tenderness of the uterus, with pyrexia, followed. The pain subsided after the application of leeches to the hypogastrium, but the fever, with remarkable prostration of strength, continued till the end of the third week. A painful sense of tension then came to be experienced in the brim of the pelvis, on the left side, and in a few days the whole left inferior extremity became affected with a hot, tense, painful, and colourless swelling. On the 21st of July (four weeks after delivery) I was requested by Mr. Cleland, her medical attendant, to see this lady in consultation with him. The pulse was 150, and feeble; there was constant nausea, vomiting, and diarrhoea; tongue of a dark brown hue; great debility; the countenance and whole surface of the body of a dusky colour; respiration hurried, with frequent cough and expectoration; occasional delirium; the whole left inferior extremity was swollen to more than double the size of the other; the femoral vein, exquisitely painful on pressure, was felt indurated and enlarged in the upper part of the thigh, and there was fulness and tension above Poupart's ligament, in the situation of the iliac veins; the foot and ankle pitted upon pressure, but the integuments of the thigh were hot and tense, and did not retain the impression of the finger. 22d. Great prostration of strength; pulse 160; respiration laborious; tongue dry and brown; diarrhoea and vomiting continue; is unconscious at intervals, and then complains of great pain along the inner part of the left thigh and in the ham; there is also tenderness of the hypogastrium, and sense of throbbing in the direction of the abdominal aorta; abdomen tympanitic. 23d. Sinking; cold extremities; pulse feeble and intermittent; singultus. 24th. Died. Inspection: present Dr. Sims and Mr. Cleland:—The uterus had sunk down into the pelvis, and was as much reduced in size as it usually is four weeks after delivery. The peritoneum at first sight appeared every where healthy, but, on closer inspection, an adhesion, by means of false membrane, was found to exist between the posterior part of the uterus and rectum. More than a pint of purulent fluid was contained between the uterus and rectum. The peritoneal and muscular coats of the fundus and body of the uterus were so soft as to be readily torn with the fingers, and of an inky black colour. The coats of the common external iliac and femoral veins, to the middle of the thigh, were all thickened, and their cavity filled with soft coagula of lymph and pus. The vena cava, to about

two inches below the entrance of the hepatic veins, was completely blocked up with a coagulum of lymph, which partially adhered to the inner surface of the vessel. Several glands in the vicinity of the vena cava and iliac veins were in a state of suppuration. The coats of the left internal iliac vein, at its termination in the oncomm iliac, were in a soft shreddy state. The right common, internal and external iliac and femoral veins, were all in a healthy state. You may hand round the preparation of the parts, in which all these appearances are still seen.

VI. Mrs. Wildman, 30 years of age, was delivered after a natural labour, in the British Lying-in Hospital, on the 27th of January, 1832. Obscure febrile symptoms took place a few days after delivery; but as there was no pain in the region of the uterus, and the patient would not admit that she was indisposed, I was not called to see her till the tenth day after her confinement; I was then informed that she had been incoherent in the night, and that she had suffered from a long and severe fit of cold shivering. The pulse was 130 and feeble; tongue of a dark glossy red colour; lips parched; tremors of the muscles of the face and extremities; the countenance of a dusky yellow colour. There was no tension, pain, or swelling of the hypogastrium; but there was exquisite pain on pressure along the course of the iliac vessels, on the left side, and down the inner part of the thigh. I now, for the first time, discovered that the whole left lower extremity was much swollen, hot, tense, and shining. 18th. The swelling of the left lower extremity, and pain in the course of the iliac and femoral veins, relieved by leeches and warm fomentations. Pulse 140, and extremely feeble; tongue dry and brown; but there is no vomiting, diarrhoea, or distension of abdomen. The conjunctiva of both eyes have suddenly become intensely red and swollen, and the vision is much impaired, if not lost; consciousness remains. The right knee-joint is now exquisitely painful when moved, but it is neither red nor swollen. A dark-coloured gangrenous spot has appeared over the sacrum. 14th. Eyes red, and enormously swollen; eyelids cannot be closed; pulse rapid and feeble; tongue, lips, and teeth, covered with sordes; severe pain in the right knee and elbow joints, and right wrist; left lower extremity less swollen. Died on the 18th. The body was inspected, at my desire, by the late Dr. John Prout, who had been present with me at the examination of all the preceding cases. The uterus had subsided into the pelvis, and no trace of disease was perceptible in the sac of the peritoneum. Both spermatic veins were healthy. The coats of the left common, external iliac, and femoral veins, deep and

superficial, were all thickened, and their cavities plugged up with firm coagula; the same was the case with the epigastric veins and circumflexa ilii. The glands in the vicinity of these veins were enlarged, red, and vascular, and closely adherent to the cellular membrane and outer surface of the vessels. The vena cava, to a short distance above the entrance of the left common iliac vein, had its coats thickened, and a soft coagulum of lymph adhering to its inner surface. The uterine, vaginal, gluteal, and most of the other veins which form the left internal iliac, were gorged with pus, and lined with false membranes of a dark colour approaching to black. The uterine branches of the right internal iliac vein were also filled with pus and lymph; but the inflammation had not extended beyond the entrance of the trunk of the vessel into the common iliac, and the right common, external, iliac, and femoral veins, were all in a healthy condition. In the muscular tissue of the cervix uteri, on the left side, was a cavity which contained 3ij. of purulent fluid. The veins proceeding from this part of the cervix were filled with pus, and a large portion of the inner and muscular coats of the uterus was as soft as lard. The conjunctivæ, which before death had been red and swollen, were now almost colourless, scarcely a vessel containing red blood being discernible.

VII. Mary Gane, set. 20, was delivered on the 21st October, 1832, of her first child, at her residence near St. Thomas's Hospital. The labour was natural, and she went on favourably till the third day, when she complained of pain and stiffness about the hypogastric and inguinal regions, extending down the thighs, with pyrexia and headache. 25th. Increased pain on pressure over the region of the uterus, extending down the right thigh; pulse frequent; rigors; offensive lochia. 30th. Rigors have been more frequent and severe, with great febrile disturbance. The pain of the uterus has never entirely gone off, and she now suffers severely from pain in the symphysis pubis. 31st. Pain of uterus diminished, but increased tenderness in the right groin, extending in the course of the femoral vessels, which are felt hard and cord-like, beneath Poupart's ligament, for a space of three inches down the thigh. The limb greatly swollen, and oedematous, and free from discolouration, except below the ham, where it is of a dark hue from distension of the saphena veins. November 1st. The limb is immensely swollen, but the femoral vein can no longer be felt in the upper part of the thigh; pitting upon pressure in different parts of the extremity; pulse rapid and feeble; tongue foul; diarrhoea; surface covered with perspiration; countenance pale and depressed. 4th. Pulse 130 and feeble; tongue loaded; diarrhoea

continues; pain in the uterine region gone. 13th. Pain and swelling have taken place in the course of the left saphena vein; swelling of right lower extremity diminished; pulse 130, and feeble; distressing diarrhoea. The soft parts covering the sacrum have become affected with gangrenous inflammation, and also the right outer ankle and foot, from which there is a dark ichorous discharge. Several large dark-coloured vesicles have also appeared over the limb. Delirium and pain of the chest ensued, and she speedily sunk. On examination of the pelvis it was found filled with purulent fluid, which had escaped through the symphysis pubis, which was separated to the distance of an inch and a half, and its cartilages gone. The right femoral vein was plugged up with fibrine, and the saphena major filled with pus. Permission could not be obtained to examine the left lower extremity, to ascertain the condition of the internal iliac vein, though there could be little doubt that the inflammation commenced in the uterine branches of this vessel.

VIII. The preparation which I shall next shew you exhibits in a very striking manner the effects produced by inflammation on the lower part of the vena cava, and the left common, external, and internal iliac, and femoral veins. A woman became pregnant who had distortion of the pelvis, and this large fibrous tumor imbedded in the walls of the uterus which you now see. Premature labour came on, and the child was expelled without artificial assistance, but in a short time uterine and crural phlebitis took place in the left side, and she ultimately died. The fibrous tumor was partially in a softened state, and all the branches of the left hypogastric vein were filled with pus and coagula of blood. It is impossible to examine this beautiful specimen of crural phlebitis without being convinced that the inflammation did not commence in the common or external iliac, but in the branches of the left hypogastric vein.

IX. In the third lecture, the uterus, with all the veins connected with it, were exhibited in the recent state, which had been removed from the body of a woman who died on the 9th of October, 1842, four weeks after delivery, and who had phlegmasia dolens in both lower extremities, the left having been first and most severely affected. The symptoms were those which characterise uterine and crural phlebitis, and you saw all the veins of the cervix uteri in the left side filled with lymph and pus, and coated with false membranes. The left internal, common external iliac, and femoral veins, were all in the same condition. The vena cava was thickened as high as the diaphragm, and a rough false membrane adhered to the whole of its inner surface. The right common, ex-

ternal, and internal iliac, femoral, and saphena veins were all inflamed, though in a slighter degree than on the left side. There was a quantity of serous fluid in the cellular membrane of the limb, but no disease of the absorbents that could be discovered. This dissection demonstrates in the most conclusive manner that in this case of phlegmasia dolens, as in all the preceding cases, the inflammation commenced in the uterine branches of the hypogastric veins, and subsequently extended from them into the iliac and femoral trunks of the affected side.

Many authors have confounded diffuse cellular inflammation with crural phlebitis, and have in consequence been led to deny that inflammation and obstruction of the crural veins is invariably the cause of phlegmasia dolens. "Drs. Otto, Duncan, and Craigie," observes Dr. Copland, "refer phlegmasia dolens to diffuse inflammation of the cellular substance, but I think on insufficient evidence. If this tissue be really inflamed in that disease, other structures participate, and it certainly is not the part first affected. In the cases which I have seen examined after death, only three in all, the nerves and veins were the parts to which the symptoms of disorder were first referred, the veins being obstructed in all the cases." Cases of diffuse cellular inflammation of the thigh in puerperal woman, which had extended from the peritoneum of the uterus, have most erroneously been represented by some as genuine cases of phlegmasia dolens, though none of the pathognomonic symptoms of the disease were present; where the pain and swelling were in fact on the outside of the thigh, and not in the course of the femoral vessels. It has also been asserted "that phlegmasia dolens has manifested itself to a very considerable extent in some cases without any inflammation of the veins whatever;" but when and where such cases happened no information is given, and in opposition to this I will affirm that no such cases have been recorded during the last sixteen years in the medical writings of this country. I believe no example of genuine phlegmasia dolens has occurred in England during this period, in which the iliac and femoral veins were not affected before the cellular membrane, lymphatics, and nerves, and other textures of the limb.

In a Work on the Pathology and Treatment of some of the most Important Diseases of Women (1833), cases and dissections are related by me, which prove that crural phlebitis is not peculiar to women who have been recently delivered, but that it may also arise from suppressed menstruation, malignant ulceration of the os and cervix uteri, polypus of the uterus, and other organic diseases of the uterine organs. Cases are also related in which crural phlebitis oc-

curring in the male sex, and where the disease commenced either in the hæmorrhoidal, vesical, or in some of the other branches of the internal iliac veins, in consequence of inflammation or organic changes of structure in one or more of the pelvic viscera,—or in the superficial veins of the legs, which extended upwards and involved the great venous trunks of the thigh and pelvis. The following is the description of puerperal crural phlebitis, which was then given, and the accuracy of which subsequent observation has confirmed. In seven of the twenty-two cases which I have observed, the disease has commenced between the fourth and twelfth days after delivery, and in the remaining fifteen it appeared subsequent to the end of the second week after parturition. In most of the patients there was either an attack of uterine inflammation in the interval between delivery and the commencement of the swelling in the lower extremity, or there were certain symptoms present which I have before described as characteristic of venous inflammation, viz.: rigors, headache, prostration of strength, a small rapid pulse, nausea, loaded tongue, and thirst. The sense of pain at first experienced in the uterine region has afterwards been chiefly felt along the brim of the pelvis, in the direction of the iliac veins, and has been succeeded by tension and swelling of the part. After an interval of one or more days the painful tumefaction at the iliac and inguinal regions has extended along the course of the crural vessels, under Poupart's ligament, to the upper part of the thigh, and has descended from thence in the direction of the great blood-vessels to the ham. Pressure along the course of the iliac and femoral vessels has never failed to aggravate the pain, and in no other part of the limb has pressure produced much uneasiness. There has generally been a sensible fulness perceptible above Poupart's ligament, before any tenderness has been experienced along the course of the femoral vessels; and in every case at the commencement of the attack I have been able to trace the femoral vein proceeding down the thigh like a hard cord, which rolled under the fingers. A considerable swelling of the limb, commencing in the thigh and gradually descending to the ham, has generally taken place in the course of two or three days, and in some cases immediately after the pain has been experienced in the groin. In other cases the swelling has been first observed in the ham or calf of the leg, and has spread from these parts upward and downward, until the whole extremity has become greatly enlarged. The integuments have then become tense, elastic, hot, and shining, and, in most cases, where the swelling has taken place rapidly, *there has been no pitting upon pressure, or*

discolouration of the skin. In several well-marked cases, however, of crural phlebitis, at the invasion of the disease, the impression of the finger has remained in different parts of the limb, more particularly along the tibia; but, as the intumescence has increased, the pitting upon pressure has disappeared, until the acute stage of the complaint has passed away. At the onset of the disease I have also observed, in several cases, a diffuse erythematous redness of the integuments along the inner part of the thigh and leg. In one individual only has suppuration of the glands taken place in the vicinity of the femoral vein; but in several, by an extension of the inflammation, the inguinal glands have become indurated and enlarged. In some women the inflammation of the femoral vein has appeared to be suddenly arrested at the part where the trunk of the saphena enters it, and the inflammation has extended along the superficial veins to the leg and foot. The swelling and pain in these instances have been greatest along the inner surface of the thigh in the course of the saphena veins. In most cases of crural phlebitis, not only the whole lower extremity, but the nates and vulva, have been affected with a hot, colourless, and painful swelling, which has not retained the impression of the finger. The power of moving or extending the leg has been lost after the disease has been completely formed, and the greatest degree of freedom from pain has been experienced by the patients, in the horizontal posture, with the limb slightly flexed at the knee and hip-joints. The severity of the pain and the febrile symptoms has usually diminished in a few days after the occurrence of the swelling; but this has not invariably happened, and I have seen some individuals suffer from excruciating pain, and violent febrile disturbance, for many weeks, or through the whole period of the acute stage of the disease. The duration of the acute local symptoms has been very various in different cases. In the greater number they have subsided in two or three weeks, and sometimes earlier, and the limb has then been left in a powerless and oedematous state. The swelling of the thigh has first disappeared, and the leg and foot have more slowly resumed their natural form. In one case, after the swelling had subsided several months, large clusters of dilated superficial veins were seen proceeding from the foot, along the leg and thigh, to the trunk, and numerous veins as large as a finger were observed over the lower part of the abdominal parietes. In some women the extremity does not return to its natural state for many months or years, or even during life. In the summer of 1831, a lady was placed under my care, for an affection of the left lower extremity, who, forty years

before, had suffered from an attack of puerperal crural phlebitis in the same side. The left thigh and leg had remained larger and weaker than the other during the whole of this long period, and was liable to suffer severely from fatigue and slight changes in the atmosphere. In four cases of this affection, after the symptoms had begun to subside, the same appearances were observed in the iliac and femoral veins of the opposite extremity, and the other thigh, the leg, and the foot, became similarly affected. In two individuals only has the disease attacked the same extremities twice.

Puzos, as has already been stated, recommended repeated and copious venesection in cases of crural phlebitis; but, in all the cases which I have seen, there has been so much feebleness of pulse, and prostration of strength, that I have not ventured to draw blood from the arm. Many individuals attacked with crural phlebitis have already suffered from hæmorrhage and uterine inflammation, and are not in a condition to lose much blood. But there are cases occasionally met with where the symptoms require, and are immediately relieved by, a general bleeding. An example of severe crural phlebitis after delivery occurred some years ago, in the practice of a medical friend, where the abstraction of twenty ounces of blood seemed at once to break the force of the attack. In a great proportion of cases venesection is not required, and the inflammation will be subdued by the repeated application of leeches above and below Poupart's ligament in the course of the crural veins. From two to three dozen of leeches should be applied immediately after the commencement of the disease, and the bleeding should be encouraged by warm fomentations and poultices. Should the relief of the local pain not be complete, it is requisite soon to re-apply the leeches, in numbers proportioned to the severity of the attack, and to repeat them a third or even fourth time, at no very distant intervals, should the disease not yield. It is requisite, in the progress of the disease, not only to apply leeches along the course of the iliac and femoral, but of the saphena veins, or to any parts of the limb where the swelling is great and the pain very acute. Some patients experience greatest relief from the use of warm cataplasms to the limb, others derive most advantage from the application of cold, or a tepid evaporating lotion. The bowels are often much disordered in this disease, but the employment of strong cathartics is always injurious. Repeated small doses of calomel and antimonial powder, and Dover's powder, should be given, with some mild purgative, not only with the view of correcting the disordered state of the bowels, but to subdue the local inflammation and the

great constitutional disturbance usually present. I believe no good is derived from mercury to salivation in this disease. It is of importance also to administer saline and diaphoretic medicines, and to procure rest and relief from pain, by anodynes, until the acute symptoms pass away. The diet should be the same as that usually allowed to patients who are labouring under inflammatory and febrile diseases. I have seen no advantage derived from the employment of digitalis in any stage either of uterine or crural phlebitis. Dr. Sims informed me that the swelling, pain, and tension of the limb, in a case of phlegmasia dolens, were strikingly relieved by puncturing the skin in different parts with a fine needle. In other cases this has done little or no good.

When the inflammatory symptoms have passed away, the limb remains in a weak oedematous state, and great uneasiness is often experienced from congestion of blood in the veins. Until the collateral branches which are to carry back the blood to the heart become enlarged, it is impossible by any means we possess to afford complete relief: the obstructed vein can never again be rendered pervious. Much benefit may, however, be derived, in this stage of the complaint, from the occasional application of leeches to different parts of the limb, and by preserving it in the horizontal position. I have seen much mischief produced by having recourse too early to remedies intended to promote the absorption of the fluid into the cellular membrane. Blisters, frictions, stimulant embrocations, and bandages to the limb, are only useful when the inflammation of the veins has wholly subsided, and other vessels have become so much enlarged as to carry on the circulation of the blood in the extremity without interruption. In the acute stage of the disease our main object is to moderate the inflammation of the iliac and femoral veins; and in the chronic form, to promote the circulation in the collateral veins by all the means in our power, and to further the absorption of the fluid effused. I have not perceived any sensible benefit accrue from the use of mercurial ointment and iodine in crural phlebitis. The repeated application of blisters is a much more powerful means of exciting the absorbents. The local abstraction of blood at the commencement of the disease is you will perceive by far the most important remedy.

ON THE
TREATMENT OF PUERPERAL
CONVULSIONS

BEFORE THE FULL TERM OF UTERO-
GESTATION*.

By S. HARRIS, M.D. of Clarkesville, Va.

OF the many accidents incident to pregnancy, that of puerperal convulsions is among the most alarming, the most sudden, and the most unmanageable. Intimately connected with and dependent on the gravid uterus, there is no period of pregnancy exempt from its attacks. It is admitted by all, that cerebral congestion is the most common cause of these convulsions; but it is contended by some that they occur under an opposite state of the brain, and it cannot be denied that there are some facts to sustain this opinion. Be this, however, as it may, they are generally preceded by undoubted evidences of a fulness of the vessels of the head, such as a flushed face, headache, giddiness, drowsiness, tinnitus aurium, &c. They are most common in the latter stages of pregnancy, and in labour during the violence of the parturient pains; and it is said that they sometimes come on after labour has terminated. It is no part of my present purpose to describe this disease, as the symptoms are familiar to almost every practitioner. My design is simply to call the attention of the profession to a material point in its treatment, when the usual remedies fail, and we are compelled to resort to delivery, but the os uteri is found undilated, and undilatable by gentle means. We are advised, and on this point I believe all agree, to bleed the patient as long as the pulse will bear it, to give cathartics, and apply cold applications to the head. But in the event of these remedies failing, we must endeavour to evacuate the uterus with as little delay as possible. Different means of effecting this object are accurately and minutely pointed out, to be used according to the circumstances of the case. We are told to deliver with the forceps, if the head of the child be engaged in the pelvis and the os uteri dilated; or if not engaged in the pelvis, but above the

brim, and the membranes have not been ruptured, the hand must be introduced, and the child turned and delivered by the feet; or if this be impossible, the perforator must be used. Now all these operations are made to depend upon the condition of the os tincæ. If not dilated or dilatable by gentle means, we are advised not to attempt any thing. All the authorities that I have consulted disapprove of a forcible entry into the uterus under any circumstances. Now I am not disposed to question the correctness of this established principle, as a general rule of practice; but in the disease which we are now considering, it frequently happens that delivery or death are the only alternatives presented. And must we, then, quietly seat ourselves, and witness a certain triumph of this terrible disorder? Do not the tears and entreaties of husband and friends justify, and even demand, a last and desperate effort to ward off the fatal result?

We will suppose that a woman enjoying apparent good health is taken suddenly with these convulsions in the fifth or sixth month of pregnancy; she is bled as far as her pulse or strength will allow, cold is applied to the head, cathartics administered either by the mouth or per anum, without any or but slight abatement of the fits. On examination per vaginam, the os uteri is found nearly closed, hard, and callous, and no manifestations of uterine contractions. The patient, during the intervals of the fits, lies in a profound stupor, unconscious and helpless, with a stertorous breathing, the eyes fixed, with dilated or contracted pupils; the heart, though still true to its office, propels the blood with a weak and vacillating action; a cold clamminess spreads over the upper portion of the body, with other equally distinctive signs of approaching dissolution. What, I ask, is to be done under such trying circumstances? Must the case be given up to nature, or are we not justified in making a forcible entry into the uterus, and extracting its contents? I am decidedly in favour of this last painful resource. And hopeless as such an undertaking may seem to be, it is nevertheless practicable in most cases, unless, perhaps, in the very early stages of pregnancy. But, it may be asked, will this forced delivery, even if it can be accomplished without a laceration

* From the American Journal of the Medical Sciences—July 1843.

of the os and cervix uteri, save the life of the woman? I answer, that to judge from the few cases of the kind which I have seen, it probably will, unless pretty extensive effusion has taken place in the brain. In support of this opinion, I will relate a case that fell under my observation in the spring of 1838.

I was called in consultation to Mrs. —, a strong, healthy, plethoric woman, about sixteen years of age, pregnant with her first child. She was in the fifth month, and up to the time of the attack of puerperal convulsions under which she was then labouring, had enjoyed robust health, with, perhaps, occasional transient pain and giddiness of the head, flushed face, and ringing in the ears. The convulsions came on suddenly, and recurred at intervals of twenty or thirty minutes. Up to the time I first saw her, which was probably ten hours from the commencement of the attack, she had had twenty-two or three distinct fits. A neighbouring physician, of some distinction, reached her in the morning, soon after the onset of the disease, and bled her freely, indeed I may say largely, and repeated the operation several times during the day. The bowels were likewise emptied, and irritants applied to the extremities. I found her, on my arrival, totally insensible to surrounding objects. The most glaring light produced no change whatever in the pupils of the eyes, which were fixed and distorted. The loudest noise excited no manifestations of consciousness. Deglutition, if performed at all, was involuntary, and the power of articulation was completely suspended. Her breathing was laboured and stertorous, and the pulse weak and fluttering, and sometimes not even perceptible at the wrist. There was no evidence of uterine action, and on examination the os tincæ was found almost entirely closed, hard, and unyielding. Viewing the case as nearly desperate, but still desirous of doing something, we determined to administer ergot, regardless of the rigidity of the os uteri. Several twenty-grain doses were accordingly put into the mouth, but from the inability to swallow, very little if any was conveyed to the stomach. No uterine contractions resulted from this experiment. The paroxysms continuing to recur with

unabated fury, I proposed as the only resource left to make an effort to deliver her. This my colleague in the case assented to, though reluctantly, as he considered it, if not impossible without certain death, to say the least of it rash and useless. I determined, however, to make an effort. Not having with me my obstetrical instruments, I was under the necessity of making a small crotchet for the purpose, out of the spindle of a cotton spinning wheel, such as is used in many families in the southern and western parts of the United States. As some of the readers of the American Journal of Medical Sciences may not be familiar with this domestic machine, I will describe that part of it which I used on this occasion, as well as on others of a like emergency, when time was not allowed to procure more suitable instruments. It is a small round iron spike, from twelve to fourteen inches long gradually tapering off from about the middle to a point at one end, while the other half remains of an uniform size, say one-fourth of an inch in diameter. The hook was readily made by heating the sharp point to a red heat, and bending it exactly as I wished. For the purpose of perforating the head of the foetus, I wrapped with tape the blade of a common dirk-knife to within half an inch of the point. With these rude instruments I prepared for the operation, by placing the nates of the woman on the edge of the bed, with a chair and an assistant on each side to support the legs (the usual position in this country for turning). With the index finger of the left hand I soon found the os tincæ, and cautiously but firmly thrust it into the uterus. The second finger, by dint of perseverance, was likewise forced in by the side of the first. This effected a slight dilatation of the passage, and after ascertaining pretty satisfactorily that the foetal head presented, I withdrew my fingers and carried up the point of the knife, carefully guarded with my finger until it reached the head, which I pierced readily by acting on the handle of the knife with my right hand exterior to the vulva. After perforating the head, I introduced the hook, and with some difficulty fixed the point in the bones of the cranium. These were, however, so soft as to yield under the slightest force. I succeeded ultimately in fixing

the point among the bones at the base of the skull. The last situation enabled me to use as much force as I pleased; but bearing in mind the delicacy of the parts thus rudely assailed, I did not exert it beyond what I supposed would have been the natural expulsive power of the uterus, under ordinary circumstances in abortion, at the fifth or sixth month of pregnancy. Though occasionally interrupted by the recurrence of the fits, the efforts at delivery were kept up at short intervals for several hours, when finally the os uteri yielded, and I succeeded in extracting the foetus and secundines. Little or no hæmorrhage ensued. The woman was then placed back on the bed in what appeared to be a truly forlorn and hopeless condition. Blisters and warm applications were immediately applied to the extremities, which were now cold and clammy. As is usually the case, she had two or three fits after delivery, but they were less severe, and occurred at longer intervals. She remained in a comatose state nearly twenty-four hours, frequently without any pulse at the wrist, or the ability to swallow either nutriment or medicine. Gradually, however, reaction came on, the breathing became less stertorous, the pulse slower and fuller, the surface warmer, the face less livid, and the eyes more natural in appearance. In this situation she remained for several hours, and finally waked up as if from a sound sleep, uttering moans and inarticulate cries of pain and anguish. Consciousness having returned, she was soon able to converse a little with her anxious friends, and take a little fluid nourishment; but the complete restoration of all her faculties was retarded for several days, in consequence of the severe shock which the brain had received. Mild laxatives, with an occasional mercurial purgative, a nutritious but not stimulating diet, frictions on the surface, with quiet but cheerful company, soon restored her to perfect health. As far as I was able to ascertain, neither the uterus nor its appendages sustained the slightest injury from the operation. She has since been pregnant three or four times, but has not as yet brought forth a living child. Generally she has an abortion about the fifth or sixth month, preceded by giddiness and pain in the

head; and on one occasion slight convulsions, which ceased after the expulsion of the foetus, but a partial paralysis remained in one arm and hand for six or eight months afterwards.

The result of this case proves, I think, beyond all question, that we are not only justifiable, but in duty bound, when all else fails, to force our way into the uterus and remove the offending cause. The practicability of this too much dreaded operation, without serious or permanent injury to the organ, is likewise demonstrated in the following case.

I was called in the month of February 1839, with two other medical gentlemen, to see Mrs. —, with puerperal convulsions, pregnant with her fifth child, and about thirty years of age. Naturally of a thin, nervous habit, she had never enjoyed robust health, and for several years previous to the attack, had been declining in strength and vigour. She was in the latter part of the fifth or first part of the sixth month of gestation. She had been labouring under the disease eight or ten hours when I first saw her, and had had probably a dozen severe paroxysms. The os uteri was undilated, and we were unable to discover any indications of labour. After bleeding freely and finding no relief, it was proposed to deliver her at once. This I accomplished in nearly the same manner as in the other case. She had only one fit after the extraction of the foetus, but remained in a state of almost hopeless insensibility for many hours. The general aspect of the case was very similar to the one already detailed both before and after delivery; but it could not be viewed otherwise than as a more hopeless one, as this lady had neither the youth nor vigour of constitution of the other. The next day after the operation she became rational, but was unable to articulate distinctly. The following evening fever came on, attended with a low muttering delirium, and a slow but full pulse. There was no tenderness or swelling of the abdomen, nor were the vaginal discharges at all different from that which usually follows abortion. There was, however, a retention of urine for several days, which compelled us to use the catheter. In order to lessen the violence of the reaction, she was bled from the arm

and cupped on the temples, cold applied to the head, and the bowels evacuated. Her case continued on for six days, with some slight remission of the symptoms in the forenoon, but a high fever with delirium in the evening. During all this time she enjoyed not one hour's refreshing sleep, nor did one-sixth of a grain of the sulph. morphia which we ventured to give her, produce more than an unquiet stupor. She would occasionally, in the morning, converse for a few moments on the subject of her children, or domestic concerns; at all other times she appeared unconscious of, or indifferent to what was passing around her. There was evidently in this case pressure on the brain, either from congestion or effusion, and the treatment pursued was strictly in accordance with this view of its pathological condition. She died on the seventh day. Had delivery been resorted to sooner, possibly the result might have been different.

We find that the *os tincæ*, though closed and rigid, will, by persevering efforts, generally admit one and sometimes two fingers, which will enable us to perforate the foetal head, if presenting, without wounding the uterus. This being done, and a proper degree of tractive force applied, the passage will generally dilate and allow the foetus to be extracted. It is admitted, I believe, by most of the standard authorities on the subject of parturition, that the child being forcibly impelled by the contractions of the uterus at the full period of utero-gestation towards the *os uteri*, contributes powerfully to dilate this opening, by overcoming the resistance of its circular fibres. Is it not probable, therefore, that if an equal degree of force be applied directly to the head of the child, and kept up at proper intervals for a reasonable length of time, that the same effect will be produced? Unaided by the concurrent action of the uterus itself, I grant that we might not so readily succeed; but it rarely happens that this sensitive organ fails to second our designs. Roused up by the rupture of the membranes, and the tractive efforts of the operator, the contractions of the body and fundus contribute more or less to the dilatation of the *os uteri*, and the ultimate delivery of the foetus.

Not having seen a case of convulsions of the epileptic or apoplectic form, earlier than the fifth month, I am not prepared to give any positive opinion as to the practicability or utility of extracting the ovum in the first period of pregnancy. But so firmly convinced am I of the importance of the operation in such cases, that I should not hesitate one moment, other things having failed, to make the attempt. I have frequently seen this disease in the latter stages of pregnancy, and during labour at the full term of gestation, and I have not yet succeeded in checking it even until after delivery, either by the natural powers of the uterus, or by an operation.

In thus presenting to the public my views, in reference to this formidable malady, based on an experience so limited, I can only hope to direct the attention of others to the subject, rather than expect an imitation of my rashness. If I have subjected myself to the imputation of having violated an established rule of practice, in the two cases reported, I have at least the consolation of knowing that the bold innovation of forcibly entering the uterus and delivering the foetus saved the life of one patient, and did not injure the person of the other. It is only as a *pis-aller* that I can recommend this course, and I venture to affirm, that if timely resorted to, it will, under guidance of reason and the promptings of ingenuity, result very often in the preservation of human life.

[Every proposition for the relief of so terrible a disease as puerperal convulsions is deserving of a respectful consideration, and therefore we have given place to the preceding well drawn up paper. The cautious practitioner will, however, doubtless require evidence of greater success from the practice advocated by our respectable correspondent, than has been adduced, and will duly weigh the consideration whether the forcible dilatation of the *os uteri* is not likely to be productive of more injury than the delivery will be of benefit.

Dr. Churchill, the author of one of the best works on diseases of women, and an experienced practitioner, remarks on this subject, "I believe there is no dispute that, until labour sets in

naturally, interference would be injurious; so that in convulsions during gestation, we have nothing to do with the uterus, but must confine ourselves to the treatment of the convulsive disease."—*Diseases of Females*, Am. Ed. p. 403.

Dr. Rigby, equally high authority, states: "The practice in former times of dilating the os uteri, introducing the hand, and turning the child, has been long since justly discarded, for the irritation produced by such improper violence would run great risk of aggravating the convulsions to a fatal degree."—*System of Midwifery*, Am. Ed. p. 385.

Mr. J. T. Ingleby entertains similar views. "From the seventh to the ninth month," he observes, "delivery, when it is expedient, may certainly be accomplished, but every objection which attaches to artificial delivery at the full term of utero-gestation, applies with peculiar force to the performance of it if undertaken before the term is completed, since the cervix uteri will not have undergone its full development. In numerous instances death has speedily followed after artificial delivery; in others, the event has not been so immediately fatal. In an instance of very recent occurrence, the comatose state in which the patient died did not take place for many hours after delivery; she was in the eighth month of pregnancy, and labour succeeded the artificial evacuation of the liquor amnii. Even admitting that the convulsions which arise previous to labour depend *primarily* upon the condition of the uterus, it is important to recollect that labour is not always necessary for their removal, and that whether delivery be effected artificially, or by the violence of the paroxysms, the convulsions may continue in full force, notwithstanding the evacuation of the uterus; possibly indeed, the impression previously made upon the brain may be increased by the efforts which attend delivery."—*Facts and Cases in Obstetric Medicine*, p. 31.

Again, he says, "It has been already stated that convulsions sometimes cease under *natural* and *spontaneous* labour-pains, nevertheless it is equally true that manual interference is, at the moment, calculated both to renew the paroxysm and render it more violent:

thus Denman found the mechanical dilatation of the os uteri productive of these effects, and the best informed writers, including Chaussier, fully confirm his statement. The principle of forwarding the dilatation of the os internum by means of the fingers, can only be commended when the orifice is in a soft and yielding condition; under contrary circumstances, the practice cannot fail to be injurious."—*Op. cit.* p. 33.

Mr. Symonds, in a paper on puerperal convulsions (*Lancet*, 8th Feb. 1834), after detailing the particulars of four cases successfully treated—first, by depletion, cold to the head, blistering, the warm bath, and camphor and opium—concludes in the following words: "Instructed by my own experience, and fortified by the authority of such writers as Denman, Blundell, and Gooch, I would say with the latter, take care of the convulsions, and let the uterus take care of itself." In this as a general principle Mr. Ingleby says that he quite concurs, and adds, "but exceptions to it may arise." When the attack appears during actual labour, our line of practice is clearly defined; we must moderate excessive action, and deliver on the first favourable moment. But should the convulsions *precede* labour, the practice pursued by Dr. Joseph Clarke (very similar to that recommended by La Motte) is the most rational that can be followed, viz. to trust to nature's efforts, aided by medical treatment, until the patient's life appears to be *immediately* endangered by the continuance of the disease, and then to interfere in the speediest and safest manner to promote delivery. The circumstances which justify interference demand an impartial and dispassionate consideration, and should embrace the state of the uterus, the presentation of the fœtus, the period of gestation, and the violence of the symptoms. An apprehension lest the patient may die undelivered has often proved an incentive for undertaking delivery at any risk, and, doubtless, the interests of the mother alone ought to decide so momentous a question; indeed, under severe and frequent paroxysms, especially of the tetanic kind, the child is frequently still-born. In Collins's cases, 14 of 32 children, including two twin births, were born

ON VIVISECTION.

To the Editor of the Medical Gazette.

SIR,

HAVING derived great pleasure from a letter in your last number from Dr. Hull, on the subject of vivisection, and having for some years past devoted at intervals some time to the consideration of that subject, I venture to offer a few remarks in corroboration of the sentiments of your enlightened correspondent. In my endeavours to promote methods of pathological investigation more strictly instructive than those commonly employed, I have been necessarily led to the examination of the general bearings of experiments on animals on the progress of physiological and especially on pathological science, and the result of such examination is the conviction, that so far as regards experiments involving the suffering of the animal, that they waste time which I am prepared to show might be better employed; that, philosophically, they are to the last degree inconclusive, and that they are morally indefensible. Either or all of these positions I am quite prepared to defend. But let me be understood: I object to no experiment which does not involve cruelty, nor do I include in the catalogue of cruel experiments those which imply the killing the animal with the ordinary expedition. Not the least interesting fact of the many which investigation of this subject discloses is, that the moment experiments cease to be cruel, they begin to be instructive; or if they are not, it is owing to some want of circumspection in the conduct of the experiment. I shall be quite ready to illustrate all that I say, on conditions presently to be mentioned; but I will now observe that it is about five years since that I offered to the Society for the Prevention of Cruelty to Animals, to make a digest of the principal experiments on living animals within the last 100 years (involving cruelty), in order to show that they had either not in the least degree assisted us in relieving disease, (because it must be remembered that is *our* object) or that if they had shown any thing in relation thereto, it was only that which might be much more satisfactorily de-

alive. Of 43 cases, including a twin birth, which occurred under Dr. F. H. Ramsbotham's observation, 21 of the infants survived. The death of the child is considered, by this gentleman, to depend rather upon a defective utero-placental circulation, than upon direct pressure; but the result may be occasioned by either cause.

"The want of success in delivering generally arises from one of two causes; the first—delivering too early, before the uterine orifice has undergone sufficient relaxation; the second—postponing the delivery until effusion has taken place, or a fatal impression been made upon the brain. Previous to delivery being attempted, sufficient relaxation of the uterus must therefore be obtained by bleeding or emetic medicines in nauseating doses, purgative enemata, and perhaps the application of belladonna to its orifice, otherwise we incur the risk either of an apoplectic seizure, or a laceration of the uterus or vagina.* This precaution has less regard to the degree of dilatation of the os uteri, (for the orifice is not unfrequently more or less open for many days before labour), than to its state of softness; and if a decided impression be made upon it during the paroxysm, the sooner delivery is accomplished the better. Although the uterine orifice often becomes relaxed earlier than we might *a priori* infer, a moderate degree of resistance is, in every delivery, both to be expected and desired: but a forcible entry into the uterus must be discountenanced by every rational practitioner. Ashwell considers that we may always dilate the uterus with the fingers: a statement which I cannot assent to, and it is with marked propriety that Collins strongly cautions the practitioner to 'avoid hasty measures for the delivery of the child.'" — *Op. cit.* p. 35, 36, 37.

All these considerations should be duly weighed, and we would particularly recommend to the junior practitioner a careful perusal of the admirable remarks of Mr. Ingleby on puerperal convulsions, in the work from which we have just quoted.—EDITOR.]

* Of five fatal cases recorded by Collins, three were complicated with laceration of the vagina.

monstrated by other and unobjectionable phenomena. The only condition was, that the Society should pay the expence of the publication; but although the offer was courteously received, either for want of funds, or some other reason with which I am unacquainted, I heard nothing more of the matter. Since that time two rather sharp illnesses have thrown some other matters in which I am engaged so much in arrear, that I cannot venture to repeat the offer; but if your or any other journal will open its columns for short demonstrations on the subject, and Dr. Hull and other gentlemen will lend their assistance, I promise to be a cheerful contributor. At pages 48, 52, and 54 to 56, of my last work, "Medicine and Surgery one Inductive Science," some remarks will be found on this matter, with a suggestion as to the mode of bringing the subject to the required test; but it is too long, I suppose, to quote. Suffice it to say, that I have plenty of material, and nothing would give me more pleasure than to see physiological science well rid of that which now misrepresents and disgraces it. One word as to coolness in operations. I agree with Dr. Hull, and having operated not a little, I know of no better rule than that of my old master Abernethy—"Never do an operation that you would not have performed on yourself, were you in similar circumstances." If, however, the leading motive should be lucre, display, or some others that I could mention, a surgeon may find himself obliged to dismiss his feelings, or lose his self-possession, and if any thing unexpectedly untoward happen, he may (as I have witnessed) be deprived of both.

I have the honour to be, sir,

Your obedient servant,

GEORGE MACILWAIN.

9, Argyle Place,
Sept. 16, 1843.

MR. LEE ON BELGIAN MEDICAL INSTITUTIONS.

To the Editor of the Medical Gazette.

SIR,

THE present brief notice of some of the Belgian medical institutions and practice may interest several of the readers of the MEDICAL GAZETTE, and

may serve as a *pendant* to that which I sent last year of those in Holland.

I am, sir,

Your obedient servant,

EDWIN LEE.

September, 1843.

Liege.—Although containing a population of 60,000 inhabitants, chiefly manufacturing and commercial, Liege possesses no good hospital; the one termed *de la Bavière* was formerly an ancient convent, the church now forming the principal ward. The surgical wards are low and indifferently ventilated; the medical wards on the first floor are loftier and more airy. On the walls are images of Saints, &c.; the sick are superintended by sisters of charity. The number of beds does not exceed 120, including those for the medical and surgical clinics. Two physicians and two surgeons perform the medical duties. The administration of this and the other charitable institutions (the Hospices, Bureau de bienfaisance, and Mont de Piété), is vested in a commission nominated by the regency. Among the most prevalent diseases at Liege, are phthisis, bronchial inflammation, scrofula, and rheumatic affections, which last are mostly treated by antiphlogistic measures, colchicum being very seldom employed. In scrofula, and incipient phthisis, the cod-liver oil is a common remedy. Inflammatory attacks, and fevers, are not usually treated by energetic depletory measures; contra-stimulants and cooling diuretic remedies, as the nitrate of potass, with an occasional laxative, being chiefly trusted to. Auscultation and percussion are not very generally employed, except by Dr. Lombard, who enjoys a high reputation in Liege. Stone cases are very uncommon.

The Hôpital de Santé is for chronic and syphilitic diseases. In order to be admitted, patients must obtain a certificate from the physician or surgeon, and from the Commissaire de Police. There are also at Liege a hospice for old men, one for old women, a lying-in and a foundling hospital, and out of the town a hospice for patients of either sex labouring under mental alienation, which, however, are little else than places of detention.

Many of the sick poor are visited at their own habitations. The University is a large detached building, containing a handsome library, cabinets of instru-

ments, anatomical and pathological preparations. Lectures are delivered within the building, but the examinations of candidates take place at Brussels. The number of the students is 450, of which scarcely 100 attend the medical classes.

The following are professors in the faculty of medicine:—

Dean, and Professor of Obstetrics, Simon. Descriptive anatomy, and general therapeutics, J. B. Royer. (Physiology, and general anatomy—Spring.) Dissections and materia medica, Vaust. Pathological anatomy, and hygiene, Raikain. Internal pathology and therapeutics, Sauveur. Surgical pathology and ophthalmology, Asiaux. Medical clinics, Lombard, and Frankinel. Surgical clinique, Delavacherie.

Brussels.—The old and ruinous hospital existing within the town was at the time of my visit about to be pulled down, and the patients transferred to the handsome new hospital St. John, in a more airy situation, on the Boulevard du Jardin Botanique, of which its extensive stone facade forms a chief ornament. It is built around a spacious court yard, at the extremity of which is a chapel, and contains 500 beds, including those for the clinics. The interior organization, and the disposition of the wards, will apparently leave nothing further to be desired in this respect. The chief physician is M. Van Cutsem; the surgeon, M. Uytterhoeven. The hospital St. Pierre, founded as far back as 1179, stands in an elevated position at the opposite end of the town. It contains 350 beds. The wards are clean and well ventilated, those for surgical diseases being on the ground, the medical on the first floor. There are besides, wards containing about 100 beds for syphilitic patients, and sick children, as also several rooms for patients who pay from two to six francs a day. The medical service is performed by a chief physician (M. Graux), a chief surgeon (M. Sentin), and assistants. Clinical instruction is given at the bed-side of those patients whose cases present the greatest interest. There are no separate clinical wards. Typhoid fevers, pulmonary complaints, chronic gastro-enteritis, scrofula, and diseases of the kidneys, are inferior orders at Brussels. The treatment of typhoid fever is mostly by a

moderate bleeding at the commencement, and subsequently a tonic or stimulating medication. When not counterindicated, the use of stimulants externally, as camphorated liniment, is likewise frequently combined with the internal measures. Aperients, and diaphoretics, are not much employed. Here, as in Paris, in almost all the patients who die from this disease, enlargement or ulceration of the follicular intestinal glands is met with. In inflammation of organs, energetic vascular depletion is not usually adopted; moderate general or local abstraction of blood, and blisters or other contra-stimulants, with appropriate internal medicines, being the means mostly adopted; more attention being paid to the patient's general condition, &c. than to the local disease, as regards the exhibition of remedies. *Tabes mesenterica* is very common among children and young persons; occasional leeching, and the exhibition of ioduret of potass, with the application of the ointment to the abdomen, a bland diet, and tepid baths, being the measures from which the greatest amount of advantage has been derived.

M. Sentin has the most private practice among the Brussels practitioners, and is known in other parts of the continent as well as in England, more especially from his method of treating fractures by starched bandages, which he applies, in all cases, from the first. Even when there is considerable swelling, and in compound cases pasteboard splints moistened so as to adapt themselves to the form of the parts being laid laterally beneath the turns of the bandage, and the interstices formed by the varying thickness of the limb being filled up by cotton wool, which is also placed along the edge of the pasteboard splints, to protect the soft parts from pressure. The application is never removed till the cure, but when matter is formed, or the swelling of the limb has subsided so as to produce slackening of the bandage, it is cut open with scissors, the superabundant edges of the pasteboard are broken off, and another bandage, pasted with the starch solution by an assistant with a painter's brush at the time of its application, is bound over the previous one, remaining until consolidation of the bone is effected.

This practice, which, with some modi-

fications, is now adopted in many European hospitals, and in private, is more particularly advantageous in fractures of the inferior extremity, from the circumstance of patients being thereby enabled to get about on crutches, or with a stick a few days after the accident, instead of remaining in bed for several weeks frequently, to the great detriment of the general health. In some cases which I treated at St. George's Hospital by Amesbury's apparatus—which, however, is too expensive and complicated, and requires more attention than the starched *appareil*—consolidation was procured within a much shorter period than by the old method, and in two or three instances the point where the tibia had been fractured could not afterwards be detected on feeling. In fractures of the upper extremity, however, this method presents little advantage over the ordinary one, nor is its application generally advisable in compound cases, for though the exclusion of the air from the wound, and immobility of the limb, are circumstances of the highest importance, still, where much injury of the parts has been inflicted, and suppuration is inevitable, serious consequences would often ensue, as was sometimes the case in the practice of Baron Larrey, who also had recourse to an analogous method of treatment in all cases in the hospital to which he was attached.

M. Sentin likewise employs the starched bandages in chronic diseases of the joints, and in some cases of tumor. Stone cases rarely occur in the hospitals at Brussels. Disease of the eyes, especially the ophthalmia formerly so prevalent in the army, now afflicts a large proportion of the inferior classes. Syphilitic cases, especially ulcerations of the face, are treated with great success by the ioduret of potass, to the extent in many instances of thirty grains daily.

Considerable sensation was excited in Brussels some time ago on account of a cataleptic patient who was magnetised at this hospital by M. Montère, in the presence of numerous physicians, students, and other persons, and who exhibited in a high degree the phenomena of clairvoyance, to the satisfaction of those present, including some members of the administration of hospitals. It is not my intention to enter into the details of this interesting case, but will

mention two or three of the circumstances.

While in somnambulism, she indicated the treatment to be pursued, and stated that she would be cured in six weeks if this treatment were followed; which in the successive *seances* was consequent, and never of a contradictory nature. After her eyes had been covered with a bandage she was able to indicate the persons behind her, their attitudes, the colour of their clothes, as well as some objects placed behind her head, notwithstanding one of the gentlemen present, as a further precaution, pressed his fingers upon the eyes over the bandage. Among others, the surgeon of the hospital of the Maternité held up behind her head several coins, which she immediately recognised; stating without any mistake which side of the coin was turned towards herself. M. Malvin, the director of the hospital, likewise addressed several questions to the somnambulist, to which she replied with the greatest exactness. Several experiments were tried to verify the abolition of sensibility, M. Sentin being present: among others, the flame of a candle was applied to her arm, without any sensation being evinced, notwithstanding she was seriously burnt. On awaking she experienced a slight degree of pain, at which she was surprised, not knowing the cause. M. Sentin having asked her whether he had any pain, she replied that he felt a pain in his left foot, which was the case, owing to a tight boot. The clairvoyance was not always present while she was in somnambulism, as she was sometimes lucid, at others not. The Hospice de l'Infirmierie is chiefly an asylum for 500 old people of both sexes. The Hospice de la Maternité contains about 50 beds: women are received in the last month of their pregnancy till after accouchement. There are also rooms for those persons who pay. A school of instruction in midwifery is attached. At the *Enfants trouvés* 500 infants is the average number of those annually received. They are for the most part sent into the country, and kept by the establishment till the age of 12 years. The *bureau de bienfaisance* supplies provisions and medical assistance at the houses of the sick poor, in different quarters of the city.

In my next I will give an account of the medical institutions of Ghent.

REPLY TO
A MEMOIR, BY M. MALGAIGNE,
ENTITLED,
RECHERCHES SUR LA FREQUENCE
DES HERNIES SELON LES SEXES,
LES AGES, ET RELATIVEMENT
A LA POPULATION.

By ROBERT KNOX, M.D. F.R.S.E.
Lecturer on Anatomy in Queen's College, Edinburgh, and Corresponding Member of the French Academy of Medicine.

DURING the winter session of 1836-37, I read to the Medico-Chirurgical Society in Edinburgh, a Memoir on "The Statistics of Hernia in Man, with some Observations on the Anatomical causes which determine its Production," which memoir was soon after published in the 128th No. of the Edinburgh Medical and Surgical Journal, and shortly afterwards republished by myself, with several other memoirs, in a small fasciculus of Anatomical and Physiological Memoirs.

These researches were originally undertaken, on my own part, with a view chiefly to shew that accurate data were altogether wanting to determine the ratio of hernia to the population, viewing the question almost in every way, and that consequently the statements of several estimable practical surgeons and others, respecting the great frequency of hernia, must, if extended to the population generally, be extremely erroneous, or, at the very least, entirely conjectural. Another object kept in view in the composition of my memoir was the ascertaining in how far a peculiar conformation of the pelvis contributed to produce hernia in either sex.

Now, sensible that my objects were these, I felt disposed at first to blame myself for a certain want of perspicuity in the composition of my memoir, inasmuch as one of the most candid critics of the day (I had almost said the most candid medical critic, the writer of at least a portion of the Medical and Surgical Journal, edited by Dr. Johnston) has said, in the notice he favoured my memoir with, that "after having objected to the conclusions of all others, Dr. Knox has arrived at none himself." But, reflecting again on the very object of my memoir, I saw that no blame could attach to me for not having put before the public data which do not exist. I

repeat, my memoir was written to shew that by far the greater number of opinions then held by medical men respecting the frequency of hernia, were mere opinions, and not derived from any proper statistics. Indeed, I might have gone a little farther, and said justly, though somewhat harshly, that the greater number of the authors whose opinions I quoted did not know the right meaning of the word "statistics." So far, then, I think the criticism alluded to has no force in its application to me, since it merely blamed me for not having obtained a ratio where no data existed. Let it also, however, be observed, that I certainly did arrive at the conclusion, that whilst hernia was "rather frequent," nay, perhaps, might ultimately be found to offer a comparatively high ratio in the hard-working labouring and mechanical class of the population, male and female, but more especially the former, there were classes remarkably free from this disease; amongst whom I included the very idle, the very rich, and, in this country, the aspirant for military honours, who would rather serve for sixpence a day, and do no work, than live *independent* by the sweat of his brow.

My next critic was a less candid one: I allude to Mr. Marshall, whose notions of statistics seem to me by no means very good. He says, that the "data drawn from dissecting rooms furnish no sure information, and especially no statistics to be depended on." Now, on the part of Mr. Marshall, this is speaking in great ignorance, and purely at random about what he does not understand; and it were easy to show, were it worth while, that the statistics of the practical-rooms, at least in this part of the kingdom, are much superior to most of his army reports in every sense. But it is not worth while to do so: Mr. Marshall can have no experience on these points.

My third critic is M. Malgaigne, who seems to me to be deficient in candour in speaking of his contemporaries. What he has said in the way of objection to my memoir may be reduced simply to two heads. 1st. He accuses me of having fallen into the strange error of "taking the ratio of hernia in a population of a certain age, and applying this ratio to the general population." I have looked over my

memoir with the greatest care and attention, and I cannot find a single passage warranting such an accusation. 2d. M. Malgaigne has pointed out a circumstance leading to error in my mode of estimating the ratio of hernia cases occurring amongst the conscripts of the French Army. The Athenæum, from which I took my information, simply stated that, of the 286,420 conscripts for 1833, there were 4,222 exempted from service as being affected with hernia. Unacquainted as I am with the routine of the French conscript laws, for the non-existence of which we Britons have every reason to be thankful to Providence, I could not possibly know that, of these 286,420 who appeared as conscripts, there were only 124,603 examined, of whom 4,222 were rejected for hernia. Thus, my average should have been rather more than three per cent. instead of one and a fraction. Now, after all, this correction makes the ratio approximate more nearly to my own conjecture. But admitting this correction to be right, as I presume it to be, does it really give us the ratio of hernia to the male population of the conscript age? I say it does no such thing; and this is precisely the conclusion I arrived at in my original memoir. The statistics of hernia (an extremely difficult question) is quite open for further inquiry, notwithstanding the laborious "Researches" of M. Malgaigne. In my observations on the Statistics of Hernia, I took occasion to point out several circumstances for which neither M. Malgaigne nor my other critics have given me credit.

1st. I believe I was the first to shew that the estimated valuations of the frequency of hernia to the general population, by Messrs. Turnbull, Munro, Sir A. Cooper, and others, were entirely worthless as statistical inquiries: this, at least, was coming to some conclusion, and not leaving the matter where I found it. 2d. The curious fact that, since the Anatomy Act came into force, hernia cases are very rarely met with in the Practical Rooms in Scotland. This I believe to be another *fact*, of which I am quite certain, in so far as regards my own Practical Rooms. 3d. I took the liberty of pointing out what I thought to be an extraordinary use or abuse of technical language on the part of Mr. Marshall, who, in the

drawing up some official reports, made the following statement. "Of 82 recruits rejected for hernia, there were, inguinal 32, ventral 44, umbilical 6." I called the attention of the readers of my memoir to the extraordinary fact of an army surgeon meeting with 44 cases of ventral, and 6 cases of umbilical hernia, in a short space of time; being a greater number of such cases than had been seen by half the surgeons of the empire. I suggested the following queries:—Were these cases of hernia? were they not rather laxity of the abdominal parietes? Mr. Marshall's statistics depend on his diagnosis, which I hope he does not consider infallible; mine are the result of anatomical investigation, made in presence of large bodies of medical students. 3d. Again, I suggested that I had seen many hundreds of the dark races (Caffres), and I had not noticed umbilical hernia to be at all frequent in the adult, from which I presume that the laxity of the abdominal walls around the umbilical orifice, if it exist in the children of the Caffre, as it is said by Mr. Marshall to do in the negro, must after a time cease. 4th. In attempting a comparison between the two great races which inhabit France, the Celt and the Kymri (which races, with M. Tiers and Edwards, he seems to consider distinct), M. Malgaigne ought, in fairness, to have stated that I was the first to attempt this new line of inquiry; instancing the Saxon Dutch at the Cape of Good Hope as being much afflicted with hernia, or at least presumed to be so on good authority, but without venturing to give to such observations the name of "statistics."

MEDICAL GAZETTE.

Friday, September 22, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

WHAT IS QUACKERY?

WHAT is quackery? A question more easily asked than answered, though few perhaps really are, and fewer still sup-

pose themselves to be, ignorant of its meaning. Dr. Johnson, while following the simple alphabetical order in his definitions, has thus suggested a remarkable development of the subject, a consideration of which may not only be interesting, but have great practical utility.

He begins with "To quack, *v. n.* (from the Dutch *quacken*, to cry as a goose) 1. to cry like a duck ; often written *quaake*, to represent the sound the better." Nothing can be more simple, more unsatirical, or inoffensive, than this primitive meaning. The word, or one like it, however, must surely have been used before Dutch was a language. It is impossible to believe that frogs were admitted to have cried out *ῥεκ-εκ-εξ*, as Aristophanes writes their croaking choruses, earlier than ducks and geese were admitted to cry quack ; and the difficulty of writing the latter word in the Greek character without the digamma, would only prove to an ingenious controversialist the necessity for that obsolete and once disputed letter. Hear Johnson again : "2. To chatter boastingly, to brag loudly, to talk ostentatiously.

Believe mechanick virtuosi
Can raise them mountains in Potosi,
Seek out for plants with signatures
To quack of universal cures.

HUDIBRAS."

It may here be noted, that a neuter verb is the only one mentioned ; the active verb "to quack," in the sense of to coddle, to physic, or advise one's self or others, seems to be a very modern invention. Perhaps no one used the verb till after modern dilettanti had thoroughly established the practice. That it is not a mere omission of the Doctor's, which he would honestly have attributed to forgetfulness, or "sheer ignorance, madam," as he did another mistake, is probable from this, that in the same page of our edition, the last

that has his own corrections, "Quadrille" means only "a game at cards ;" the dance and the doctoring were not yet subjects for the full flow of London talk. Next comes "Quack, *n. s.* from the verb, a boastful pretender to arts which he does not understand. 'The 'change, schools, and pulpits, are full of quacks, jugglers, and plagiaries.'—*L'Estrange*."

The 'change did not, in the time referred to, as it does now, suggest only the notion of Spanish actives and the like, but was frequented by physicians as well as merchants, so that the art of physic, though not expressly mentioned, was not perhaps meant to be excluded from those touched by the writer. To resume. 2. "A vain boastful pretender to physic ; one who proclaims his own medical abilities in public places. 'At the first appearance that a French quack made in Paris, a boy walked before him publishing with a shrill voice, My father cures all sorts of distempers, to which the doctor added in a grave manner, the child says true.'"—*Addison*. 3. An artful tricking practitioner in physic. "Despairing quacks with curses fled the place."—*Pope*. The natural sound of the well-known bird, the simple etymon, gradually made to include the idea of boastful yet hardly dishonest assumption, now conveys that of deceit and knavery. The awful brows of the literary giant must have been more closely knitted when he wrote as follows. "Quackery, mean or bad acts in physic ;" *in physic ! intra muros peccatur*. No example is given—could none be found ? and did the doctor with a seer's eye merely imagine in that century a word, for a thing to be invented in a future one. Surely the man who read a dictionary, and complained that though the author seemed very clever, his style was rather unconnected, did not read attentively enough,

or did not read Johnson. His dictionary, treated in the synthetical way, seems sometimes like a series of Essays—quite an anthology, from the abundance and beauty of its quotations; nay almost a poem, with the cantos shuffled.

To examine the subject more seriously. The regular practitioner is not more exempt from temptations to quackery, than the professor of religion is from temptations to hypocrisy, and a little attention will enable us to trace the progress of the former evil, the pathology of quackery from its first attack in the healthy subject, by following the alphabetical order of words in the dictionary.

The first symptom is a temptation merely to talk loud, to make himself heard—simply to quack (the verb neuter), natural to all, especially to youth, and harmless enough if it goes no further; but it is very apt to lead to *v. n. 2*—boasting, or making an undue parade of acquirements, real or [fancied]; and as great modesty usually attends great knowledge, a want of it is generally found amongst the ignorant and superficial. Forwardness, then, shallowness, and ignorance, lead to boasting. A shallow man thinks much of his own powers, and has not yet discovered his deficiencies; he assumes a character that does not belong to him, but he does it in ignorance, and without intentional dishonesty; he speaks only what he thinks when he boasts of his knowledge; he is merely mistaken. Many remain in this happy state of ignorance, quacking away, *tout bonnement*, without meaning or knowing it, in the daily use of the neuter verb, 2.

But worse threatens. He who has for some time sustained a character for knowledge which he does not possess, however honestly he may have believed that he did, is liable one day to be undeceived on this point; and then, if he

have a conscience, he feels called upon to be modest—to leave off boasting. If he do this, all may be well—another stage of the disorder has been gone through safely; if not, and this abstinence is difficult to such persons, he is in danger of becoming what is accurately defined “quack, noun substantive;” from the verb 1, a boastful pretender to an art which he finds he does not understand as well as he once said he did; and when his medical abilities are proclaimed in public places—when his own peculiar proselytes cry out in their various shrill tones that he cures all or any manner of distempers, he admits with much gravity of countenance that they say very true, and thus he furnishes as good an example as that in the dictionary of *n. s. 2*.

From the passively appropriating unmerited applause to the actively becoming an artful tricking practitioner in physic, *n. s. 3*, is a very easy transition; it follows naturally on more boasting, more case-hardening by time and competition, and to one strongly predisposed is quite unavoidable. It is obvious that each of these stages had its premonitory symptoms, and that previously to each, conscience might have suggested salutary treatment, and saved the patient. Those in whom the malady has fairly run its course to this melancholy point, have by that time generally given proof of their state, by publishing either in bold whitewash, or by hand-bills, or by advertisement in that particular column which every newspaper dedicates to their especial use.

Is thy servant a dog, that he should do this thing? is the natural exclamation on witnessing these gross offences against professional and general morality; but there are certain of our authors, who, although they seem to be restrained by timidity, or, one would

fain hope, some better motive, and who never get farther than a discreditable monograph on a popular malady advertised among the light reading of the day, yet differ, in reality, rather in degree than in kind from the most unblushing.

Against the boastful pretender to an art which he does not understand, the legislature confesses its inability or unwillingness to protect either the public or the profession. It must be evident, as we have elsewhere observed, that although acts of parliament may compass the punishment of particular quacks, yet they are powerless to prevent quackery. That portion of the public who have liberty to choose for themselves, who have intelligence enough to understand plausible arguments, but not knowledge enough to detect fallacies, must be, and always will be, the subjects to keep up the demand for quacks. Pretenders clever enough to get on without the realities of regular education, and powerful enough to despise its forms, will always be found to supply the demand. But even practitioners regularly educated will always be found in greater or less number to make up by quackery for those qualities which should have enabled them to compete with their professional brethren, and thus mislead many who would shrink from employing a professed and unlicensed quack.

The quackery of the dictionary—mean or bad acts in physic—can be prevented only by the prevention of meanness and badness in those who practise physic. A sound healthy training of the moral and intellectual faculties, diligence in the pursuit of science and cultivation of art, modesty in the self-estimation of attainments, moderation in desires for mere applause or emolument, whatever in

fact strengthens the intellect or revives honesty, will conduce to this end.

A profession, every member of which had these qualities in abundance, might indeed have quacks for its rivals, but would triumph without a combat.

THE CARLISLE CONTROVERSY.

THIS unseemly feud still continues. The Carlisle Journal of Saturday, the 16th inst. contains a second letter from Mr. Steel, the editor, to the Bishop of Carlisle. He defends himself for having drawn the public attention to Clark's case, and says, "I undertook the unpleasant task, not in concert with the medical men—the 'Medical Trades Union,' as they have been called with as much vulgarity as indecency—but as a duty, which my position as a journalist, and a governor of the Institution, fairly imposed upon me."

He is highly indignant with the Committee of the Infirmary for having unanimously declared that the accusations of neglect and improper treatment against their medical officers were totally unfounded, as proved on the inquest. Mr. Steel, also, stoutly defends the calling of an inquest; and thinks it not only justifiable, but quite the usual sort of thing in such a case—an opinion in which few reasonable persons will agree with him. The instances which he cites to strengthen his argument are not in point. On the 17th of August, it seems, an inquest was held in Lancashire on an unfortunate pauper, who died of disease of the lungs, which had been overlooked by the parish surgeon, who pronounced his sickness all a sham. Or, as another example, an inquest was lately held on the body of a woman who died after delivery. In both these instances the supposed error of the practitioner was immediately followed by the death of the patient; in the Carlisle case more than seven months intervened, as well as a long treatment by other practitioners. Mr. Steel answers the charge of falsifying the verdict of the jury in Clark's case, by giving a letter from Mr. Carrick, the Coroner, who furnished the verdict published in the

Journal of the 2d inst. and affirms it to be correct.

The following extracts will interest our readers, as it is obvious that the controversy, though nominally carried on by the editors of the Journal and the Patriot, is really sustained by professional combatants. Each faction in Carlisle might say to the mouth-piece of its rivals—

Non me tua fervida terrent
Dicta, ferox; Dii me terrent, et Jupiter hostis.

*From the Carlisle Journal of Sept. 16th.**

This, my Lord, settles the question of the coroner's duties and responsibilities, and I venture to prophecy that we shall not again hear a repetition of the threats which have been so abundantly thrown out within the last ten days, of instituting legal proceedings against him for doing that which, had he failed to do, would have subjected him to fine and imprisonment. Of Mr. Carrick's mode of conducting the inquest it is unnecessary to say much. The Coroner's Court is a Court of *inquiry*,—and, if it be not intended to frustrate the very object of its institution, a much wider latitude must be given to the examination of witnesses than is either necessary or required in our courts of record. In the one case, the coroner has often to grope his way in the dark, amidst unwilling or hostile witnesses, whilst in the other every thing is prepared, and it is known exactly what each individual can say, and the precise bearing of his evidence upon the case. Here strict rules may be observed; but were they to be applied by the coroner, in nine cases out of ten his inquiry would prove a total failure. The medical journals remark upon Dr. Jackson and Mr. Elliot being allowed to put questions to the witnesses. In making such remark, they were not aware that these gentlemen were present as accused parties—as men who, though courting the investigation, had been pointed to by Dr. Barnes as the men by whose treatment the death of Clark had been accelerated; and standing in that position, they were fully entitled, in that or any other court, to put such ques-

tions as were relevant to the object of the investigation.

With respect to Dr. Lonsdale's connection with this case, your Lordship, at all events, will not fail to appreciate the dishonesty of the attempt to detract from the weight of his evidence by insinuating the imputation of malevolence; as you will have no difficulty in estimating the amount of truth in the assertion that he was "an unsuccessful competitor with Dr. Barnes for practice in the district," whilst residing some years ago as a general practitioner in your Lordship's own neighbourhood. The very grossness of the assertion defeats its object.

From the Carlisle Patriot of Sept. 16th.

Mr. Steel then enlarges upon the treatment of the patient Clarke in the Infirmary, but it is clear that all his showy information upon this part of the subject is derived exclusively from the doctors who attended Clarke for four months previous to his death, and under, or in spite of, whose treatment he sunk. Dr. Jackson and Mr. Elliot agreed to consider Clarke's case one of that particular kind of scrofulous affection of the hip-joint commonly known as *morbus coxarius*, which is a surgical case, usually occurring in young children, and never within the reading or experience of even the Medical Trades Unionists, in adults of fifty years of age, as Clarke was. All their charge, all their treatment, and the *hope* of their conspiracy, rested upon the correctness of this view of his case. But in point of fact it has been proved, we may say to demonstration, that this patient's affection was one of "*rheumatism*," to which he had been constantly subject for eight years, and more, previous to his death, and with which several members of his family were affected; but it was accompanied by chronic inflammation of the ligaments and tendons surrounding the joint, and this constituted the kind of *morbus coxarius* for which Dr. Barnes treated the deceased. The erudition of Mr. Steel, therefore, however laboriously got up for the nonce, the reading and experience, such as it was, of the doctors who operated upon Clarke, and the testimony of those who subsequently saw him, and even of that "eminent" personage who pretended

* In our last number, the extract beginning, "When I left" (page 873, col. 1), and ending, "remarked it" (col. 2), should have been separated from the previous passage, as it is taken from a different part of the Carlisle Journal.

to give an opinion without having seen the case at all, were utterly inapplicable to the particular affection under which Clarke laboured when a patient of the infirmary, and in this opinion we are borne out to a considerable extent by the opinions of the medical journals, which we publish in full in our last page. * * * They gave him professional attendance for 17 weeks, and then the man died; upon which they requested the coroner to hold an inquest upon the body of one who had virtually become their own patient—because, forsooth, they did not feel easy at the imputations likely to attach to their treatment. They have attempted, therefore, to remove the blame from their own shoulders to the medical officers of the infirmary, who, it must be remembered, had not seen the man for nearly eight months, and who, therefore, could know nothing about the cause of his death, much less be held responsible for it.

REGULATIONS TO BE OBSERVED BY STUDENTS

INTENDING TO QUALIFY THEMSELVES
TO PRACTISE AS
APOTHECARIES IN ENGLAND AND
WALES, 1843.

[We have just received the new edition of the Regulations of the Society of Apothecaries, which we subjoin in full, believing it may be convenient for medical students to have them before they commence their winter courses.—ED. GAZ.]

EVERY Candidate for a Certificate of Qualification to practise as an Apothecary, will be required to produce Testimonials,

1. Of having served an Apprenticeship, of not less than five years, to an Apothecary:

No gentleman practising as an apothecary in *England or Wales* can give his apprentice a legal title to examination, unless he is himself legally qualified to practise as an Apothecary, either by having been in practice prior to or on the 1st of August, 1815, or by having received a certificate of qualification from the Court of Examiners. An apprenticeship for not less than five years to Surgeons practising as *Apothecaries* in *Ireland and Scotland*, gives to the apprentice a title to be admitted to examination.

2. Of having attained the full age of 21 years:

As evidence of age, a copy of the baptismal register will be required in every case where it can possibly be procured.

3. Of good Moral Conduct:

A testimonial of moral character from the gentleman to whom the Candidate has been an apprentice, will always be more satisfactory than from any other person.

4. And of having pursued a Course of Medical Study in conformity with the Regulations of the Court.

Course of Study.

Every Candidate whose attendance on Lectures commenced on or after the 1st of October, 1835, must have attended the following Lectures and Medical Practice during not less than three winter and two summer sessions: each winter session to consist of not less than six months, and to commence not sooner than the 1st nor later than the 15th October; and each summer session to extend from the 1st of May to the 31st of July.

First Winter Session.—Chemistry. Anatomy and Physiology. Anatomical Demonstrations. Materia Medica and Therapeutics; this course may be divided into two parts of fifty Lectures each, one of which may be attended in the Summer.

First Summer Session.—Botany and Vegetable Physiology; either before or after the first winter Session.

Second Winter Session.—Anatomy and Physiology. Anatomical Demonstrations. Dissections. Principles and Practice of Medicine.

Second Summer Session.—Forensic Medicine.

Third Winter Session.—Dissections. Principles and Practice of Medicine.

Midwifery, and the Diseases of Women and Children, two courses, in separate sessions, and subsequent to the termination of the first winter session.

Practical Midwifery, at any time after the conclusion of the first course of Midwifery Lectures.

Medical Practice during the full term of eighteen months, from or after the commencement of the second winter session; twelve months at a recognised hospital, and six months at a recognised hospital, or a recognised dispensary; in connection with the hospital attendance, a course of *clinical lectures*, and instruction in *morbid anatomy*, will be required.

The sessional course of instruction in each subject of study is to consist of not less than the following number of lectures:

One hundred on chemistry. One hundred

on *Materia Medica* and Therapeutics. One hundred on the Principles and Practice of Medicine. Sixty on Midwifery, and the Diseases of Women and Children. Fifty on Botany and Vegetable Physiology.

Every *examination* of an hour's duration will be deemed equivalent to a lecture*.

The lectures required in each course must be given on separate days.

The lectures on Anatomy and Physiology, and the Anatomical Demonstrations, must be in conformity with the regulations of the Royal College of Surgeons of London in every respect.

Candidates must also bring testimonials of instruction in Practical Chemistry, and of having dissected the whole of the human body once at least.

The above course of study may be extended over a longer period than three winter and two summer sessions, provided the lectures and medical practice are attended in the prescribed order, and in the required sessions.

Those gentlemen whose attendance on lectures commenced before the 1st of Oct. 1835, will be allowed to complete their studies in conformity with the previous Regulations of the Court.

Recognition of Lecturers and Schools.

No Member of the Court of Examiners will be recognised as a lecturer on any branch of medical science.

The Court will not recognise any lecturer unless he lectures in connection with a recognised medical school; nor will they recognise a lecturer on more than *two* branches of medical science; nor will they recognise a lecturer until he has produced very satisfactory testimonials of his attainments in the science he purposes to teach, and of his ability as a teacher thereof, from at least two persons of acknowledged talents and distinguished acquirements in the particular branch of science in question; nor will they recognise a lecturer until he has given a public course of lectures on the subject he purposes to teach; but if, after such preliminary course, the lecturer shall be recognised, certificates of attendance on that course will be received.

Satisfactory assurance must also be given that the teacher is in possession of the means requisite for the full illustration of his lectures, viz. that he has, if lecturing—

On Chemistry, a laboratory and competent apparatus:

On *Materia Medica*, a museum sufficiently extensive:

On Botany, a *hortus siccus*, plates or drawings, and recent plants:

On Midwifery, a museum, and such appointment in a public institution as may afford the means of practical instruction to the pupils.

The lecturer on the Principles and Practice of Medicine, if he lectures in London, must be a member of the Royal College of Physicians of London; and if in a provincial town, either a member of the Royal College of Surgeons of London, or a graduated Doctor of Medicine of a British University of four years' standing, unless prior to his graduation he had been for four years a licentiate of this Court.

The lecturer on *Materia Medica* and Therapeutics must be a member of the Royal College of Physicians, or a graduated Doctor of Medicine of a British University of four years' standing; or he must have been a licentiate of this Court for the same period.

The lecturer on Midwifery must be a member of one of the legally constituted Colleges of Physicians or Surgeons in the United Kingdom, of four years' standing, or he must have been a licentiate of this Court for the same period.

The names of the lecturers recognised by the Court may be known on application to the Secretary at the Hall of the Society.

The certificates of teachers recognised by the constituted medical authorities in Dublin, Edinburgh, Glasgow, and Aberdeen, as also those of the medical professors in Foreign Universities, are received by the Court.

Much inconvenience having arisen from the presentation of schedules signed by *lecturers unknown to the Court*, it is particularly requested that the Registrars of the medical schools will furnish a correct list of their recognised teachers to the Secretary of this Court, at the commencement of every winter session.

No Hospital will be recognised by the Court, unless

1. It contain at least one hundred beds:
2. It be under the care of two or more physicians, members of the Royal College of Physicians of London, or graduated Doctors of Medicine of a British University:

3. The physicians give a regular course of clinical lectures and instruction in morbid anatomy:

4. The apothecary be legally qualified, either by having been in practice prior to the 1st of August, 1815, or by having received a certificate from this Court.

No Dispensary will be recognised by the Court, unless it be situated in some town where there is a recognised medical school, and be under the care of at least two physicians and an apothecary legally qualified.

No Medical Practice will be available, unless it be attended in conformity with the course of study prescribed for pupils.

* The Court particularly request attention to this clause.

Registration of Testimonials.

All testimonials must be given on a printed *schedule**, with which students will be supplied at the time of their first registration :

In London, at this Hall.

In Edinburgh, at Messrs. Mac Lachlan and Stewart's, booksellers.

In Dublin, at Messrs. Hodges and Smith's, booksellers.

In the Provincial Towns, from the gentlemen who keep the registers of the medical schools.

All students, in London, are required, *personally*, to register the several classes for which they have taken tickets ; and those only will be considered as complying with the regulations of the Court, whose names and classes in the register correspond with their schedules.

Tickets of admission to lectures and medical practice must be registered in the months of October and May ; but no ticket will be registered unless it be dated within *seven* days of the commencement of the course : and certificates of attendance must be registered in the months of April and August. Due notice of the days and hours of such registrations will be given from time to time.

The Court also require students at the provincial medical schools to register their names in their own hand-writing, with the registrar of each respective school, within the first twenty-one days of October, and first fourteen days of May ; and to register their certificates of having duly attended lectures or medical practice within fourteen days of the completion of such attendance.

The registrars are requested to furnish the Court of Examiners with a copy of each registration *immediately* after its close, as those students only will be admitted to examination whose registrations have been *duly* communicated to the Court.

Names of Gentlemen having the care of the Registers.

Bath.—R. T. Gore, Esq. Lecturer on Anatomy.

Birmingham. — W. Sands Cox, Esq. Lecturer on Anatomy.

Bristol.—Dr. Wallis, Henry Clark, Esq. Lecturers on Anatomy.

Hull.—Edward Wallis, Esq. Lecturer on Anatomy.

Leeds.—Thomas Nunneley, Esq. Lecturer on Anatomy.

Liverpool. — Dr. Malins, Lecturer on Medical Jurisprudence.

Manchester. — Thomas Turner, Esq. ;

Thomas Fawdington, Esq. Lecturers on Anatomy.

Newcastle.—William Dawson, Esq. Lecturer on Midwifery.

Sheffield. — W. Jackson, Esq. Lecturer on Anatomy.

York.—John Hopps, Esq. Lecturer on Anatomy.

Preliminary Examination.

Students may undergo their Latin examination at any time after their first registration, except during the months of August and September. A book is opened at the Beadle's office at the Hall, for the signatures of those gentlemen who are desirous of undergoing this examination, to which twenty will be admitted on each successive Saturday ; but unless twenty names are entered on the list, no examination will take place. Candidates are required to attend at half-past three o'clock, and those who fail to pass this examination satisfactorily, will not be re-admitted until they appear for their general examination.

Examination.

Exery person intending to offer himself for examination must give notice in writing to the Clerk of the Society on or before the Monday previously to the day of Examination, and must at the same time deposit all the required testimonials at the office of the Beadle, where attendance is given every day, except Sunday, from *Ten* until *Four* o'clock.

The examination of the candidate for a certificate of qualification to practise as an Apothecary, will be as follows :—

In translating portions of the first four books of Celsus de Medicinâ, and of the first twenty-three chapters of Gregory's *Con-spectus Medicinæ Theoreticæ*.

In Physicians' Prescriptions, and the *Pharmacopœia Londinensis*.

In Chemistry.

In Materia Medica and Therapeutics.

In Botany.

In Anatomy and Physiology.

In the Principles and Practice of Medicine. This branch of the examination embraces an inquiry into the pregnant and puerperal states ; and also into the diseases of children.

The examination of the candidate for a certificate of qualification to act as assistant to an apothecary, in compounding and dispensing medicines, will be as follows :—

In translating Physicians' Prescriptions, and the *Pharmacopœia Londinensis*.

In Pharmacy and Materia Medica.

By the 22d section of the Act of Parliament, no rejected candidate for a certificate to practise as an apothecary can be re-examined until the expiration of six months from his former examination ; and no rejected candi-

* It is particularly requested that the lecturer himself will fill up the blanks in the schedule, specifying the mode of attendance.

date as an assistant until the expiration of three months.

The Court meet in the Hall *every Thursday*, where candidates are required to attend at a quarter before four o'clock.

The Act directs the following sums to be paid for certificates.

For London, and within ten miles thereof, ten guineas.

For all other parts of England and Wales, six guineas.

Persons having paid the latter sum become entitled to practise in London, and within ten miles thereof, by paying four guineas in addition.

For an Assistant's certificate two guineas.

By order of the Court,

HENRY BLATCH, Sec.

Apothecaries' Hall,
Aug. 1843.

For information relative to these Regulations, students are referred to the Beadle, at Apothecaries' Hall, every day (Sunday excepted), between the hours of ten and four o'clock.

It is expressly ordered by the Court of Examiners, that no gratuity be received by any officer or servant of the Court.

Information on all subjects connected with the "Act for better regulating the Practice of Apothecaries," may be obtained on application to Mr. R. B. Upton, Clerk of the Society, at the Hall every day (Sunday excepted) between the hours of one and three o'clock.

QUALIFICATIONS OF MEDICAL OFFICERS OF POOR LAW UNIONS.

(From the *Western Luminary*.)

WE have been favoured with the following letter and opinion relating to a matter of great importance to members of the medical profession, by Mr. J. G. Bidwill, clerk to the St. Thomas Union.

"Poor Law Commission Office, Somerset House,
August 31, 1843.

"Sir,—In consequence of a communication made to them by Her Majesty's Principal Secretary of State for the Home Department, the Poor Law Commissioners have consulted the Attorney-General and another counsel on the competency of medical practitioners possessing Scotch and Irish qualifications to act as officers in a union or parish under the Poor Law Amendment Act.

"The effect of this opinion (a copy of which is annexed for your information) is as follows:—

"1. That persons having a surgical diploma or degree from a Royal college or university in Scotland or Ireland, are legally

as competent to be medical officers under the Poor Law Amendment Act as persons having the diploma of the Royal College of Surgeons in London.

"2. That persons having only Scotch and Irish medical qualifications are not, as such, competent to practise pharmacy in England and Wales.

"The commissioners think they are, by this opinion, justified in admitting persons having a surgical diploma or degree from a Royal college or university in Scotland or Ireland to the same rights under the Poor Law Amendment Act as members of the Royal College of Surgeons of London.

"The commissioners will, therefore, be prepared to consent to such arrangements, and to make such modifications in their general order of the 12th of March, 1842, as may be necessary to give effect to the above recited opinion of the Attorney-General.—I am, sir,

Your very obedient servant,

"E. CHADWICK, Sec."

Question arising out of the Case.—

"Whether persons on whom medical degrees, diploma, or licenses have been conferred by the universities or other medical authorities in Scotland or Ireland, are competent to be appointed and to act as medical officers under the 4th and 5th William IV., c. 76?"

Opinion.—"We are of opinion, that as far as the question of surgery is concerned, those persons who have a surgical diploma, or degree, from a Royal college or university in Scotland or Ireland, are (in point of law) as competent to be appointed and to act as medical officers under the statute referred to as the persons who have the diploma of the Royal College of Surgeons in London.

"With respect to pharmacy, the right to practise in England and Wales is confined to those who have the license or certificate of the Apothecaries' Company, and other persons whose rights are saved by the Apothecaries' Acts; and in our opinion persons having Scotch and Irish medical degrees are not among such last named persons.

"F. POLLOCK.

"S. MARTIN."

NEWS FROM ANTIGUA.

WE are indebted to a correspondent for three numbers of the Antigua Weekly Register, being those for the 4th, 11th, and 18th of July. The most interesting article contained in them is the report of a trial for poisoning, which took place on the 14th of June. The prisoner, a woman named Patience, was indicted for having poisoned four of her half-brothers with arsenic. She had already been indicted for

the same offence last December; but the jury were unable to agree upon their verdict; and the Commission having expired, the trial was necessarily cut short. This year the March sessions were postponed, on account of the earthquake in February.

The facts of the case are simple enough. The children died after eating porridge prepared by the prisoner; and arsenic was found not only in the porridge, but in the stomachs of two of the victims. Moreover, one Robert Brown, shopman to Dr. Fergusson, declared at the inquest that he had not sold any arsenic to Patience, but declared afterwards that he *had*. As this second declaration, however, did not take place till Brown's memory had been refreshed by a proclamation offering a reward for the discovery of the murderer, the jury do not appear to have believed it. We suppose that Brown was a witness at the trial, but in the report before us his evidence is merely given at second-hand by Dr. Fergusson.

When the earthquake occurred in February, "Patience was locked up in the room allotted to her on the upper floor of the jail, and as the walls fell she made her way through the crumbling masses, and leaping from the gallery into the yard, escaped without a contusion. Although it is unquestionable that she was frequently absent from the prison at night, owing to the insecure state of the ruins, she invariably returned, and remained in custody until the morning of her trial." This circumstance, no doubt, had its weight with the jury, who, after an absence of a quarter of an hour, returned into court with a verdict of acquittal.

"The prisoner was immediately discharged amidst the noisy and indecorous expressions of applause indulged in by the crowd which thronged the court and its approaches. Only one man was seized, who was joining in the uproar; and he was forthwith committed by the Bench to the Common Jail for thirty days."

This trial leaves an unsatisfactory impression on the mind: one is scarcely convinced of the innocence of Patience; and if she is innocent, what must Robert Brown be? The earth, vast as it is, is scarcely wide enough for both!

We will extract another paragraph from these Registers, of a more agreeable cast.

"We are informed that fifteen fugitive slaves, from Guadeloupe, arrived in a small boat at the Island of Montserrat last week."

Our colonies now enjoy, like their mother country, the privilege of giving freedom to the slave; to *him* every rock over which the British flag floats is a sanctuary, where "the wicked cease from troubling, and the weary are at rest."

VARUS MENTAGRA AND GUTTA ROSEA, THE SYCOSIS MENTI AND ACNE OF WILLAN,

TREATED WITH SULPHATE OF IRON EXTERNALLY.

By W. DAUVERGER.

Of all the modes of treatment recommended for these obstinate affections, the following appears to have been the most useful in the author's hands.

The sulphate of iron in different forms is the most efficacious local remedy for the pustular inflammation of gutta rosea, and mentagra.

It is used in solution, either by bathing the part affected, or by applying linen dipped in it, or by sprinkling the ulcerated parts of the mentagra with a mixture of charcoal and sulphate of iron. This mixture need not be finely levigated, for it then forms a crust too easily, becomes lumpy, and is not easily removed by washing the beard. In spite of his previous opinions, M. Dauverger also tried a pommade of sulphate of iron, but was obliged to give it up. The following are the formulæ employed by him.

No. 1.—Sulphate of iron twenty-five grammes. Distilled water two hundred grammes. Dissolve.

No. 2.—Sulphate of iron fifty grammes. Distilled water two hundred grammes. Dissolve.

No. 3.—*Ferro-carbonic powder*. Sulphate of iron ten grammes. Charcoal thirty-five grammes. Powder and mix.

The author first treats the inflammatory symptoms with emollients; when he thinks them sufficiently reduced, he orders the patient to bathe the part twice a day with two glasses of warm water containing one or two spoonfuls of the solution No. 1. A quarter of an hour afterwards, he prescribes a local bath of an emollient decoction; and afterwards, if possible, the application of a poultice of the same kind. When no further improvement takes place under this treatment, he has recourse to No. 2, which is twice the strength of the former, and proceeds in the same way. The author employs general means of treatment at the same time.—*Gazette Médicale*, Sept. 9, 1843.

CONVENIENT MODE OF ADMINISTERING OIL OF TURPENTINE.

By M. BOUCHARDAT.

THE oil of turpentine is very often used internally, and might be employed still

more frequently, were it not that the usual formulæ for its administration, such as the terebinthinous ether, or Durand's remedy, turpentine emulsion, and the different terebinthinous mixtures, all fail in masking the disagreeable taste of this medicine. The following, however, is the form of an electuary which M. Bouchardat assures us may be administered with the greatest ease.

Take of gum acacia, ten grammes; mix it with ten grammes of water; add of white honey, fifty grammes; oil of turpentine, fifty grammes; carbonate of magnesia, q. s. Make a soft electuary.

The dose is from 2 to 10 grammes (36 to 180 grains) a day, in unleavened bread.

In some cases a little opium, or from 10 to 20 drops of Rousseau's laudanum, may be added to the mucilage in the above mixture.—*Bulletin Général de Thérapeutique*, and *Gaz. Médicale*.

ADULTERATION OF COMMON SALT AT PARIS.

THREE years ago, it was found that of three thousand samples of common salt taken from the druggists of Paris, more than a tenth part was adulterated. The same fraud has just been discovered among a number of grocers. On making the visits enjoined by the law (which ought to take place in the other towns of France likewise), it was found that some samples showed traces of copper, and were adulterated with a large proportion of impure carbonate of soda (*sel de varech*), containing iodine. Three specimens contained small crystals of a salt of copper.—*Gazette Médicale*, August 26th.

NARROW ESCAPE OF A DRUGGIST.

A DRUGGIST was lately summoned before the police tribunal of the Seine, for having infringed the 34th article of the law of the 21st Germinal of the year XI, which enacts that poisons are to be kept in a separate place, and to be locked up, under a penalty of 3000 francs. The court was of opinion, however, that the sale of the poison was necessary to bring the offence within the meaning of the enactment; and as this had not occurred in the case before them, they merely put into execution the 471st article of the penal code, and adjudged the druggist to pay a fine of five francs, and the expenses.—*Gazette Médicale*.

APOTHECARIES' HALL.
LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, September 14, 1843.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XLV.

*On Diseases of the Brain and Mammæ in
Puerperal Women.*

MILIARY fever, intestinal and remittent fever, ephemeral fever or weed, pneumonia, bronchocele, stranguary, paralysis, diarrhoea, tympanites, and various spasmodic and nervous disorders, have all been enumerated by systematic writers as peculiar to puerperal women, but as I have no observations of the slightest importance to make respecting these, I shall conclude this department of the course—the pathology of the puerperal state—with a few very general remarks on diseases of the brain and nervous system, and of the nipples and mammæ. From sympathy with the great uterine system of nerves after delivery, there is often a predisposition manifested to disease in the brain, and violent cerebral derangement is produced by causes which, at other times, would have had no effect. In the fifth vol. of the Transactions of the London College of Physicians there is a Paper, by Dr. J. Clarke, on the Effects of Certain Articles of Food, especially of Oysters, after Child-birth, in which are related fatal cases which followed the use of oysters in the puerperal state; and the same effect has been produced by other articles of diet. Fourteen days after delivery a lady was attacked with giddiness, then with violent pain of the head, neither of which yielded to the common remedies. The symptoms increased rapidly; she became senseless and delirious, and convulsions and death followed. Towards the close of the disease

it was ascertained that she had eaten oysters on the day preceding the attack. A young, healthy, plethoric woman, three weeks after a natural labour, was attacked with pain of the head. A day before she had eaten five or ten oysters, which had been dressed by boiling them in the liquor contained in the shells. Venesection, emetics, and purgatives, were employed, and the symptoms were mitigated for a time; but convulsions came on, and compression of the brain, and she died in no long time. Dr. J. Clarke has also related the case of another young healthy woman, who began a few days after delivery to complain of headache, and a sense of internal fulness in the head. These symptoms not having yielded to bleeding, purging, and low diet, a state of coma came on, and she died in sixteen hours. On the day preceding the attack she had eaten twelve raw oysters. On the third day after a natural labour, a woman, who was recovering in the most favourable manner, was suddenly attacked with a severe fit of cold shivering, followed by violent headache, throbbing of the temporal arteries, intolerance of light and sound, and other symptoms which indicated the existence of a dangerous affection of the brain. The pulse was 130, skin hot, tongue loaded. The abdomen was soft and puffy, and not affected by pressure. I ascertained that the attack was produced by the patient having eaten a quantity of ham twelve hours before. The symptoms were relieved by calomel and purgatives. Another woman, on the eighth day after a natural labour, was suddenly attacked with insensibility and convulsions. Twenty ounces of blood were taken away by cupping from the temples, and repeated doses of active cathartics were administered, and she recovered. A few hours before the attack she partook rather heartily of roasted chicken and salted tongue, with a friend who had come to visit her.

Inflammation of the brain and its membranes, in puerperal women, is not a disease of frequent occurrence. The symptoms are

those of common phrenitis, not of insanity. There is headache, flushing of the face, throbbing of the arteries, intolerance of light and sound, and delirium. General and local blood-letting, and active purgatives, should be had recourse to as soon as possible, and all the other remedies usually employed in inflammation of the brain: the patient should be kept in a dark room, and ice in a bladder applied over the shaven scalp. Puerperal mania is a much more common disease than inflammation of the brain, and the symptoms and treatment do not essentially differ from mania as it occurs in women who have not been pregnant, or even in the male sex. Without knowing the history of the patient, it would be impossible in any case to ascertain, from the phenomena alone, whether the disease had followed delivery. In puerperal women it assumes all the varied forms of ordinary insanity, occurring sometimes with symptoms of deep depression or melancholy, and at other times with symptoms of great excitement—talking incessantly and vehemently, pouring forth a torrent of words, and running from one subject to another without the least order in their ideas. In some cases the disease first manifests itself by want of sleep and restless nights, and a peculiar irritability of temper, the temper being ruffled at the merest trifles. Often it is first marked by some unreasonable dislike to the nurse, and she is accused unjustly of carelessness and inattention, or the husband is charged with infidelity, or some other crime. In some cases the aberration of mind is preceded by headache and other symptoms of cerebral irritation, quick pulse, and hot skin; while in others there is little derangement of the bodily functions, the circulation being almost natural, the skin cool, and the digestive organs very slightly disordered. Sometimes puerperal insanity is preceded by an attack of violent uterine irritation; there is pain of the hypogastrium, increased by pressure, and some other symptoms of uterine inflammation, which have speedily disappeared on the supervention of the mental disorder. In the greater number of cases puerperal mania occurs after natural labours, and has not been preceded by any peculiar derangement of the digestive organs during pregnancy, or uterine hæmorrhage during labour.

There is an hereditary predisposition to the disease in a considerable number of those who become affected, and some have suffered from it repeatedly in the puerperal state. The disease is attended with much greater danger when it occurs soon after delivery, with symptoms of violent excitement of the brain, than when it commences several months after, during suckling, in the form of melancholy madness. Dr. Burrows published a table of fifty-seven cases, of which ten died. Of *ninety-two* patients at the Salpêtrière, six

died, or one in fifteen. Of these ninety-two cases recorded by M. Esquirol, sixteen occurred from the first to the fourth day after delivery; twenty-one from the fifth to the fifteenth day; seventeen from the sixteenth to the sixtieth day; nineteen from the sixtieth day to the twelfth month of suckling; and in nineteen cases it appeared after voluntary or forced weaning. M. Esquirol infers that puerperal mania occurs more frequently as the consequence of delivery than of nursing, and that the more distant the time at which it occurs from the period of delivery, the less it is to be feared. Of these ninety-two cases, eight were idiotical; thirty-five melancholic; and forty-nine maniacal. The ages of these numbers were as follows:—twenty-two from 20 to 35 years of age; forty-one from 25 to 30; and twelve were upwards of 40: therefore, neither delivery nor suckling, according to this statement, modify derangement as far as age is concerned, for in this disease, produced by other circumstances, it most frequently occurs between the ages of 30 and 35. Sixty-three of the cases related by M. Esquirol were married women; twenty-nine single. Fifty-six out of the ninety-two were entirely restored to health; thirty-eight of these recovered in the first six months. The appearances on dissection, it is stated, threw no light on the nature of the disease. These ninety-two cases of puerperal mania were treated by mild purgatives frequently repeated, by blisters to the nape of the neck and limbs, enemata, and baths; bleeding was seldom indicated. In the treatment of puerperal mania the greatest attention should be paid to the state of the brain and of the digestive organs. If the countenance is flushed, the carotid and temporal arteries throbbing violently, the head should be shaved, and blood drawn by leeches from the temples. When there is strong general excitement of the circulation, combined with these symptoms of local determination to the brain, blood should be drawn from the arm in quantity proportioned to the severity of the symptoms. In ordinary mania, decided benefit is sometimes produced by moderate general depletion, and after this great advantage follows the application of ice, in a bladder, to the scalp, or a cold evaporating lotion. Light and noise should be carefully excluded, and a nurse accustomed to the charge of insane persons should have the care of the person. It must be a mild, but vigilant and firm control, which is exercised, and especial care taken that patients who are sometimes violent and vindictive inflict no injury upon themselves or those around them. The windows should be secured, and all sharp and cutting instruments should be put out of their way. Women are not unfrequently, at the commencement of the disease at least, fully aware of the disordered state of their minds; they feel that they have not their

wonted power over trains of thought passing through their minds, and their ideas succeed one another with extraordinary rapidity, and in a manner different from what they did in a state of health. The condition of the mind during sleep or dreaming is also peculiar. Often when the disease is forming, the ideas have all a relation to the process of delivery. A lady now afflicted with puerperal mania was delivered unexpectedly at the end of the sixth month of pregnancy when sitting up—the child literally dropped from her, and had nearly fallen upon the floor; she cannot now, though several months have elapsed, be persuaded that the same accident is not about to take place, and keeps her hands nearly all day long in a position to prevent it. The mother of this lady had one or more attacks of puerperal mania, and the disease was obviously hereditary. A disordered state of the digestive organs is not unfrequently a concomitant of puerperal insanity, and in a few cases this has appeared to be the exciting cause of the complaint, for relief has almost immediately followed the action of brisk cathartics. Whether we view deranged states of the digestive organs as causes or consequences of puerperal mania, these should be effectually removed by repeated doses of calomel and purgatives, and the condition of the alvine evacuations frequently ascertained. Bleeding, general or local, is not required in the greater number of cases of puerperal mania, and the frequent and long-continued use of active cathartics is injurious, especially when the disease is accompanied with symptoms of general debility and exhaustion. More benefit is then derived from narcotics, especially acetate of morphia, nourishing diet, and gentle exercise in the open air. Benefit has also been obtained, in some cases, after the acute stage of the disease has passed away, and convalescence has commenced, by allowing the patient occasionally to communicate with her relatives, from whom she had been separated.

The affections of the nipples and mammæ during suckling, though attended with little danger, often produce the greatest suffering. When the breasts have become suddenly distended after first labours, and where the child has not been applied sufficiently early, constitutional disturbance of great severity sometimes takes place. There is a rigor, succeeded by intense heat of skin, quick pulse, oppression of breathing, headache, flushed face, and sometimes slight incoherence or delirium. The tongue becomes dry, and there is urgent thirst. However violent the symptoms of milk fever may be, little danger is to be apprehended; none, in comparison with uterine inflammation or puerperal fever, which ought not to be confounded in any way with milk fever. If the breasts are hard and distended on the third or fourth

days after delivery, and there is no pain increased by pressure in any part of the hypogastrium, however severe the febrile disturbance may be, there is comparatively little risk, and the symptoms will gradually subside if the proper treatment is adopted. Active saline cathartics ought to be liberally administered, and diaphoretics at short intervals, and the over distension of the breasts should be relieved by warm fomentations, or frictions, and having the milk drawn off. The exhausting syringe, or glass tube and ball, are often employed for this purpose, but the safest and most efficacious method is to procure a child a few months old, and apply it to the breasts. Blood-letting is rarely necessary in milk fever, and it is better to relieve the determination of blood to the head, where it is great, by leeches to the temples, and a cold evaporating lotion. The early application of the child to the breasts, warm fomentations, and poultices, or occasional friction with oil or camphorated liniment, and the exhibition of cathartics and diaphoretics, and low diet, are the best means of preventing attacks of milk fever: where women are not to suckle their children, the secretion of milk should be lessened by the exhibition of saline purgatives soon after delivery, and the sparing use of liquids. The breasts may be covered with fine linen rag, moistened with the following, or some similar, tepid lotion. Camphor. ʒj. ; Spirit. Vin. Rectif. ʒjss. ; Aquæ ʒviii. Nurses sometimes cover the breasts with diachylon plaisters, and the pressure probably acts by arresting the secretion. Sometimes, however, this is done very imperfectly, and the breasts are very large and distended, and painful for two or three days, and then the secretion begins to diminish. The application of warm fomentations and emollient poultices are upon the whole better applications; they are more soothing. They allow a small portion of milk to flow from the nipples, and the milk soon recedes, with low diet and cathartics. If the distension is very great and painful, and there is much constitutional disturbance in spite of all this, it is best to relieve the breasts by drawing off a portion of the milk.

Ulceration of the nipples occurs either as a simple superficial excoriation or as a deep crack. Some women suffer so severely after every confinement from excoriation and ulceration of the nipples, that they are altogether unable to suckle their children, however anxious to do so. No sooner does the child begin to suck, than the skin covering the nipple gives way, and if the suckling is continued, large foul painful superficial ulcers or deep cracks, take place, which bleed every time the child is applied. The pressure of the child's gums prevents the ulcers from healing, the edges of the sores are drawn

asunder every time the child is applied, and they are thus prevented from healing. To obviate the effect of this mechanical irritation, shields and prepared teats are employed, but children often refuse to suck with these, and they are obliged to be put aside. If one nipple is excoriated, and the other is not, the child should be more frequently applied to the sound than the sore nipple. These excoriations and ulcerations of the nipples would all cicatrize, if it were possible to leave them sufficiently long in a state of rest. A great number of different applications have been recommended in these cases; but I am unable to explain to you precisely the principle upon which they act. The good they do is probably chiefly effected by allaying the excitement of the parts, or by acting as gentle stimulants and astringents, as similar applications act upon common ulcers in other parts of the body. The following are some of the applications in common use. \mathcal{R} Sodæ Sub. Borat. \mathfrak{zj} . Aquæ distill. \mathfrak{z} ijss. Spirit. Vin. rectific. \mathfrak{z} ss. M. Or alum. sulph. gr. iij. Aquæ \mathfrak{zj} . M. or Zinc. Sulph. gr. xv. Aquæ Rosas. \mathfrak{z} iv. An ointment now extensively used, and with great advantage, consists of \mathfrak{zj} . of the Balsam of Peru to \mathfrak{z} vj. of Unguent. Cetacei. Sometimes the Unguent. Hydr. Nitr. Oxid. mixed with a small proportion of opium, answers very well, or ointment of bismuth, or zinc ointment, or simple cerate. Some sprinkle a little gum arabic over the nipple. Where there is a granulating surface, looking like a raspberry, a solution of lunar caustic, two grains to the ounce of water, applied with a camel's hair brush, answers very well. Another method of applying the lunar caustic is to touch the nipple, after carefully drying it, with a sharp pencil of nitrate of silver, and afterwards covering it with a little simple ointment. I have seen all these applications, and many others, tried without success, and the ulcerations have at last healed up under the use of a bread-and-water or linseed-meal poultice, spermaceti ointment, or the most simple unctuous application. Not unfrequently ulceration of the nipples gets well, where the applications have not produced the effect,—the last, however employed, generally receives all the credit for the salutary change.

Inflammation of the mammæ often occurs spontaneously, and cannot be referred to an ulcerated condition of the nipples, exposure to cold, external injury, improper diet, mental excitement, or any other adequate reason. It may take place during the whole period of suckling—three, six, or even twelve months, after delivery, and it has sometimes occurred after weaning. Most frequently, however, inflammation of the mammæ takes place within a month after delivery; sometimes it occurs before the

end of the second week. A hard lump is often at first felt in the breast, which is painful on pressure, without any redness of the integuments covering it; but as the inflammation extends, the integuments assume an uniform redness, and this is more or less diffused according to the extent of the part affected. Rigors, quick pulse, headache, thirst, and other symptoms of constitutional disturbance, usually accompany the affection; but these vary very much in severity in different cases. Where the inflammation is in the cellular substance under the skin, or in a superficial portion of the gland, suppuration soon takes place, and the pus is often discharged through an opening in the skin near the root of the nipple. In other cases a large portion of the gland is inflamed, and the matter makes its way very slowly to the surface. Different modes of practice have been adopted in this disease. I believe it to be unnecessary here to abstract blood from the arm; and in a large proportion of cases warm applications are more useful than cold evaporating lotions. When there is much pain, tension, and hardness of the breast, apply twelve or eighteen leeches to the affected part, and foment the bites till a sufficient quantity of blood has been procured. Then a warm linseed-meal poultice should be laid over the part, which should be renewed every four or six hours. The bowels should be very freely opened by calomel, antimony, and some saline cathartic, as senna and salts, and afterwards the febrile symptoms allayed by saline diaphoretics, and rest procured by anodynes. If the inflammation is severe, it is often necessary to reapply the leeches a second or third time, and the poultices and fomentations should be continued, or warmth applied by means of these wooden bowls, till resolution or suppuration takes place; and when pus is formed, it is in general the best practice to allow the matter to make its way to the surface, and be discharged by ulcerative absorption of the parts intervening between the surface and the cavity of the abscess. The circumstances which ought to guide us in opening mammary abscesses have thus been clearly stated by Sir A. Cooper:—"If the abscess be quick in its progress, if it be placed on the anterior surface of the breast, and if the sufferings which it occasions are not excessively severe, it is best to leave them to their natural course, rather than to employ the lancet for the discharge of the matter. But if, on the contrary, the abscess in its commencement be very deeply placed; if its progress be tedious; if the local sufferings be excessively severe; if there be a high degree of irritative fever, and the patient suffer from profuse perspiration and want of rest, much time is saved, and a great diminution of

suffering produced, by discharging the matter with a lancet." "Still, it is wrong to penetrate with the lancet through a thick covering of the abscess, as the opening does not succeed in establishing a free discharge of matter, for the aperture closes by adhesion, the accumulation of matter proceeds, and ulceration will still continue. On this account the opening should be made where the matter is most superficial, and the fluctuation is distinct; and it should be in size proportioned to its depth." "Several abscesses," adds Sir Astley, "sometimes form in the same breast, quickly succeeding each other, and lead to very protracted sufferings. In these cases opium and quinine will be required to lessen irritability, and support the strength of the system. Sometimes an abscess is produced at a great depth in the breast, and discharges itself by several different apertures, forming sinuses of various extent. The best mode of treatment in these cases, as far as I have had an opportunity of observing, is to inject them with a solution of two or three drops of the strong sulphuric acid to an ounce of rose water, and to apply the same solution by folds of linen cloth over the bosom, by which the secretion of milk is checked, and adhesion is produced."

ON THE MINERAL WATERS OF GREECE.

BY DR. JOHN BOUROS,

Professor of Special Medical Pathology, and of the Internal Clinique, at the University of Athens.

GREECE possesses mineral waters varying extremely in natural and chemical composition. The greater number, however, are saline and sulphureous, and are consequently connected with volcanic phenomena of the soil. On the other hand, chalybeates, properly so called, are much less numerous, and I do not know of a single acidulous spring.

All our springs, therefore, may be divided into four classes: the first comprehending thermal sulphureous waters, the second thermal saline waters, the third cold saline waters, and the fourth thermal chalybeates.

Hot sulphureous springs.—Of the sulphureous springs, the most important in Greece, and perhaps one of the most important in the world, is one which rises in the northern part of Greece, in the ancient Phthiotis, about the distance of half an hour* from the city of Patraziki, towards the road that leads to Lamia. In a beautiful and

fertile plain surrounded on one side by lofty mountains, and on the other by the distant sea, the water smokes and boils, as it rises into a large and deep basin, in the middle of a kind of hill formed by the calcareous precipitate which it continually deposits. The temperature of the water in this basin varies in its different parts from 23° to 35° R. (83½° to 110½° of Fahr.); while in the centre it rises as high as 40° R. (122° Fahr.) and perhaps more. The water has a greenish tint, and is turbid; but as soon as it cools, it becomes limpid, and deposits a yellowish sediment. It sends forth a very penetrating odour of sulphuretted hydrogen, and has a saltish, acidulous, and not disagreeable smell.

Sixteen ounces of this water have been found, on analysis, to contain—

	Grains.
Muriate of Soda . . .	48.100
Muriate of Lime . . .	3.543
Sulphate of Magnesia . .	1.800
Sulphate of Lime . . .	2.043
Carbonate of Lime . . .	5.210
Carbonate of Soda . . .	1.900
Silica	3.000
Extractive matter. . .	2.005

together with fifteen cubic inches of carbonic acid gas, and twelve cubic inches of sulphuretted hydrogen gas.

At the bottom of the basin is an abundant sediment, a kind of greasy and blackish mud, with a strong odour of sulphur. From the ingredients of this water one might infer its efficacy in some diseases, which has been fully confirmed by long experience. But as the springs have hitherto remained uncovered, and are at some distance from the town of Patraziki, they are but little frequented. At present, however, the royal medical council is occupied in building an establishment capable of containing a great number of patients.

Other springs of this kind, not less important to the physician, and far more interesting to the geologist, are contained in the island of Negropont, at its north-west extremity towards the harbour of Edipsus. In this place, with the sea on one side, and a mountain formed of transitional calcareous matter mixed with argillaceous schist and serpentine, on the other, at least twenty hot springs rise in the circumference of a square French league; and they deposit so much calcareous sediment, that they have formed entire mountains. In this space, which appears empty, and resembles the lid of a great cauldron, are plainly seen many spots which in other times gave exit to springs, but which are now closed; either through earthquakes, which, according to Strabo, once occurred, or from the great quantity of calcareous matter deposited by these springs.

* If in Greece or Italy distances are calculated after the German fashion, this would be about one English mile.—*Translator's note.*

The springs pour forth with vehemence and noise a great quantity of foaming and steaming water, which loses itself in the sea; but from one of them in particular the water issues in such abundance as to turn a mill, and with such force as easily to throw out large stones which may have fallen into the mouth of the spring.

Its temperature is very high, being 73° of Reaumur ($196\frac{1}{2}^{\circ}$ Fahr.); so that it warms the sea, when calm, to the distance of fifty or sixty feet. The water is limpid, has a bitter taste, gives forth a penetrating smell of sulphur, and has a specific gravity of 1.016.

Sixteen ounces, when analysed by Signor Landerer, Professor of Chemistry in the University of Athens, were found to contain—

	Grains.
Muriate of Soda . . .	68.000
Muriate of Magnesia . .	3.500
Muriate of Lime . . .	2.084
Carbonate of Lime . . .	2.043
Carbonate of Soda . . .	4.200
Sulphate of Magnesia . .	11.240
Sulphate of Lime . . .	3.000
Silica	2.000
Iron	1.005

together with eight cubic inches of carbonic acid gas; thirty-two cubic inches of sulphuretted hydrogen; and a little extractive matter.

The abundant sediment of peroxide of iron which is seen all around might make one suppose that the quantity of iron contained in these waters is greater than Signor Landerer found in them. However this may be, the thermal waters of Edipsus are among the most efficacious, and their reputation as a remedy ascends to the remotest times. This is still shown by some remains of ancient baths and aqueducts, and is confirmed by a passage of Plutarch, where he says that Sylla frequented the thermal springs of Edipsus, in order to get rid of a species of gout by which he had been attacked at Athens.

In the great work of the French scientific expedition in the Morea, (t. ii. p. ii. p. 43 and 239) mention is made of another thermal water in Negropont, in the plain of Lelas, which enjoys a certain reputation among the natives; but as nothing more is said of it, it is impossible to know to what class it belongs.

Between the waters of Patraziki and Edipsus there is another spring of the same kind, on the mainland, which has given its name to that historic spot where Leonidas fell with the three hundred Spartans. I mean Thermopylæ (*i. e. the warm gates*.)

These ancient gates of Greece are composed on one side of Mount Ceta, which is

formed of transitional calcareous matter, mingled with argillaceous schist, and a little serpentine; and on the other of the Sinus Maliacus or Gulf of Zituni. At the foot of Mount Ceta rises a hill entirely formed of a transitional calcareous stone, and giving free passage through various fissures to a copious thermal spring, which falls into the sea after passing through a plain about one French league long, and depositing calcareous sediment in various forms. The temperature of this limpid water is from 52° to 54° R. (149° to $153\frac{1}{2}^{\circ}$ Fahr.); its taste is salt, its odour sulphureous and penetrating. Chemical analysis has shown that its constituents are the same as those of the spring at Edipsus.

In another part of Greece, which has undergone great volcanic revolutions, and at no very distant epochs, as Strabo reports, and as the very nature of the soil shows, namely, in that part of Peloponnesus which extends to the Saronic gulph, other sulphureous springs occur; particularly in the eastern part of the peninsula of Mettana, the greater portion of which is formed of trachite. Several springs of limpid water rise, within a circumference of 40 or 50 metres, above a small harbour surrounded on the west by rocks of porphyry, trachite, and calcareous matter; and they fall into a lake formed of sea water. Their temperature was 25° R. ($88\frac{1}{2}^{\circ}$ Fahr.) while that of the atmosphere was 24° R. (86° Fahr.)

The constituents of these waters are not yet known, but we have placed them among sulphureous springs, on account of the great quantity of sulphuretted hydrogen gas which they emit, and which has given them the popular name of *βρωμολίμνη*, or *stinking lake*. This must be the fountain which, according to Pausanias, first appeared in the reign of Antigonos, King of Macedon, and whose appearance was preceded by a volcanic eruption on this spot.

On the north side of the peninsula, opposite the island of Ankistri, there is another spring of the same class. It is very near the sea, and mingles with it, so that its temperature cannot be exactly determined; but it must be high, as the water heats the sea for a circumference of about ten metres. However, a thermometer which M. Virlet immersed in the channel from which the water issues rose to 37° Centigr. ($98\frac{3}{4}^{\circ}$ Fahr.) The inhabitants of Mettana give the name of *βρωμα* (stink) to this fountain, from the odour of the sulphuretted hydrogen gas which it emits in abundance. It seems that this spring first rises, as M. Virlet asserts, from another level 50 or 60 feet higher, where some ruined baths, of mediæval construction, are still to be seen.

In the gulph of Patrias, on the mainland of Greece, to the west of Lepanto, and near the mountain of Kaki-Scala, there rises a ther-

mal spring, which emits a strong smell of sulphuretted hydrogen, and is of the temperature of 32° R. (104° Fahr.). This fountain appears to have afforded considerable materials to the mythology of the ancients, who placed upon this smoking and stinking spot the tombs of the Centaurs who were buried under the mountain called *Taphius*, or the sepulchral; while they derived the old name of the inhabitants of these regions, the Ozoli (or, *strong-smelling*) from the stench of the spring.

The last spring of this class which we shall mention is one which rises in the island of Milos, on the south of mount Kalamo, from a grotto which the inhabitants call *θειοφείον* (*sulphur mine*) because its walls are covered with crystallized sulphur, and the water emits a strong smell of the same mineral. Its temperature is 47° R. ($137\frac{1}{2}^{\circ}$ Fahr.).

Hot saline waters.—The first place in this class is due to the one in the island of Thermia, which is at present so much used that it deserves especial mention. It is necessary to observe that near this spring there is another, called *Caccavo*, which from the quantity of iron that it contains, belongs to the class of chalybeates; but to avoid repetitions we will speak of both at the same time.

The island of Thermia appears a continuation of the promontory of Sunium (now Cape Colonna); and is formed of primitive mountains of micaceous and argillaceous schist, together with rocks of crystallized calcareous matter. This island boasts of a phenomenon hitherto unique in geology, I mean a spacious cavern in a schistous mountain, near the village of Sillaca; and in the whole island there is not a single fountain of water fit to drink, so that the inhabitants use wells.

There are three copious springs of thermal water, the first of which is called *λουτρόν* (*the bath*), and the remaining ones, which are very near each other, and hardly 50 metres from the *bath*, are known under the name of *Caccavo* (*cauldron*).

Not the slightest mention of these waters occurs in ancient authors, although some small monuments and sepulchres found in these spots make us presume that the virtues of the springs were not unknown to our ancestors. The first historical indication of these waters that I know of is the name of the Island Thermia, which first occurs in Mela the geographer, instead of Ophiussa, Kythnos, or Dryopis, its ancient appellations; and there is no doubt that the name was conferred on the island, for the same reason that it was given to other places, and to Diana herself (*θερμία*) as the patroness of thermal waters. In the middle ages the

baths of Thermia were already in use, as may be seen from the remains of an aqueduct of that period.

The water of the *bath* is of the temperature of 32° R. (104° Fahr.) in the middle of the cistern; but at the mouth of the fountain I found it 33° R. ($106\frac{1}{2}^{\circ}$ Fahr.) when the atmosphere was 10° R. ($54\frac{1}{2}^{\circ}$ Fahr.) It has neither smell nor colour; its taste is saline and bitter; its specific gravity is 2.015*; it is limpid and deposits no sediment. Sixteen ounces of this water afforded by evaporation 117.333 grains of a white salt of a saline and bitter taste, the composition of which was as follows:—

	Grains.
Hydrochlorate of soda	42.096
„ lime	4.320
„ magnesia	2.402
Carbonate of lime	3.614
„ soda	2.942
Sulphate of magnesia	6.634
„ lime	2.004
Water	53.000

With traces of ioduret of soda, of bromide of soda, and of silica. It contained two cubic inches of carbonic acid gas.

According to the commission, the water of *Caccavo* is of the temperature of $45\frac{1}{2}^{\circ}$ R. ($134\frac{1}{2}^{\circ}$ Fahr.) I found it, however, to be only 42° R. ($126\frac{1}{2}^{\circ}$ Fahr.) while the atmosphere was at 10° R. ($54\frac{1}{2}^{\circ}$ Fahr.)

At its source it gives forth numerous bubbles, in the gases which it develops; it diffuses a weak sulphureous smell, has a light yellow colour, is limpid, has a specific gravity of 1.039, and deposits a copious sediment of peroxide of iron.

The chemical analysis of the commission afforded a great quantity of carbonic acid; and four ounces of the water gave by evaporation the following ingredients:—

	Grs.
Carbonate of iron	2
„ lime	8
„ soda	2
Muriate of soda	28
„ magnesia	21
„ lime. . . .	6
„ potash	9
Sulphate of lime	4
„ magnesia	2
With traces of silica.	

The Commission could not discover any trace of hydrosulphuric acid.

According to Signor Landerer, sixteen ounces of this water afforded by evaporation 367 grains of salt, consisting of the following ingredients:—

* Probably a misprint for 1.205.—*Translator's Note.*

	Grains.
Carbonate of iron . . .	3·436
„ lime . . .	12·840
„ soda . . .	5·462
Hydrochlorate of soda . .	64·939
„ lime . . .	12·402
„ magnesia . . .	21·040
Water	206·000

Although the odour indicates the presence of hydrosulphuric acid, he could not find any; but he found both hydrobromate and hydriodate of soda.

These are the physical and chemical properties of the waters of Thermia, which have been shown by long experience to be very efficacious, particularly against chronic rheumatism and arthritis, paralysis, and some lymphatic swellings. His Majesty's government erected an establishment three years ago for those who frequent this bath.

At the western part of the island, near the ruins of the ancient city, in the centre of a small harbour called Apocriosis, and near a church dedicated to St. Nicholas, there is another spring, a very small one, which appears to have the same chemical qualities as the Caccavo water.

The island of Santorino contains several thermal waters of the same nature. In the western part of this singular island I met with a spring which rises near the sea from the trachite forming the base of an enormous rock. Its temperature was 28° R. (95° Fahr.), while that of the atmosphere was 14° R. (63½ Fahr.)

The water is limpid, without odour, and contains in sixteen ounces:—

	Grains.
Sulphate of magnesia . . .	12·500
Muriate of soda . . .	8·740
„ magnesia . . .	3·550
Carbonate of soda . . .	2·143

with a small quantity of carbonic acid and extractive matter.

This fountain is called in the country *Placa*, and it seems to have been long used, as an artificial ditch is still to be seen there, covered with an arch, now ruined by the waves of the sea.

At a short distance south of the *Placa*, there is a place called *Thermi*, from another warm spring which rises very near the sea from trachitic rocks. Its temperature is 28° R. (95° Fahr.) The water is limpid, very salt, somewhat pungent, and diffuses an odour of sulphur.

The inhabitants of Santorino first used it against rheumatism in particular; but about the year 1816 they had given it up, from some untoward symptoms which it produced; in 1834 I found it again under a layer of sand above three metres thick.

By continuing to coast the island, towards the south, many springs of the same nature

are found in different parts, which being on the shore of a very deep sea, are frequently covered by it.

The island of Milos certainly owes its existence (which is of no long date) to a volcano still burning, which penetrates it with its fire in such a manner that fissures and smoking caves are to be seen in many places; and if one digs anywhere a little below the surface, the temperature is high, and often insupportable.

This island naturally contains a great number of hot springs, but it would be superfluous to give a list of them all. It will be sufficient to mention one of them, which enjoys a certain reputation among the inhabitants of the island, and bears the name of "the salt-baths" (Λουτρά της άλμυκής).

To the south of the new city, at the distance of a quarter of an hour's walk from the harbour of Panagia towards the east, there is a low grotto of volcanic sandstone, 45 metres long. It seems to be artificial, from the seats cut in the sandstone, as well as from an aperture in the upper part to let in light. In this grotto there is water enough for a whole bath; its temperature is 22½° R. (82½° Fahr.). When the thermometer, however, was plunged into the spot from which the water seemed to issue, I found the temperature to be 29° R. (97½° Fahr.); while the external air was hardly 16° R. (68° Fahr.) It was limpid, salt, and without smell; and on its surface were floating many pieces of a delicate crust composed of carbonate and sulphate of lime. Its ingredients are salts in the state of carbonates, sulphates, and hydrochlorates. According to some writers it also contains sulphate of alumina in small quantity. (*Exped. Scient. en Morée*, t. ii. p. ii. p. 289.)

The salt baths, not very long ago, were much more frequented for cutaneous diseases, rheumatism, and paralysis. In a barren plain, about 500 metres south-west of the grotto, a volcano phenomenon takes place which is worth mentioning; namely, that a kind of boiling mud is thrown up, from a subterranean volcano, through numerous apertures; and when this is going on, it is observed that the quantity of the water mentioned above increases.

Mr. Ross, Professor of Archeology at Athens, has found a warm spring in the southern part of the island of Serfo, under a mountain containing much iron, and near the ruins of an ancient tower. Two leagues and a half from the city of Corinth, towards the north-east of the gulph bearing the same name, several warm springs rise from a compact calcareous rock, which have given the name of *Lutraki* (*little bath*) to a neighbouring village. One of these springs, from spouting forth the greatest quantity of water, is called κεφαλόβρυσις (*chief fountain*).

About three leagues from this place, near the small harbour of Kenchriè, it seems that the thermal waters still exist which formed of old the "hot baths of Venus."

Lastly, the members of the scientific expedition to the Morea found another thermal water, copious and very salt, in the eastern part of the Peloponnesus, ten leagues from Patras, near the harbour called Kunupeli; its temperature was $28\frac{1}{2}^{\circ}$ R. ($96\frac{1}{2}^{\circ}$ Fahr.)

Cold saline springs.—These are very common in Greece, and are much used as purgatives, whence the natives call them laxative waters, or, in some places, hard waters. They have not been accurately examined by any chemist. Among these are—

1. The mineral spring in the harbour of Munichia in Attica, which Professor Ross believes to be the Sirangium of the ancients.

Remains of an artificial Roman basin are still to be seen there, showing that it was used in old times. This water in the dose of two pounds is slightly laxative; and I have myself observed good effects from its use in what are called obstructions of the abdominal viscera, particularly of the liver.

2. Upon the island of Ægina, not far from the city, there is a saline water, which seems to be of the same nature as the preceding one, and produces the same effect.

3. In the harbour of Naussa, in the island of Paros, hardly ten minutes' walk from the city of the same name, I found a saline spring which the inhabitants call *di Santi Anargiri*, and employ as a purgative in the spring. Its use seems to be at least as old as the middle ages, as I have already shown in the journal entitled *l'Esculapio*.

4. Dr. Röser, our illustrious and learned first physician, when accompanying his Majesty to continental Greece and the Peloponnesus, found other springs of this kind; but as they are not yet sufficiently known, we can merely indicate the places where they exist. At Malvasia, at St. Nicholas, at Marattonisi, (with an ancient inscription) at Levezora (with an ancient bas-relief), at Limeni, at Barboni, at Lutrò in the Gulph of Arta, at Voniza, where the springs form marshes which infect the town, at Galaxidi, in the Gulph of Corinth, and at Aspra Spitia.

Chalybeate springs.—Besides the chalybeate water of Caccavo, which we mentioned in speaking of the island of Thermia, Greece possesses a spring of the same kind at Milos, but still richer in iron. Towards the south of the new city in this island, an hour's distance from Panagia, there arises on the beach, and in the very sea itself, from different springs, upon a soil formed of tertiary rocks, and covered by sand, a copious stream of the temperature of 45° to 48° R. ($133\frac{1}{2}^{\circ}$

to 140° Fahr.) It is saline, and rather astringent, with the odour of carbonic acid gas; and it deposits upon the sand a large quantity of a yellowish brown sediment, indicating the peroxide of iron. Sixteen ounces of it afforded:—

Carbonate of iron	16.000
„ lime	4.050
Muriate of lime	1.643
„ soda	75.000
Sulphate of lime	2.634
„ magnesia	61.859

with carbonic acid in an undetermined quantity, and traces of bromate of soda.

The large quantity of iron shows that its medical virtues must be considerable, and the natives of the island use it with great success against paralysis, and some atonic diseases; but as the waters are still uncovered they cannot be easily frequented by foreigners*.

CASES OF PHLEBITIS,

WITH SOME PRELIMINARY REMARKS ON ITS PATHOLOGY AND TREATMENT†.

By N. CHAPMAN, M.D.

Professor of the Theory and Practice of Medicine in the University of Pennsylvania.

It very rarely happens that phlebitis originates spontaneously. Never have I seen a case of it, or met with any on record which I would admit as indisputable. Cruveilhier, I am aware, it is said, has related one of the vena porta, which is often quoted. But so far from this being true, he expressly says, that the suppuration was of the cellular sheath,—the vein itself being perfectly sound. Generally it proceeds from some mechanical injury done to the vein by venesection, or other surgical operations, amputation, the extirpation of tumors, and such like deep and extensive incisions, involving large vessels. The tying of varicose veins, as was formerly practised so commonly, proved a very prolific source of it, and we are not without examples of its happening in the same way to the hemorrhoidal veins, of which, I once saw an instance, under the care of the late Professor Physick. Compression from adjacent tumors does also induce it, and much is imputed to the introduction of a virus into the circulation by

* From *Il Filocamo*, an Italian medical journal of considerable merit, published in Malta.

† From the American Journal of the Medical Sciences—July 1843.

inoculation, or otherwise. Breschet goes so far as to affirm, that it may be occasioned by bleeding with a lancet previously used in vaccination, not thoroughly cleaned, and he cites several cases, where it proceeded from the cuts of a scalpel charged with the matter of putrid bodies. Even the washing their excoriated hands, in water, employed in the protracted maceration of flesh, he saw do it in some of the attendants on a dissecting-room. Dance mentions an instance of a surgeon, who died of an attack of it, brought on by puncturing a small phlegmon with a carefully wiped bistoury, with which he had, a month before, laid open an anthrax. Numberless facts to the same purport might be adduced.

As a common cause, is also held to be the absorption of pus or acrid fluids from foul ulcers, or the secretion of various surfaces, as of the uterus and other organs, and parts, to which so much, we have seen, has been referred in the production of phlegmasia dolens, &c. But in respect to the latter, I have always been exceedingly distrustful, and cannot help believing, that under these circumstances, the inflamed veins, which may be detected, have become so by a derivation from the structure through which they pass being previously in that state. For example, in hepatitis, or pulmonitis, &c. discovering these vessels phlogosed, it is to be taken as the effect, and not the cause, the secondary and not the primary lesion. This proneness of the veins to be thus affected, was remarked by Hunter, especially in those who had died of amputation, compound fractures or gangrene, and the observation does not want confirmation. My impression on the whole, is, that phlebitis is owing almost exclusively to a wound of the vessel, and that it is perhaps never directly occasioned by a virus. Certainly, it may be excited independently of any. There are times and individuals, at all times, when the slightest incision or puncture, or even a scratch, will lead to the most disastrous results of this nature, from the cleanest instruments. Every practitioner is aware, that at particular seasons, phlebitis is very apt to follow venesection, and I have known a lady for thirty years who has never been bled during that period, however care-

fully the operation may have been performed, without suffering in some degree from it;—and on three occasions so severely, as to place her life in imminent danger. Even the pricking of a finger from a needle brought on immense tumefaction of the arm, up to the shoulder, with the other phenomena of well-marked phlebitis;—and the late Professor Physick, who saw the case with me, mentioned that he had met with two others precisely like it. The instances of tumefaction from the insertions of a virus, I presume to be affections of the lymphatics. Notwithstanding all which has been urged of late to the contrary, I cannot believe that veins in any mode are absorbents;—and it is truly said by an eminent authority, “that whatever may be found in those vessels, whether pus, or other unusual matters, is generated within, and not introduced from without.”

Except in traumatic phlebitis, and particularly from venesection, it is not uniformly easy to distinguish the disease, and when seated in the veins of the interior, never, perhaps, with any precision or certainty. The obscurity arises, under the most favourable circumstances, from the resemblance it bears to the inflammation of the lymphatics, and still more to that of the cellular tissue. Between these three affections, at their height, the difference is less appreciable, since the cellular membrane mostly becomes involved, in which event the peculiarities of the others are merged and concealed. Diffusive inflammation of this tissue fills up all interstices and inequalities, forming a perfect rotundity of surface, dense, smooth, and polished. But in the early or last stage, prior to excessive tumefaction, or in its subsidence, the phlogosed vein may be felt in a tortuous course, hard and knotty, and sometimes, also, the lymphatics enlarged and indurated.

That this is a dangerous disease sufficiently appears from the preceding history of it. Timely attended to, it is for the most part easily arrested. But permitted to proceed till the vein is intensely inflamed, and especially suppuration has freely taken place, with the establishment of the multiplied sympathetic affections incident to this stage of the case, our efforts are mostly

impotent, and death is to be anticipated. Yet, in a state apparently so desperate, the natural resources are sometimes applied successfully.

By Hunter it was declared, that the veins in phlebitis reveal on dissection, inflammation, suppuration, and even ulceration. Experience has since fully confirmed the accuracy of his report, and to which, in relation to the appearance of the vein itself, little has been added. Beginning usually in the internal or lining tissue, the phlogosis, when intense and persistent, may pervade the whole of the vascular parietes. Extravasations of lymph are common, and distributed in a similar manner. Deposits of it are on either surface or both, and inter-tissual, or in other words between the membranes. The same may be said of pus, and of ulceration, existing in one or the entire coats. But of these several anatomical characters, something more must be said. The inflammation is faint, or of a rose, or of a deep scarlet, or brownish hue, in specks, or striated or arborescent, local or extending along to the heart, continuously or in detached patches, between which the intervening spaces are healthy. Collections of pus and of lymph are detected sometimes in the calibre of the vessel to an amount very seriously to embarrass, or even to obstruct the circulation, and coagula of blood have been seen, though seldom, separately or united to the other matters, having the same effect. There are instances, too, where, from adhesions of the sides of the vessel, a total obliteration is produced, and should recovery take place, it becomes ultimately a dense, impervious cord. The ulcers are few or many, superficial or deep. I once saw several that had gone entirely through the walls of the vessel. Lymph having been deposited on the exterior surface, it occasionally agglutinates the vein to the surrounding cellular surface, and abscesses are formed. Generally the texture of the vessel is softened, sometimes to pultaceousness, and in one instance, from the colour, the odour, and other circumstances, I had reason to suppose the existence of gangrene, as well of it as the adjacent cellular membrane.

These are the principal lesions, which may be restricted to a single vessel or extend to others more or less diffusely—or indeed, according to some writers,

involve any one, or every organ of the body, at different times, in inflammation and its consequences. Excepting, however, the purulent depositions previously noticed, I am not sensible of any thing in the consequent derangements meriting further attention. Disseminated through the structure of the organ, they are detected from the size of a pea to a walnut, or sometimes double or treble, or quadruple the size; the number always larger as they are diminutive. They are infiltrations of pus collected at a point or points, and not properly abscesses, as they have seldom or never any regular cyst. The organ is usually found mostly inflamed immediately around the deposit. It is the fashion of the day to elevate in importance and frequency the diseases of the veins, and the accounts we receive respecting them are exaggerated, and must be received with qualifications. Even more than the heart and the arteries are they susceptible to *inhibition*; and mere redness, which I suspect has been too readily admitted as evidence of phlogosis, proves here equally delusive. Coloration, with injection of the vessels of the surface, warrants a suspicion of the existence of this state, though not conclusive. Demonstration of it is only afforded by the presence of lymph or pus, or thickening or softening of tissues, or other changes of structure.

Contemplating the pathology of this affection, we are at once struck with some circumstances in it exceedingly anomalous and heteroclite. The mode sometimes, of its origin, and that a trivial lesion of a vein, so often extensively injured with impunity, should lead to such wide constitutional disturbance, and this nearly always showing a tendency to typhoid debility and vitiation, are certainly very extraordinary. I have already alluded to the singular predisposition in these cases, without, however, assigning the nature of it, which I am unable to do. It occurs, perhaps, most frequently in various cachectic states, while on other occasions it is met with apparently in the soundest and most healthy conditions. Could it be demonstrated that the local inflammation was rapidly and widely diffused through the veins, so as to embrace any large portion of them, then an explanation would be afforded of the enormous mischief pro-

duced. Granting it sometimes happens, it cannot be averred that it generally does. The contrary, indeed, is nearer true, or that in a large number of instances of traumatic phlebitis, especially from venesection, the inflammation is restricted to a few inches from the wound, and though it may run up to the heart, it seldom involves other veins. The phenomenon is only explicable on the supposition of the sympathies of the rest of the veins with the affected one. Considering that these vessels form a natural and homogeneous system engaged in the same operations, it is presumable independently of other proof, that they have a very intimate consent of parts, by which there is a reciprocity of sufferings, oftener, however, of functional irritation than positive disease; or, in other words, that what was primarily a local phlegmasia is rendered a constitutional affection, without an extension of actual inflammation. Different, however, is it in a more advanced stage of the case, where the adynamic degeneration has supervened. Great reason is there to suppose that suppuration here exists, and that the immense change thus suddenly wrought in the character and physiognomy of the disease proceeds from the mingling of pus with the blood. Endo-carditis alone, to which it has been imputed, will not account for it. The phenomena of the two cases are dissimilar, and those of the veins are precisely such as are induced by injecting certain fluids, and above all, putrid fluids, into the circulation. Nor is the amount of matter secreted inadequate to the effect. In three extremely grave instances of phlebitis from bleeding, attended by me, at each visit I pressed out of the orifice of the vein half an ounce or more of an ill-conditioned or illaudable pus.

Not conversant with any other form of the disease than that of which I have just spoken, and entertaining the conviction it is the only one capable of recognition with any certainty, at all events in time to do any thing efficient, I shall confine my practical remarks to it. These, however, should a case of spontaneous origin be detected in season, will be equally applicable to it, so far, at least, as concerns the general treatment.

We are, in the first place, to support the limb, so as to secure an absolute

state of rest, and which can only be attained by putting it into a nicely adjusted case. It is very much the custom here to have one carved, that it may be more exactly accommodated to the contours of the part, by which the main object is better secured, and the pain of motion prevented. The suspensory sling, made of a handkerchief, tied round the neck, commonly used elsewhere for the arm, is a miserable contrivance, having unquestionably often led to the most disastrous consequences. The antiphlogistic plan is now to be adopted, and, as part of it, venesection would seem to claim priority of attention. Experience, however, teaches, that the benefit resulting from it is never proportioned to what might be reasonably anticipated—that it is sometimes utterly unavailing—and that a very serious objection to it is, that it is very apt to be followed by a fresh attack of phlebitis, evidence of which has come under my own observation. It may therefore be best not to resort to it unless excitement is high and general—leeches, on the whole, being decidedly preferable. These are to be liberally applied along the course of the vein, and again and again repeated. Emollient cataplasms or fomentations may also be useful, and especially where the swelling is extensive. The case proving obstinate, menacing a serious career, of all remedies the one deserving of the greatest confidence is a blister. Numerous are the instances in which I have witnessed its superior efficacy; and I believe there is little division of sentiment as to its extraordinary value among the profession in this part of the country. From what I have seen and heard I cannot entertain a doubt that it will at once arrest a large majority of cases. But though coming from the late Professor Physick—published by him some forty years ago, and since frequently alluded to with the highest commendation in the writings of this country, it seems to have attracted scarcely any attention in Europe, or, at least, I do not find it noticed in the treatises on the subject I have consulted, with a solitary exception: Cooper, in his Surgical Dictionary, appropriates a paragraph to it, without praise or censure. The manner of application is, to place a narrow strip of epispastic plaster along the course of

the vein, as far as it appears to be inflamed, cutting an opening in it at the orifice, over which a soft poultice is to be placed; and the blister having drawn, is to be so dressed as to be kept freely discharging. Little further of any peculiarity appertains to the management of this state of the affection. Evacuations of the bowels, and the ordinary antifebrile mixtures, are usually directed. But enormous doses of tartarised antimony are recently praised, and so is the profuse use of mercury. It is difficult to discern the motive for such practice; there is no evidence of its success, and much in it to condemn. Chiefly do I rely, at this juncture, on a combination of calomel, ipecacuanha, and opium, in moderate portions, and where pain and restlessness are prominent, increase considerably the latter article, or give at once the Dover's powder largely. The promotion of perspiration, I very strongly suspect, has not here been duly appreciated.

As the case advances, the indication arises to prevent the pus, the secretion of which may now be apprehended, from being transmitted to the heart; and with this view divers expedients have been suggested to interrupt the communication. Compression above the orifice was practised by Hunter, so as to obliterate the canal by adhesion of the sides of the vessel. But this having failed, after a fair trial, was abandoned, and a division of the vein substituted with probably no greater success. Discouraged from the further prosecution of it, a ligature was next advised, and which, though promising more fairly, I do not know has ever been attempted. The project, therefore, of arresting the pus, would seem to be deemed hopeless.

That the two first operations should not have answered is sufficiently intelligible. Compression adequate to the end could not be made, it is presumable, without at the same interrupting the arterial circulation; and independently of the pain induced by it, I doubt exceedingly its feasibility at all, in a limb so swollen as happens at the period when the experiment becomes justifiable. Cutting the vein in two does not intercept the progress of the blood effectually, while every objection to the ligature applies to this operation in an equal force. Determining, therefore, on any of these expedients,

the ligature should be preferred. Yet it must be confessed, that it would be a very serious affair to lay open and tie a vein in the state of parts so irritated as they are when the operation is most demanded, and whether it would be for good or for evil, is uncertain.

Caused as it may be, whether by the introduction of pus, as I think it is, or in any other mode, when the typhoid malignant stage sets in, whatever is calculated to uphold or renovate the vital forces is resorted to, with however seldom any advantage.

Designing to annex some cases, in which the treatment of this affection is more detailed, I have now, to avoid the prolixity of repetitions, presented only an outline of it. The first of these cases is probably the second on record of suppurative phlebitis, it having been preceded only by the one reported by Mr. Hunter, to which I have before alluded.

It is given as it was originally published, more than thirty years ago, in the Eclectic Repertory, one of our journals, which will account for some circumstances in the narrative not otherwise very intelligible.

CASE I.—In the month of March 1810, I was requested by the late Mr. Thomas W. Francis, of this city, to visit his coachman. On inquiring into the case, I learned that three days before, while on a journey, he had been attacked in the evening with slight symptoms of pleurisy, which very readily yielded to a moderate bleeding.

The next morning he felt for the first time some degree of pain and tension in the right arm, in which he had been bled. But the uneasiness was so trifling, and in other respects he was so well, that he continued on the journey. The exertion of driving, as might have been expected, aggravated exceedingly these affections. Yet such was his anxiety to reach home, that he studiously disguised his real situation, lest he might be left behind—and obstinately persevered, against every remonstrance, to perform his duties as coachman. But on the last day of the journey, overcome by the severity of his sufferings, he reluctantly consented to be placed in the carriage, and was in this way conveyed to the city.

My attendance on him commenced in the night, an hour or two after his arrival. Even at this early stage, the case presented a very serious aspect. The arm was swelled to perhaps twice its natural size, and the pain and inflammation were excessive. By

pressure, a copious stream of purulent matter issued from the orifice, and I could distinctly trace the enlargement of the vein for several inches, imparting the sensation of a hard, inelastic tube, enclosed under the integuments.

Nor were these the only untoward circumstances of the case. There was also considerable pain in the left side, with a universal soreness pervading his body. Little or no fever was indicated by the pulse, which was weak, irregular, and quick;—of a contracted volume, and rather corded. It was more a disturbed than a febrile pulse—certainly evincing nothing of an inflammatory diathesis. But though apparently not much if at all feverish, he was greatly harassed by restlessness and inquietude. The temperature of his body was unequal and fluctuating. When his attention was fixed by conversation addressed directly to him, his mind seemed perfectly rational; but otherwise he quickly became flighty;—talking incoherently, and endeavouring to get out of bed. Whatever were my doubts as to the ultimate event, I entertained none respecting the nature of the complaint, or the cause which had produced it. I was at once satisfied that the whole of the existing mischief was attributable to inflammation of the vein, extending probably to the heart, and to the introduction of pus into the blood. To the latter cause I the more promptly imputed the train of nervous affections, as I had seen, in a series of experiments, phenomena of the same kind induced by the injection of pus, of milk, of oil, of mucilage, and other bland fluids, into the veins of different animals.

Nor could I hesitate long as to the practice to be pursued. To subdue the inflammation of the vein, and arrest the pus in its passage to the circulation, were obvious indications.

Notwithstanding the feebleness of arterial action, I bled him to the amount of twelve ounces. I suspected a state of depression, and thought it not unlikely that the pulse might rise by depletion. Where so large a vessel was inflamed, and seemingly too, the heart itself, it certainly was not unreasonable to conjecture that the want of diffused excitement was owing to this condition of the system. But my anticipations were not realized. The bleeding was indeed followed by no sensible effect, and the blood was without any very peculiar appearances. It did not, it is true, separate as it ordinarily does. The serum and crassamentum were commixed, as if slightly stirred together. I could detect no pus in the blood.

I next enveloped completely the arm with a blister from the elbow to the shoulder, excepting at the puncture, which was covered with a small emollient poultice to facilitate the evacuation of the matter. During the

night I ordered, moreover, that he should take at stated intervals a solution of salts till it purged him actively.

In the morning he appeared in some respects to be better. The blister had drawn well, and the pain and swelling were in consequence considerably reduced. Neither was he so restless or irritable, and his mind had ceased to wander.

When at night I again called, he was much as he had been at my preceding visit. The swelling of the arm was perhaps somewhat further abated. But in a few hours afterwards the pain in the side, which at no period had entirely subsided, reverted with violence. It did not, however, raise his pulse.

Convinced by a variety of considerations that the pain proceeded from inflammation of the heart, I placed a large blister over the region of that organ. Though relieved by this application of the pain, I had the mortification of seeing him the succeeding morning in a situation of increased danger. With a pulse weak, quick, and tremulous, he was wild and distracted. I directed that he should lose six or eight ounces of blood by cups, from the neck and temples, and to have a blister put on behind each ear.

It now appeared to me to be literally of vital importance to intercept the pus in its course to the circulation. I, therefore, resolved without delay to make use of compression, though it seemed still to be forbidden by the tumefaction of the limb. A bandage and compress were accordingly applied a short distance above the puncture. But nothing material was gained by these applications. The swelling of the arm however declined, and no inconvenience was experienced from the compression. The pus continued to flow profusely from the orifice: this was late in the evening.

My visit the next morning found him worse. To all the bad symptoms which previously prevailed, were now added some still more inauspicious. The morbid sensibility of his body had become so exquisite, that he could not bear the slightest touch, or scarcely the weight of the bedclothes without complaining. So sensibly alive was he to every sudden impression, that by opening or shutting the door, or walking across the room, or by a question put to him in a sharp tone of voice, or by a strong glare of light, he was startled and sometimes exceedingly agitated.

At this critical juncture I resorted to the advice of Dr. James, who very obligingly met me in consultation. We agreed to give the camphorated emulsion in large doses, and to have stimulating injections repeatedly administered. But this treatment was equally unavailing, and my patient progressively sunk. Low delirium, cold extremities,

tremors of the nerves, and convulsive cough, soon supervened. His pulse became hardly perceptible. The pupils of the eyes were widely dilated, and his countenance assumed an expression uncommonly haggard, phrenesied, and distressed. Desperate as I deemed the case, I did not permit my exertions to be relaxed. By the constant use of the most powerful stimulants, such as camphor and opium, the volatile alkali, the spirits of turpentine, ether, wine, and brandy, I protracted his existence for three days longer, without having however, during this interval, a single gleam of hope afforded me by any change of his recovery.

The morning after my patient expired, I made an examination, with a view of ascertaining the exact state of things. I exposed the vein from the wrist to the axilla. The external surface of the vessel was in many places inflamed, and especially above the puncture. Between this and the shoulder, matter had escaped from the vein by four distinct sinuses into the neighbouring cellular membrane, forming small abscesses. Two of these sinuses were high up the arm.

I dissected very carefully the parts adjacent to the wound. Directly around it there was an abscess containing, I presume, a large spoonful of pus, mixed with a dark fetid sanies. Sphacelus had already destroyed a portion of the cellular texture.

I next laid open the vein. There was inflammation more or less, from a little below the elbow to the final point of my dissection, without being anywhere very great. By the appearance of the coat of the vein there was, however, the amplest proof of its having existed in the highest grade, and which is abundantly shown by the formation of the sinuses, &c. Below and above the orifice for several inches, gangrene had taken place, bounded by an extensive erysipelatous blush, and the inner surface of the vessel within this space, had begun to slough.

The quantity of pus in the cavity of the vein was small. It ought, indeed, to have been stated that for two or three days prior to his death the discharge from the orifice had gradually diminished. No disposition whatever was evinced any where along the canal of the vein, to an adhesion of its sides. My wish to extend the dissection was frustrated. Enough however has been brought light by this partial exposition, to confirm my original notions as to the nature and causes of this series of extraordinary affections.

In reflecting on the management of the case, I have only to regret having confided too much in compression as a means of promoting adhesion. But surely I shall escape censure, for having adopted a measure which had been approved by the very high and concurrent authority of Hunter, Cooper,

Abernethy, &c. &c. I had never before an opportunity of trying compression under such circumstances, or of seeing it employed. My conviction now is that it will rarely succeed. It is confessedly at all times difficult to produce a union in tubular or fistulous ulcers, even where pressure can be used. It is yet more so, to effect a coalescence between the opposite surfaces of blood-vessels, because, among other obstacles, the coagulable lymph which is the medium of attachment, must in a great measure be swept away by the circulation as fast as it is deposited. It is besides almost impracticable to make adequate compression on any of the veins of the arm, without interrupting the return of the blood. I confess, however, that these speculative objections to the practice, have less weight with me than the melancholy instance of its failure which I witnessed. In the case of my patient the experiment was fairly made,—for five days and nights successively, I continued the compression, and with the utmost vigilance to the due regulation of it. Distrusting, therefore, the efficacy of this expedient, if ever I should meet with a similar case I would apply a ligature to the vein. The operation, however, will not often be necessary. It can only be required where suppuration has taken place, and there are grounds for the apprehension that the matter is travelling into circulation. Cases of this sort are extremely rare. Few, at least, have been recorded. I have met in my researches with only one at all analogous. They have hitherto been contemplated by writers rather as a possible than an actual occurrence.

Injuries to the veins from bleeding are, for the most part, attended by only circumscribed inflammation. The suppurative process seldom ensues. Even when it happens it is generally limited to the vicinity of the wound, through which the pus is either freely evacuated, or is lodged in the surrounding cellular texture, and the abscess thus formed may be made by an opening to discharge externally, if, contrary to the ordinary course, it does not do it spontaneously.

CASE II.—It was in 1816, I think, for, owing to a casualty the date cannot be ascertained exactly, that I was requested by Dr. M. Phillips, a young physician of this city, to visit with him an elderly man, a native of Germany, whom he considered very strangely and alarmingly affected. Five days previously he had been bled for sciatica, and, according to the popular prejudice of his country, in the foot of the same side in which the pain was seated. Being relieved of the rheumatism by the loss of blood, he the next day resumed his occupation of driving a cart, and of course was much on his feet. Early in the evening he came home with

severe pain shooting up the leg, ascribed to a return of rheumatism. This increasing during the night, with considerable swelling of the limb, Dr. Phillips was sent for, who, adopting a similar view of the nature of the case, treated it in the usual manner by general and local bleeding, purging, the mild diaphoretics, and divers local applications, fomentations, liniments, &c. Great as the pain and swelling were, his pulse had never been full or active, the temperature even of the part high, or, indeed, any very unequivocal evidence of fever, and though the orifice of the vein had not united, there was nothing very peculiar about it. The man becoming, however, restless and delirious, with chills, rigors, and other alarming symptoms, I was consulted. The preceding account I derived from the attending physician, and which was confirmed by the wife of the patient.

On entering the chamber I was struck with the wild and phrensiad expression of countenance, and soon perceived that he was greatly agitated and distressed. Not content scarcely for a moment in any one position, he was alternately up and down, or tossing himself from side to side of the bed, and had evidently a sort of spasmodic jerking of the limbs. Examining the case, I found his intelligence very imperfect, the pulse feeble and tremulous, the skin cool, covered with a dewy sweat, especially about the forehead and neck, and there were nervous tremors, and difficulty both of articulation and deglutition. The whole of the leg, and part of the thigh, were prodigiously swollen, tense, and pale, and around the orifice, which was closed by some thick glutinous matter, was an abscess of nearly an inch in diameter that had not before been observed. By gently pressing it, a sanious fluid flowed out freely, and from stroking the vein above it, amounted altogether to an ounce and a half. The whole of the affected portion of the extremity was covered with a blister except at the orifice, over which a poultice was placed, and opium, the carbonate of ammonia, and brandy toddy liberally given. In the evening he appeared decidedly worse, having had several tetanoid spasms, and becoming so furiously deranged, that several men were required to restrain him from acts of violence. He died in the night in a convulsion, of which he had several previously. Every effort was resisted to get an autopsic inspection even of the vein.

CASE III.—Not long after the preceding, I saw, with Professor Physick, a third case of this affection. It was in a middle-aged lady, corpulent, plethoric, and of sedentary or even sluggish habits. Frightened by a recurrence of an apoplectic admonition, which she had experienced several times before, she determined at once to resort to venesection.

No longer, owing to extreme obesity, could blood be obtained from the arm, and on this occasion a vein in the hand was opened. Eleven days after this, and when the incision had completely healed, which indeed it did very promptly, she for the first time complained of sharp darting pains along the course of the vein up the limb. As Dr. Physick, her family physician, was confined at the period by sickness, the bleeder who had performed the operation was sent for, by whom she was told that a nerve or a tendon had been pricked, and that nothing was to be apprehended, as it was an injury temporary in its nature, and readily cured. Directing her to wear the hand in a sling, and to bathe it with an emollient liniment, he retired. But henceforward the pain and swelling of the forearm rapidly increased, and the same person was again consulted, who now advised the loss of blood by leeches, which were several times repeated, followed by poultices. No advantage, however, was gained by these applications, and she becoming a good deal weakened, and slightly wandering in her slumbers, Dr. Physick was urgently requested to see her. Discerning her perilous situation, and from the infirmities of his own health being incapable of paying her the attentions he thought she required, he waited in the house till I came to his assistance. The preceding history of the case was then related by him to me. This was late in the afternoon. Her general condition reminded us much of that of the incipency of low typhoid fever. The eyes were injected, the pupils slightly dilated, with a swimming fatuous expression, and she felt some uneasiness of the head. Deep sighing was frequent, and though she had vomited once or twice she still complained of epigastric oppression and of nausea. There was some distension of the abdomen, probably owing to the loaded state of the bowels, as she was constipated; the temperature of the surface unequal; the extremities cool and pallid, while the head was preternaturally warm, and the face rather florid. Her pulse was quick, irritated, and corded, of very small volume, and so irregular as to be somewhat intermittent. Depression of spirits was very conspicuous, and she frequently declared that her sensations were such, that she was sure her death was inevitable.

To the elbow, the arm was much swollen and exquisitely tender, with little pain in it, either lancinating or pulsatory, and pretty nearly of the natural hue, except here and there some livid spots appeared. The orifice was inflamed, and its lips pouting, and slightly retorted. Discovering some sanguinolent matter on the poultice, the vein was delicately pressed, when there oozed out nearly a couple of drachms of pure pus.

We recommended that a stimulating enema should be immediately given to empty the bowels, and if not succeeding, an infusion of senna and salts, administered in repeated doses, till the effect was attained. The arm was also to be covered with a blister, except at the orifice, over which a poultice was to be placed, and then secured in a case. These instructions were faithfully executed, and on my return in a few hours, I learnt that she had been amply purged with the medicine. Yet her condition had deteriorated, by an aggravation of cerebral and nervous disorder, and of jactitation and wretchedness. An opiate was now ordered. The report of the morning was, that she had slept altogether some hours, with, however, much muttering delirium. No improvement could we discern in any respect; on the contrary, as related to the general condition, manifestly worse. The blister not having drawn, it was replaced by a fresh one very carefully prepared, and bound on the limb by strips of adhesive plaster. Dover's powder and wine whey were given during the day. Towards evening we saw her again, and thought her better. For several hours she had been comparatively tranquil, and took eagerly some nourishment, sago, with wine and nutmeg. The nervous system was more steady, the intelligence perfect, the swelling of the arm considerably reduced, of the purulent discharge scarcely any, and the aspect of the wound greatly improved. Having drawn well, the blister was removed, and dressed by a mixture of the basilicon and mercurial ointments. Her recovery henceforward advanced so rapidly that I ceased to take notes of the case.

This is one of the many instances, certainly, however, not of equal severity, which I could recite of the extraordinary control of vesication over phlebitis. Except it, nothing here was resorted to of any decided curative power, and the whole of the beneficial effects may be justly ascribed to it. With entire rest of the limb, I have much reason to suppose that it will arrest a very large proportion of these cases antecedently to the suppurative stage, and even then where the attack is mild. Endocarditis, however, taking place, or such a quantity of pus having entered the circulation as to induce a state of poisoning, with all those complications of typhoid affections consequent on it, then I believe that it, in common with every thing else hitherto devised, will prove nugatory. Fortunately, however, the most violent forms of the disease are not common. The inflammation in traumatic phlebitis is usually local, and when more extensive and suppurative, the quantity of pus secreted is small, or if copious, its introduction into the circulation is very often prevented by some of those provisions wisely instituted by nature, to which I have previously alluded.

ON SEMINAL DISCHARGES FROM THE URETHRA.

BY JAMES DOUGLAS,

Lecturer on Anatomy at the School of Medicine,
Portland Street, Glasgow, &c. &c.*(For the Medical Gazette.)*

SINCE reading the papers in the GAZETTE, by Mr. Phillips, on involuntary discharges of spermatic fluid, I have always intended to send a note of my small experience on this subject, but have delayed rather too long for it to come into close enough relation with his. The readers of the GAZETTE will probably remember, however, that after describing the causes and the debilitating effects of these discharges, Mr. Phillips explained M. Lallemand's plan of treatment, by cauterising the prostatic portion of the urethra with the nitrate of silver, and gave an account of the cases in which he himself had put it in practice.

In October, 1837, I read a paper on spermatorrhœa before the Glasgow Medical Society, in which I gave an account of Professor Lallemand's opinions on this subject, and the history of a case which had occurred to myself. The patient was a medical man, and he was so impressed with the truth of M. Lallemand's doctrine, with which I had made him acquainted, that he formed the resolution of visiting Montpellier, and being operated on by the professor himself. This was accordingly done; but he did not remain sufficiently long under M. L.'s care to see that there should be no need for a repetition of the application. He was, however, greatly benefited, the discharges having become much more rare. Some months after he desired me to cauterise the prostatic urethra for him again, which I did very freely, and a renewed improvement was the result, although the discharges have never entirely ceased.

Last year a case occurred to me, which I treated with a different local application. As it appeared to me that the effect of the caustic on the urethra must be very much the same which its solution has on the conjunctiva, diminishing its sensibility or irritability, I thought that perhaps a solution of opium might serve the purpose as well, or perhaps better, attempting at the same time to give tone to the parts by the use of general means.

R. M'G., æt. 28. Nov. 20th, 1842. About six years ago fell into the practice of masturbation; at that time having never touched a woman. For about twelve months was much given to that bad practice, and ever since has continued it occasionally. About seven months after first commencing masturbation had sexual connection, and but seldom since.

Five or six months ago he complained to me of frequent slight headache, and giddiness in looking down, which he attributed to derangement of the stomach, and treated as such, with but partial success.

In August last he first noticed that he lost semen at night during sleep; not thrown out in the way of ejaculation, but running from him gradually, and without any pleasurable sensation; also without any lascivious dreams, and with scarcely any erection. About the same time he noticed the semen to be parted with when at stool, and frequently also when making water.

In the beginning of October he told me of this complaint. I inquired whether he had given up the bad practice which occasioned it, and he pled guilty to still polluting himself with it sometimes. I made him promise to give it up entirely, and this promise he has faithfully kept. I then put him on an ounce of steel (Tr. Mur. Ferri), and ordered the shower-bath, cold, every morning. By the end of October he said that he felt his general health improved, but that the emissions still continued. I then ordered a mixture of mucilage with watery solution of opium, 1 gr. of opium and 3 grains of acetate of lead to the ounce of the mixture, to be injected into the back part of the urethra, and even into the bladder. In ten days I doubled the strength of the opium. This was used three times a day. When the injection was first allowed to pass back, it produced a sensation of heat, and afterwards a pleasing soothing feeling. It has now been used for three weeks, and the improvement is very marked. He has now no nocturnal emissions, and very rarely when at stool, and these only to a very small extent.

I recommended him at this date to change the muriate of iron for the carbonate, and to continue the shower-bath and the injection.

Dec. 6th—Has improved very much in his general appearance. Uses the

injection now only before going to bed. Has had no nocturnal emissions since former date (Nov. 20th), and very few when at stool, and none at all with his urine. I advised him to continue.

This summer I had occasion to see him on account of dysentery, and learned that he was almost entirely free of his annoyance, the only remedy which he still uses being the shower-bath.

Should this treatment, by injecting the solution of sugar of lead with opium, mixed with mucilage, be found generally serviceable, it will have the advantage of not requiring the confinement which is necessary for some days after the application of the nitrate of silver.

Glasgow, 35, North Frederick Street,
September 16, 1843.

EFFICACY OF WARM INJECTIONS IN STRICTURE.

To the Editor of the Medical Gazette.

SIR,

I READ some short time back, in one of the medical periodicals, an account of a case of stricture, in which the medical gentleman in attendance found use in applying a warm fluid to the strictured portion of the urethra, through the means of an ordinary catheter.

Now it struck me at once that an instrument much more fitted to the purpose, and much more likely to succeed, would be a catheter with its orifice at the extremity instead of at the side as is usual.

I had one made, therefore, and for greater convenience a stop-cocked syringe, holding about an ounce, fitted to its other end.

My mode of applying it is this: I fill the syringe with some warm bland fluid (oil, or barley-water, for instance), and I then connect it with the catheter, and gently pass the latter down to the stricture. The moment I feel the resistance, I turn the stop-cock with the index-finger of my right hand (steady-ing the penis with my left), and propel a jet of the warm liquid upon the strictured portion with moderate force, taking care, of course, not to press the apparatus forcibly against the urethra, but keeping all firm and "well in hand."

I have tried this in four cases, and several times in each case, in which I

had before failed entirely in passing the smallest catheter, and in all with decided and instant success, the instrument always passing freely, and without the slightest pain.

I do not know whether this is novel, but as I have not seen it before myself, and as we are all bound to do our best for suffering humanity, you may perhaps think the observation worth a place in your widely circulating journal.—I am, sir,

Your obedient servant,

FRANK HUDSON.

2, Onslow Place, Brompton,
Sept. 18, 1843.

MR. LEE ON BELGIAN MEDICAL INSTITUTIONS.

To the Editor of the Medical Gazette.

SIR,

A VARIETY of interesting cases daily present themselves at the Eye Dispensary, which was established at Brussels some years ago by M. Cunier, who, in the treatment of ophthalmia and its consequences, seldom has recourse to vascular depletion, but trusts chiefly to derivatives, as laxatives, mercurials, and counter-irritants, with sedative or slightly stimulating lotions; the solution of nitrate of silver in variable proportions (from two grains to ten to the ounce of water), a few drops of which, instilled into the eyes at stated intervals, being one of the most frequent applications. Many patients, however, afflicted with the military ophthalmia (especially those from the country), frequently neglect to apply for relief until the disease has made such progress as to destroy the sight. M. Cunier has no exclusive method for the removal of cataract, sometimes performing extraction, at others depression. He has performed the operation for artificial pupil with great success in several bad cases. One of these patients, who had been blind for twenty-five years, in consequence of military ophthalmia, so far recovered his sight from the operation, as to conduct himself without any guide in the streets, and to read the larger letters on the printed bills. The case is recorded in the *Annales d'Oculistique*, a volume of which is published annually.

Prior to the revolution, medical practice and instruction was in a very

backward state in Belgium; and during the existence of the provisional government, the medical professors of one of the universities created a *free* faculty of sciences, of which the diploma might be obtained by almost any applicant; and this had a most prejudicial effect. "All that there was in the country of barbers and ignorant men hastened to present themselves before this *soi-disant* faculty, to purchase the diploma of candidate of sciences, and thus prepare the way for the acquisition, with very little trouble, of that of doctor in the three departments of medicine. The persons cannot be sufficiently stigmatised who thus degraded the honourable profession of medicine, by inundating the country with those medicators who go about bleeding and purging the community without control*."

Shortly afterwards, however, a new organization of the profession was effected. A free university was inaugurated at Brussels in 1834, the *personel* of the secondary school, which had till then existed, forming the nucleus of the faculty of medicine; and a central jury of examination was instituted, before which candidates for the diploma from the other universities were bound to appear. A Catholic university was founded at Malines, and subsequently transferred to Louvain; the universities of Liege and Ghent remaining the national ones, and kept up by the state. An Academy of Medicine was likewise formed, which, with the medical societies of Ghent, Antwerp, and Bruges, greatly contributed to diffuse information by the publication of their memoirs, to raise the condition of the profession, and to form a closer union of its members. The community of language with France, and the reprints, in a cheap form, of most of the valuable works published in Paris, had likewise great influence in extending professional knowledge. There appear now in Brussels a *Gazette Médicale*, an *Annales de Médecine*, a *Bulletin Médical Belge*, and one or two other periodicals. The *Encyclographie des Sciences Médicales*, published monthly, gives the substance of whatever is valuable in the chief medical journals of France, England, and Germany.

"Clinical instruction," says an author,

* *Coup-d'Œil sur les Institutions Médicales Belges*, par C. Broex.

whose favourable account of medicine in Belgium, as compared with France, bears the impress of great partiality, "is acquired by each pupil having the charge of a certain number of patients, respecting whose cases he is interrogated at the bed-side, reporting upon their progress from day to day: the professor verifies the exactness of the report by comparing it with that of the *interne*, and by examining the case himself; a disputation being carried on respecting the progress of the disease, and the treatment to be adopted. On the admission of a patient, the pupil to whom he is confided is required to examine the peculiarities of the case, before the professor and the students. The most prominent symptoms are noted daily upon a paper, placed at the head of each bed, on which are likewise indicated the remedies prescribed. An autopsic examination is made of the patients who die; the pathological alterations, and their reference to the symptoms during the course of the disease, being remarked upon by the professor. In the surgical department operations are frequently performed by the *internes* and the more advanced pupils, in the presence of the professor, who superintends their performance. Professorships are not obtained by the method of *concours* in the Belgian universities. The free university of Brussels forms, however, an exception in this respect. The professors are appointed by the directors of the universities, who are guided in their choice by the previous reputation of the candidates, their scientific publications, or a personal appreciation of their merits*."

Another author, however, of the highest reputation in Belgium, (M. Guislain, *Lettres Médicales sur l'Italie*) on comparing the internal organization of the hospitals in his own country with that of others, acknowledges their superiority in some respects. "As regards their localities, several of our most important establishments are susceptible of great ameliorations: they are in many parts ancient buildings, with vast wards, most frequently without fire-places; the roofs displaying immense wooden rafters, supported by columns, whose antique capitals recal

the epoch to which they belong. Almost always these buildings are faulty as regards the hygienic department, and also with respect to the patients being placed too closely together; for, except a few tolerable establishments, and two or three new institutions, all of them are in a state of degradation such as is unparalleled in other parts. There is much likewise to be desired as regards the furniture of our hospitals: the iron beds have no curtains, and where there are any they are not so appropriate to their purpose as in the establishments in the north of Italy. Our store-rooms, our kitchens, are far from presenting the abundance and comfort of those in the English hospitals; our baths and douches, where there are any, cannot be compared with those of Italy and France, which country might give us some excellent lessons in all that regards the internal administration of hospitals, which is generally neglected with us, and conducted in a mere routine manner.

"In Italy, there is an air of richness and profusion in the interior of charitable institutions, amidst the misery, often very great, which is met with in the streets. In Belgium, on the contrary, where there is a much greater amount of general comforts, our hospitals, and hospices, present an appearance, if not of indigence, at least of distress; a want of uniformity in the beds, in the colour and the material of the coverlets, which are for the most part coarse and old; a cloathing like the costume of Harlequin, patched all over; blackened walls, badly painted windows and doors, roofs which allow the rain to penetrate, and even snow to fall on the patients' beds; damp cells, in which the insane are crouched up in their dirt; doors which do not shut; 'windows broken and mended with paper.' Every where an inferiority is perceived in the administrative department, which, in many respects, is essentially egotistical, bureaucratical, wishing to economise in every thing, even in the common necessities for patients; most frequently having recourse to that worst of all measures, that of contracting for the care and attention towards the unfortunate, and neglecting all direct control and superintendence. It is this deplorable system, which sends out, in many places, foundlings, orphans, the blind, the old; the insane

* Parallele entre l'Enseignement Médical des Universités de Paris, Berlin et la Belgique, par le Doct. Van Meerbeck.

to lodge with poor or avaricious peasants; it is this system which peoples our country places, as also our hospitals, with pallid, scorbutic, scrofulous individuals; which causes a frightful mortality among the indigent, because the inadequate food which they receive is not sufficient to keep up their strength; because their clothing does not preserve them from the effects of atmospheric vicissitudes."

"There is, likewise, (continues M. Guislain), great room for improvement in the medical administration of our establishments, and particularly with reference to the appointment of the physicians and surgeons, who are generally nominated by the local authorities, upon the presentation of the administrative commissions of the civil hospitals. This method is essentially adverse to the interests of the science; we would wish to see the appointment of the medical attendants of these institutions determined by some learned body, capable of eliminating, in a proper manner, the merit of the candidates, either by a faculty of medicine, an academy, or a medical commission."

After citing the mode of election pursued at Lyons, as a model, M. Guislain further observes:—"Let us hope that our local administrations will follow the example, and abandon an old routine system directly opposed to all the principles of equity, and especially to the progress of the science. The position of a well-informed young physician is often very disheartening, amidst the obstacles by which he is surrounded, and which prevent the development of his capabilities. What a pinery for good subjects, what hopes, what a guarantee for the future, does not the method of the *concours* offer! And compare this excellent institution to our nominations by favour, in which the number of friends, the always painful and humiliating supplications, intrigue, and low manoeuvres, but too often gain the advantage over real and modest merit. The good of this method consists in its preparatory tendencies in the constitution of a school, for the development of talents formed for practice, and for the production of distinguished characters. Let it not be said that there exist insurmountable obstacles; these can only come from men behind the spirit of the age; for experience has already decided as to the

value of the mode of competition, inasmuch as the trial has already been in operation for more than fifty years in the above-named city, as well as elsewhere. It is true we have already made a step forward in this direction, since the clinical professors of our state universities are now elected by *concours*." I have quoted thus largely the remarks of M. Guislain, as affording a more correct account of the administration of affairs in Belgium than could be given by a traveller through the country. His work, however, was published in 1840, and it appears to me that ameliorations have been effected in some respects since that period.

Belgium possesses some handsome and extensive military hospitals, and the government has lately established *hospitaux des invalides*, where patients with incurable disease of the eyes are likewise received.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE CARLISLE CONTROVERSY.

"Adhuc sub iudice lis est."—HOR.

It was acutely observed by Cullen, that there are more false facts than false theories in the world. We might add, that most erroneous theories, when analysed, are found to consist of little more than imaginary facts in a state of temporary cohesion. But, alas! facts are very difficult to ascertain; the calm philosopher does not always succeed in his search; what chance has the sectarian, the party-man, the controversialist? Our brethren at Carlisle continue their hopeless debates over the grave of James Clark, "and find no end, in wandering mazes lost."

A fresh series of facts has been published in the Carlisle Patriot of the 23d inst., which, if uncontradicted, would turn the scale greatly in favour of the medical officers of the Infirmary.

The committee of the Cumberland Infirmary, having considered the great difference between the evidence given at the inquest by their own medical officers, and that of the practitioners by whom Clark was attended during the last seventeen weeks of his life, resolved to investigate the matter farther. Accordingly, they requested Mr. W. N. Hodgson, Mr. Page, and Mr. Donald, to go down to Beaumont, and make farther inquiries respecting Clark's case. Mr. Page is, of course, the surgeon of the Infirmary; who the other two inquirers are, we know not. The first person whom they examined was Mr. John Hodgson, a farmer, who had been foreman of the coroner's jury. He told them that he had long known Clark, who had been lame for many years, and even eight years ago could hardly get home from his work, so severe were the pains in his limbs. "We used always to say James Clark was as good as a weather-glass. He could always tell the weather by the pains in his joints." Clark came out of the Infirmary about the same as he went in, and continued to go about until the doctors came, who cut him and put on a splint. After this he could no longer hobble about, and was in the most exquisite torture. Five days after the operation, "he shouted aloud with the pain."

We have already seen, that when Clark was an out-patient, he was able to go in a cart, to the Infirmary, once every week. We here find, from the evidence of William Irving, that Clark went in a cart on the Saturday before the operation to Thrustonfield Mill, three miles from Beaumont, each way; and even drove himself back. He repeated the journey in the following week, the morning before, or the very day, he was "cut." "He was not worse then, not any lamer, than he had been for a very long time before. I helped

to lift him out of the bed. He was then as bad as he could be. This was after he was cut."

Thomas Todhunter, one of the jurors, says that Clark "was completely done after they cut him," yet he was in great spirits, for the doctors said they would cure him with a stiff joint. Till the doctors cut him he was walking about, not more lame than usual. He often told Todhunter he wished the doctors had never come to him.

An important fact is mentioned by this witness, and confirmed by several of the others, which certainly lightens the complexion of the case for both sets of doctors, the Infirmary, and the anti-Infirmary ones. Some weeks before the operation, Clark had a severe fall; so serious, that one of the witnesses heard that "Jemmy Clark had got a fall out of his back door and knocked his haunch out. This was a common report in the village." In speaking of the fall, Clark said to Todhunter, "I thought I'd been killed altogether, I never suffered such pain in my life." It is obvious, on the one hand, that, after this accident, Clark's case may have been extremely different from the one treated at the Infirmary. On the other hand, it is possible that the inflammation produced by the fall may have rendered measures excusable, or necessary, which would have been inadmissible before; yet we see that in spite of the fall the patient was going about as usual up to the day of the operation.

James Pearson, who was also a juror, and knew Clark, says that when he came out of the Infirmary he could walk, and Pearson "saw no odds in his lameness between going in and coming out." After the operation, the scene was changed; he was then "bed-fast."

John Graham, another juror, gives very similar evidence. Clark had been

in the field where they were dressing sheep, a few days before he was cut. Graham gives the *before* and *after* as follows:—

Before.—“He said his pain had been removed in the Infirmary, but he was still weak, and he thought it would be a long time before he would be strong. He was in a kind of low-spirited way. He said doctors could’nt mend rheumatism.”

After.—“I saw him a week or two after he was cut. Some methodists were praying with him. He was then very bad. The doctors said at the inquest that they cut him and relieved him of pain, but they never said more wrong than that—it was an untruth altogether. Every one in Beaumont knows he was far worse of pain after he was cut.”

A strange illustration of Cullen’s axiom remains still to be stated—it seems difficult, if not impossible, to ascertain what the verdict of the coroner’s jury really was. In the Carlisle Journal of the 2d inst. it was made to include an approbation of the treatment pursued by Dr. Jackson and Mr. Elliot. In the Patriot of the 9th, this was characterized as a deliberate and desperate falsehood. In the Journal of the 16th appeared a letter from Mr. Carrick, the coroner, stating that he himself had furnished the Journal with the verdict characterized as false. On the 23d, the Patriot contains a statement signed by ten of the twelve jurymen, denying that the jury either expressed or entertained the opinion that the treatment of Dr. Jackson and Mr. Elliot was correct, and all that could be done for him under the circumstances. Of the remaining jurors, James Sewell cannot remember anything that was said or done on the day of the inquest; while William Armstrong says “there has been a great deal too much fuss

about it already; it is only a piece of spite of the doctors against one another, and I shall say no more about it one way or another.” But in answer to some questions by Mr. W. N. Hodgson, he denied that he had disapproved of the treatment of Dr. Barnes, or approved of that pursued by Dr. Jackson and Mr. Elliot.

In consequence of this evidence, and more of a similar kind, the Committee came to the conclusion that the evidence of all the persons examined at Beaumont was at variance with the statements made by the practitioners who last attended the deceased. “For instance,” say the Committee in their minute, “they [namely, Messrs. W. N. Hodgson, &c.] learned that instead of Clarke being standing at his door and hobbling into the house when first seen by them, [*i. e.* Dr. Jackson and Mr. Elliot,] he was at the time sitting over the fire with his nephew—that instead of his being in the last stage of hip-disease, the slightest motion giving him the most excruciating pain, and his being just about dying, he had been, up to the time of his being operated on, in the habit of going about as usual, and on that very day had been a journey of six miles in his cart, before nine in the morning—that instead of his having no rheumatism, his rheumatism was considered as good as a weather glass in the village, and had been so for years—that instead of no hopes being held out when first seen by these medical men, he had told numerous persons that the doctors had promised to cure him, with a stiff joint,—that instead of the palliative treatment having answered its end, it was well known in Beaumont that he was far worse of pain after he had been cut; that he had received a severe blow on the part where the abscess was found, three weeks before it was

opened, and that the statement in the *Carlisle Journal*, that the jury were satisfied with the treatment of Dr. Jackson and Mr. Elliot, is altogether without foundation, they never having expressed, or even entertained, such an opinion."

Our readers will now be ready to exclaim—

Claudite jam rivos, pueri, sat prata biberunt; but we must just touch on a point or two more.

In the first place, then, the *Patriot* of the 23d inst. contains a calm and judicious letter addressed by Sir John Fife, of Newcastle, to Dr. Barnes.

After observing that no man can judge of the treatment of a case which he does not see at the time, he adds, that "a medical coroner would have understood this, and if he committed himself by asking those who last treated the case what they thought of the former treatment, an impartial coroner would also have asked the first medical attendants what they thought of the treatment of those who saw the last of the case."

Secondly, supposing an inquest to have been held, which was certainly unnecessary, a post-mortem examination ought not to have been omitted.

Lastly, the machinery of the law is very defective in a case like this. The *venue*, we believe, cannot be changed in an inquest; yet a jury of Cumbrian villagers, and a group of medical practitioners eager to attack their rivals, do not seem very fit instruments for the investigation of hidden truth. The coroner, too, had been deeply tinged with the medical politics of Carlisle, and was evidently an Anti-Infirmity man to the backbone. Can any remedy be devised for these evils? For justice, like Cæsar's wife, should not only be pure, but unsuspected.

A FREAK OF THE STARVATIONISTS.

"VAULTING ambition doth overleap itself," says Shakspeare; and it must be confessed that the "vaulting ambition" of our poor-law people sometimes overleaps itself most grotesquely. The subaltern imps, who endeavour to curry favour with the great Lords of Somerset House, overdo the thing in the excess of their zeal, forgetting that, in a country which possesses a free press, some measure of decency must be observed.

On the 8th of this month, three young men were brought up before Mr. Long, at the Marylebone Police Office, charged with refusing to work, and being otherwise disorderly, in the Strand Union Workhouse, Cleveland Street, Fitzroy Square.

It seems that the regular diet in this receptacle is as follows:—

"Six ounces of bread, with butter, and half a pint of gruel, in the morning. Three days a week they have five ounces of meat, and half a pound of potatoes for dinner; on three other days they have soup without meat, and on one day, making up the seven, suet-pudding weighing fourteen ounces. They have also six ounces of bread each day for supper, with some cheese if they like it*."

"Then they have no bread at dinner?" asked Mr. Long.

"No, sir," replied the accusing Bunyard.

But the point of the epigram is yet to come. The men, having been idle and refractory, were condemned to pick an increased quantity of oakum, namely, six pounds a day, and with only six ounces of bread instead of twelve. They were willing to do three pounds of oakum daily; but no—halve the bread, double the oakum, is the rule in Cleveland Street Workhouse.

Mr. Long, however, thought that the usual diet could not be lessened with safety, and refused to interfere against the prisoners. This case, at any rate, requires no comment.

* From the evidence of Bunyard, porter of the Workhouse.—*Times*, Sept. 9, 1843.

PATHOLOGY.

DR. BOYD has published a lengthened Report on Vital Statistics, to which Mr. Gulliver has added some interesting notes on the morbid parts, which last we subjoin.

Brain.

Yellow or rusty coloured matter in the site of old apoplectic affections was found to contain oily molecules and granular corpuscles, in a matrix of fine granular matter, and shapeless yellow fragments. Dr. Davy found the colouring matter to be peroxide of iron.

Yellow matter in the pia mater.—In two cases, in which old apoplectic cells existed in the brain, microscopic granular masses, of a deep yellow colour, were clearly seen in some parts of the *pia mater*, although the membrane had only a diffused yellowish appearance to the naked eye. The yellow matter seemed to be the peroxide of iron. In one of these cases, the *pia mater* was studded with microscopic crystals of an intense orange colour.

Old blood clots in the cerebrum.—Two were carefully examined. They had a dull red colour towards the centre, brownish nearer the surface, and yellow at the circumference. They contained a great quantity of minute molecules, larger oily globules, and granular corpuscles. Bits of the clots dried by heat on paper gave it a greasy stain. The yellow matter was peroxide of iron. Dr. Davy examined one of the clots, and found that it contained fatty matter, chiefly olein. The molecules and granular corpuscles, he concluded to be, at least in part, composed of olein; and in the lower portion of the clot he found yellow colouring matter consisting of peroxide of iron.

Lungs.

The inflamed lungs were not more commonly of a red or ruddy colour, than of a brown or leaden hue. The latter variety sometimes inclined to a slate tint. Whether the brown consolidation be or be not a chronic stage of the red,* the two kinds were found to differ in more respects than in colour. They were often more or less blended together; and occasionally existed distinctly in different parts of the same lung. The brown variety, though most commonly seen in old cases of phthisis, was repeatedly present in lungs quite free from tubercle.

Minute Molecules.—Smooth, circular, oil-like particles, varying in diameter from

$\frac{1}{8000}$ to $\frac{1}{800}$ th of an English inch; pellucid and nearly colourless when examined singly, yet generally paler and brighter in red than in brown pulmonary consolidation. The molecules were especially abundant in the early stages of pneumonia, and usually rather plentiful at every period of the disease. The molecules seem to be analogous to the elementary granules of Henle.*

Pale Exudation Corpuscles,—commonly about $\frac{1}{800}$ of an inch in diameter, but varying from $\frac{1}{800}$ th to $\frac{1}{700}$ th, were the chief objects observed in red pneumonia. They generally resembled the corpuscles of fibrinous exudations; were more or less globular, not so frequently oval; pale or nearly colourless; semitransparent; and less distinctly granulated than the dark exudation corpuscles. A great many of the pale corpuscles often presented all the characters of pus globules, but this was seldom the case with the majority. Although the pale corpuscles usually contained merely minute molecules and very fine granular matter, the larger cells sometimes inclosed others which had still smaller nuclei. The pale exudation corpuscles appear to be allied to the elementary cells of Henle.†

Dark Exudation Corpuscles.—They appeared of a dull brown colour, nearly opaque, as frequently oval as globular, often shapeless, commonly $\frac{1}{400}$ th of an inch in diameter, but almost always varying from $\frac{1}{800}$ th to $\frac{1}{600}$ th. Their dark appearance may arise from their opacity, as they may sometimes be seen to be whitish by reflected light. They were most distinctly granulated, being made up of molecules, sometimes with larger oil globules; had occasionally a nucleus, though generally not; were as frequently without as with an envelope; and when this existed, it generally formed a smaller proportion of the corpuscle than the cell-wall of the pale exudation globule. A quantity of very minutely granular matter was now and then seen in the dark exudation corpuscles. Sometimes the envelope was but partially full of the molecules, sometimes it was full to bursting. The dark exudation corpuscles are similar to the objects described by Gluge‡ and Bennett§ in softened brain, and by Dr. Henderson|| in pneumonia; and to the aggregation or granular corpuscles of Gerber.¶

The dark exudation corpuscles were the chief and characteristic compound particles observed in brown consolidation of lung, just as the pale exudation corpuscles were the

|| Lond. and Edin. Monthly Journ. October 1841.

¶ General Anatomy, Atlas, p. 5.

* Dr. Williams observes that the colour of the inflamed part in chronic pneumonia, varies from a dary dingy red, to different lighter shades of reddish brown or buff.—On the Diseases of the Chest, 4th edition, London, 1840, p. 143.

principal objects in red consolidation. But the two kinds of corpuscles were frequently seen together, especially in those parts of the inflamed lung which were of a brownish hue; and in some old cases of phthisis, molecules and the dark corpuscles were found rather plentifully in portions of the lung not in the least consolidated, but rather emphysematous, yet of a dull-brown or lead colour.

Fatty Globules.—larger than the molecules, were very commonly noticed in every variety of pneumonia and pulmonary gangrene. The fatty matter was especially abundant in the brown consolidation occurring in phthisis. The fatty globules were usually isolated, often irregular in shape, or drawn out by adhesion to the object plate, as if semifluid, and quite destitute of any envelope. They were sometimes aggregated, with or without a matrix of minutely granular matter; occasionally they were attached to or contained in a flat membranous fragment like an epithelial cell; and it was not unusual to see them clustered within a dark exudation corpuscle.

Shining corpuscles, concentrically striated.—rounded, lenticular, or oval; margins smooth, sometimes undulating, the stripes running parallel to the circumference; generally single, but occasionally including one, two, or three bodies, more or less similar to the shell; diameter very variable, though commonly about $\frac{1}{800}$ th of an inch. These are probably identical with the lenticular spheres figured by Gruby* in the expectorated matter of phthisical patients. The striated corpuscles were occasionally observed in red pneumonia, unaccompanied by tubercular disease, and very commonly in brown pneumonia, especially in old cases of phthisis. The striated corpuscles sometimes occur in other diseases, and even where no disease is suspected. I have observed them in the thymus body.

Smooth pale Globules.—of different sizes, but usually about $\frac{1}{2400}$ th of an inch in diameter, were frequently seen in red pneumonia. They were less commonly found in brown pneumonia. They are very delicate, soft, and fugitive; are destroyed by vegetable acids, and by water.

Colouring Matter.—Shapeless fragments of a bright-yellow, sometimes of a deep-orange colour, were often seen in red pneumonia. Their appearance was granular, obscurely crystalline, laminated, or rounded, and their colour was rendered more distinct by acetic acid. In the bronchial tubes of a still-born child, yellowish green matter was found in great abundance, which had exactly the same characters under the microscope as meconium from the same child. The pul-

monary parenchyma of this child had a healthy appearance, till examined microscopically, when the greenish matter was observed in considerable quantity. The black pigment of the lungs was, as usual, generally observed in irregular shapeless masses, composed merely of a congeries of extremely minute circular particles; but in many cases these particles were contained in distinct rounded cells about $\frac{1}{800}$ th of an inch in diameter, the intensely black contents contrasting strongly with the pale semitransparent cell-wall. In many cases, rounded masses of the black matter existed without any envelope; and occasionally a similar mass had about a third or fourth of its circumference occupied by a pale crescentic body, which sometimes appeared to be an imperfect cell-wall; and sometimes a smooth and rounded nucleus only partially covered by the pigmentary granules.

Tubercle.—The precise seat of pulmonary tubercle was often within the air cells;* and occasionally also in the filamentous tissue between them. In a child of eleven months the lungs were studded with small miliary tubercles, a careful examination of which showed the tubercular matter partly filling the interior of the air-cells, and partly the tissue situated exterior to them.

Chemical Observations.—Dr. Davy frequently examined the minute molecules, and found them to be chiefly composed of olein. In a recent examination of the pale exudation globules, he concluded that the cell-wall was in a great part formed by margarine, and the included molecules of olein. In the brown exudation corpuscles he found a considerable quantity of olein and some margarine.†

Although acetic acid, strong or dilute, often exerts no evident action on the juice of pneumonia, yet it is remarkable that this acid sometimes produces a tolerably copious precipitate or clot in the juice. Occasionally this clot is tenacious, and presents even a fibrous appearance when examined by the microscope. The same observations apply to the action of acetic acid on purulent matters.‡

A portion of lung (Dr. Boyd's case 490) in which the black pigment was remarkably abundant, was examined by Dr. Davy, who found that the colouring matter differed chiefly from soot in containing a little peroxide of iron, *i. e.* the black pulmonary matter yielded the oxide on incineration.

Liver.

Jaundiced Cells.—A woman, æt. 35, had

* See Willis's Translation of Wagner's Physiology, part 2, p. 360, fig. 175.

† On this subject see Henle, l. c. p. 162 and 118; Acherson, Paget's Report, p. 7; Bennett, Edin. Med. and Surg. Journ. No. 155.

‡ See Dr. Guterbock's account of Pyine, De pure et Granulatione, Berol. 1837; and Dr. Davy's Researches, Phys. and Anat. Vol. ii. p. 475.

* See Dr. Goodfellows' Translation, Microscopic Journal, September 1842 to January 1843, plate 6, figs. 89-95.

many of the tissues jaundiced. The cells of the liver were surcharged with greenish yellow biliary matter, so as to contrast remarkably with the cells of the healthy liver. A like case occurred in a child, of which the notes made at the time will be subjoined, as the subject is interesting in relation to the question of the ultimate secreting structure.* October 14, 1842: Dr. Boyd's case 515; a female fourteen days old; received part of liver, aorta, and costal cartilages, all of which were of a deep yellow colour. Cells of the liver intensely yellow under the microscope, whether viewed by reflected or transmitted light; the greater part of the colouring matter granular, or in minute shapeless fragments; some of it apparently fluid, especially near the edges of the cells; the granular part chiefly collected around the nucleus, though also irregularly scattered throughout the cell. Some of the cells, excepting a part near to the circumference, were rendered opaque by the accumulated colouring matter within them. Cells from the healthy liver of a child, aged three years, examined at the same time for comparison, afforded a striking contrast, as they were destitute of the colouring matter around the nucleus, were throughout of a light brownish colour, and nearly transparent. Some cells from the healthy liver of a woman, *set.* 90, presented a similar contrast to the jaundiced cells.

Waxy-looking liver.—Some portions from two cases were nearly of the colour of crude bees'-wax, and stiff or tenacious in texture. These characters appeared to be owing to an unusual accumulation in the liver of viscid biliary matter, with a large proportion of mucus. In neither case did the organ contain more fatty matter than in the healthy state.

Kidneys.

Lithic acid in the tubules.—A female child, born prematurely, died nine days afterwards. The cut surface of the mamillæ of the kidneys presented a multitude of streaks, from distension of the tubules with a reddish-brown solid matter, which Dr. Davy ascertained to be either lithic acid or lithate of ammonia, most probably the former.

Yellow matter.—In the substance of the medullary and cortical part of the same kidneys there were numerous very distinct microscopic particles, of a very bright yellow colour. They had a granular appearance, were quite plain after several days' maceration in water, and not affected by acetic acid.

The quantity of the yellow matter was not sufficient to enable Dr. Davy to ascertain its nature; but he agreed with me that it was different from the contents of the tubules.

Fatty matter.—The kidneys of a woman, aged 37, who died of chronic arachnitis, had a great number of white specks on the surface, and imbedded in the cortical part, very plain to the naked eye, though generally only from 1-100th to 1-50th of an inch in diameter. The specks were made up of a congeries of fatty globules, very characteristic under the microscope. In the kidneys, said to be affected with Bright's disease, from a woman, aged 58, there were in the juice a multitude of fatty globules, and a few small pearly crystalline plates. Dr. Davy extracted a little margarine, cholesterine, and a trace of olein, from a fragment of one of the kidneys.

Cysts containing margarine, olein, and yellow granular corpuscles.—In the cortical part of the kidneys of a man aged 55, who died of phthisis, there were several round or oval cysts, about a third of an inch in diameter, some of which contained a limpid yellow fluid, and others a pulpy matter, of the same colour. In some of the cysts this substance was tolerably stiff, resembling the meliceris and atheroma of authors. In the fluid were many round granular corpuscles, of an intense yellow colour, mostly with envelopes, and of very different sizes, but generally about 1-600th of an inch in diameter. There were also numerous pale fatty globules, often aggregated into clumps. In the pulpy and stiffer substance the fatty matter was so abundant as to render thick paper transparent when dried on it by heat.

Cysts containing cholesterine, and pale granular corpuscles.—In the preceding instances the fatty matter was chiefly margarine and olein; in two other cases the fatty substance was nearly all cholesterine. There were cysts filled with a limpid fluid, and imbedded in the surface of the kidneys. Each cyst was about the size of a pea. A great quantity of plates of cholesterine were found, principally sticking to the walls of the cysts. The fluid also contained many pale, round, nearly transparent, and minutely granular corpuscles, generally about 1-1300th of an inch in diameter. The kidneys were otherwise healthy.

Testicles.

After middle life the seminal tubes were often more or less obstructed with molecules, generally aggregated into irregular masses, nearly opaque, either of a dull brown, yellowish, or lead colour. Occasionally they were aggregated into oval or round corpuscles, mostly destitute of an envelope; and they were not unfrequently seen within bodies which were probably the

* See Goodsir on the Ultimate Secreting Structure, Trans. Royal Soc. Edin. Vol. xv.; Carpenter on the Origin and Functions of Cells, p. 23, from Brit. and For. Med. Rev. No. 29; Henle, Anatomie Generale, par Jourdan, p. 211.

seminal cells. This state of the tubes was almost always found in old subjects; it was by no means rare before 30 in persons who had died of lingering diseases; and was generally coincident with a fewness or total absence of the spermatozoa*. Larger oil globules were sometimes seen within the tubes. There is reason to believe that the molecules contain a large proportion of olein.

Black pigment in the intestinal mucous membrane.

Sometimes there were black specks, sometimes a diffused brown or black colour, of the mucous membrane of the large intestine†. The affection was most frequently observed in the rectum, especially in elderly people. The pigmentary granules were occasionally observed in rounded cells; but the black matter, like that of the lungs and bronchial glands, had generally no appearance of a special apparatus, but was scattered in shapeless masses, and had just the same chemical characters as the black pigment of the lungs.

Arteries.

Fatty degeneration.—This very commonly existed in the substance of the inner and middle membranes, often between them, and sometimes in the outer coat. Though most common in old age, it was twice seen in subjects not past 21, and once in a boy of 16. Even in the early stage of the disease, the fatty matter was easily recognizable in the well-known opaque whitish spots, or thickened parts of the inner tunic of the vessel. The disease was observed in the aorta and its valves, in the cerebral arteries, in the iliac and femoral arteries. In a man who died of apoplexy, the coats of the arteries of the brain, even of the smallest branches, were studded with, and made fragile by, fatty patches. I have elsewhere described the disease, and the nature of the fatty matter‡.

Black pigment.—Black and brown specks and patches were sometimes observed in the large arteries. This was caused by black pigmentary granules, in greater or less quantity, without any evident cells; generally confined to the inner membrane, but extending in one instance to the middle coat, and sometimes situated between these tunics. The pigment had the same chemical charac-

ters as that of the lungs. This discoloration of the arteries was observed where the inner tunic had become partially broken and detached near to old fatty and bony deposits.

Softened fibrine.

Several specimens from the veins were examined. The central pulpy part of the clot was found to consist chiefly of granular matter and minute molecules; larger fatty globules, and shrunken cells. Sometimes still larger compound granular corpuscles were also observed, either encysted and more or less opaque, or naked and appearing like a congeries of minute oil globules. Occasionally there were corpuscles resembling those of purulent matter; but the bulk of the softened fibrine was still granular matter, the corpuscles being much less abundant than in regular pus. The pus-like corpuscles of the fibrine were not enlarged by water; some of them were not much affected by acetic acid; others had the cell wall rendered fainter, or nearly invisible, by the acid, so as to expose nuclei resembling those of the pus globule*. Around the fluid or pulpy part, where the brine was tolerably firm, but had begun to soften, corpuscles of the character just mentioned were commonly abundant, often with an intervening tissue of very delicate fibrils, and the corpuscles were especially numerous in clots of a buff colour, opaque, with an appearance of commencing diffuence, although nowhere broken down or fluid. These clots were most commonly noticed in the heart; and they would sometimes form a viscid ropy compound, as is generally the case with fresh primary cells, when triturated with concentrated solutions of alkaline or earthy salts, or of pure alkalies.

PHYSIOLOGICAL NOTICES.

1. *The left ventricle* begs to announce to the Presidents, Vice Presidents, and Councils in Trafalgar Square and Lincolns' Inn Fields, that it cannot possibly continue to propel *venous blood through the liver* more than a quarter of a century longer. It will be happy to propel arterial blood through the hepatic artery until dooms-day, or any later period the authorities may be pleased to specify, but is fully determined to take the earliest opportunity of resigning the undignified office of propelling portal blood through the portal trunk, branches, plexuses, and hepatic veins.

2. *The spleen* humbly begs to inform the

* See a case of the seminal tubes of a bear obstructed by fatty matter, in my *Observations on the Semen and Seminal Tubes*.—*Proc. Zool. Soc. of London*, July 26th, 1842.

† See Dr Hodgkin's *Observations on Colour*.—*Lectures on Morbid Anatomy*, Vol. i. p. 297, et seq.

‡ In a paper read at the Royal Medico-Chemical Society, February 28, 1843.—*Abstracts of the Edinburgh Monthly Journal*, No

* As to the action of this acid, see Dr Bennett's *Observations*,—*Microscopic Journal*, January, and Gerber's *Anatomy*, note, p. 95, fig.

same learned bodies that it (spleen) is the root of an unfortunate *vein* out of employment; but which vein, *although* a vein, has certain remarkable peculiarities which render it perfectly competent to carry on the circulation through the liver, and serve in the triple capacity of recipient cavity, propulsive agent, and afferent vessel. An auricle, a ventricle, and an artery, do no more.—N.B. The duties of the office being slow and easy, a “nominal salary” only will be required.

3. *The thyroid gland* begs to express its conviction that the left ventricle cannot efficiently propel blood through the cerebro-spinal capillaries by applying propulsive force to that blood only behind or on the arterial side of those capillaries. It has also to state, that if the honourable Presidents, Vice Presidents, and Councils Chirurgorum et Medicorum, will permit the left ventricle to send it (thyroid gland) plenty of blood laden with propulsive force, that it is ready to pledge its honour, as an organ, not to rob that blood of such propulsive force, but to see it duly conveyed to, and allow it to impinge on, the tardy currents in the internal jugulars and left vena innominata. By this *tour-de-maitre* the thyroid gland confidently believes it would be easy to increase the rapidity of the return of blood to the heart by the superior cava, and thereby to accelerate and strengthen the *cerebro-spinal circulation*,—the only function in which the thyroid gland can condescend to play a subordinate part.

4. *The thymus* is a remarkably sleepy organ, and therefore not a communicative one.

August 7, 1843.

DR. JOHNSON ON VIVISECTION.

[As the subject of vivisection has recently excited some discussion in our pages, we think it may not be uninteresting to give Dr. Samuel Johnson's remarks on the subject, as published in an early number of the *Idler*.]

THE idlers that sport only with inanimate nature may claim some indulgence; if they are useless, they are still innocent; but there are others, whom I not how to mention without more emotion than my love of quiet willingly admits. Among the inferior professors of medical knowledge, is a race of wretches, whose lives are only varied by varieties of cruelty; whose favourite amusement is to nail dogs to tables, and to open them alive; to try how long life may be continued in various degrees of mutilation, or with the excision or laceration of the vital parts; to examine whether burning irons are felt

more acutely by the bone or tendon; and whether the more lasting agonies are produced by poison forced into the mouth, or injected into the veins. It is not without reluctance that I offend the sensibility of the tender mind with images like these. If such cruelties were not practised, it were to be desired that they should not be conceived; but, since they are published every day with ostentation, let me be allowed once to mention them, since I mention them with abhorrence.

Mead has invidiously remarked of Woodward, that he gathered shells and stones, and would pass for a philosopher. With pretensions much less reasonable, the anatomical novice tears out the living bowels of an animal, and styles himself physician, prepares himself by familiar cruelty for that profession which he is to exercise upon the tender and the helpless, upon feeble bodies and broken minds, and by which he has opportunities to extend his art of torture, and continue those experiments upon infancy and age, which he has hitherto tried upon cats and dogs.

What is alleged in defence of these hateful practices, every one knows; but the truth is, that by knives, fire, and poison, knowledge is not always sought, and is very seldom attained. The experiments that have been tried, are tried again; he that burned an animal with irons yesterday, will be willing to amuse himself with burning another to-morrow. I know not, that by living dissections any discovery has been made by which a single malady is more easily cured. And if the knowledge of physiology has been somewhat increased, he surely buys knowledge dear, who learns the use of the lacteals at the expense of his humanity. It is time that universal resentment should arise against these horrid operations, which tend to harden the heart, extinguish those sensations which give man confidence in man, and make the physician more dreadful than gout or stone.—*The Idler*, No. 17.

CASE OF ARTIFICIAL ANUS.

By R. G. WHARTON. M.D.

Grand Gulf, Mississippi.

I WAS called in August, 1841, to see a negro child, five or six days old, belonging to Mr. D. G. Humphreys, whose umbilical cord had sloughed off close to the abdomen, leaving a circular opening at least one and a half inches in diameter, penetrating through the abdominal parietes and a corresponding portion of the intestinal canal. The gut adhered firmly to the circumference of the

abdominal opening, and the bowels were evacuated exclusively through this channel. I could not ascertain what was the cause of the sloughing. Its general health was good, though it suffered a good deal from occasional paroxysm of pain proceeding apparently from irritation of the ulcerated opening. The inner surface of the exposed portion of the intestine was of a very deep red, owing probably to its exposure to the external air. I ordered simple poultices of powered slippery elm, made with the infusion of oak bark, to be constantly applied with a tolerably firm bandage, and emollient and oily enemata several times a day, to excite the action of the lower bowels. This last means afforded great relief to the pain, and after a few days fecal matter was discharged in small quantities, per anum. The local applications were occasionally varied; and under this treatment the umbilical opening gradually contracted, so that in three or four months it had become quite small, only a small quantity of the fluid portion of the fecal matter passing through it. I then touched it with argent. nit. which formed an eschar, and I suppose it had healed long ago, as I ordered it to be touched occasionally. At present (May 1843), however, there still remains a small circular ulcerated surface, very red, about two lines in diameter, from which there is a slight oozing of the watery part of the contents of the intestinal canal. This circular ulcer is surrounded by a large circular cicatrix, showing the original seat, though contracted about one third of the primary opening. I ordered the application of the nit. argent. and had the child watched so as to prevent his rubbing off the eschar, which seems to be the cause of its not having closed up before now. The child is large for its age, and perfectly healthy.—*American Journal of the Medical Sciences.*

CÆSAREAN SECTION ON A DWARF.

By Dr. CYRUS FALCONER.

THE patient was only three feet six inches in height, with ill-proportioned form. When seen by Dr. F. she had been in labour upwards of fourteen hours; the left foot of the foetus was presenting at the os externum. On examination, Dr. F. found that "the sacrum projected towards the pubis so as to give the superior strait the character of a fissure; the antero-posterior diameter being certainly not over one inch and three-fourths. The leg of the presenting foot occupied the full breadth of the fissure, affording an evidence but too conclusive that nature was not competent to the delivery.

The os uteri was well dilated, and the pains incessant and severe."

The Cæsarean section was resolved upon, and executed in the following manner:—A somewhat oblique incision was made, "beginning at the upper part, near the margin of the linea alba, crossing towards its centre in the descent towards the pubis," this being necessary "in order to get an opening large enough to extract the foetus." When the peritoneum was opened, much difficulty was experienced in preventing the escape of the intestines. The uterus being then divided, the foetus was exposed, its back presenting to the incision, "Although," says Dr. F., "I began my incision considerably above the umbilicus, such was the relative size of the child that I found it impracticable to extract it, until I had extended the opening in each direction; approaching nearly to the cartilage of the lower true rib above, and the pubis below. During my efforts to accomplish the delivery, considerable extravasation took place. The relative size of the child and mother can only be conceived by the reader, when he remembers the height of the mother—three and a half feet—and learns that the child was about the ordinary size, weighing, by conjecture, from seven to eight pounds.

"I at length succeeded, by grasping the thighs, in elevating the breech, and delivered the child, as in a breech presentation; it soon cried lustily, and was separated from the cord. The uterus now contracted powerfully, the placenta was expelled, the extravasated blood removed as much as possible, and we then proceeded to dress the wound.

"Four or five points of the interrupted suture were employed—long adhesive strips were applied between the sutures, leaving a space at the lower portion, for the escape of any discharge that might accumulate. A broad compress was next applied, and the whole covered with a broad, firm bandage, tolerably tight.

"During the operation, the patient made very little complaint; she now said she felt very comfortable, and expressed much gratification at being relieved by an amount of suffering so much less than she had apprehended. An anodyne was administered, and finding her, at the end of a couple of hours, still comfortable, and inclined to rest, I left her."

Before morning, however, inflammation was developed, and the patient died on the eighth day.

"The child did well, and is now a vigorous, healthy, and well-formed little girl."—*Ibid.*

TREATMENT OF VASCULAR NÆVUS.

PROF. N. R. SMITH, of Baltimore, has devised the following method of treating vascular nævus. He saturates a thread with a saturated solution of caustic potash. This is dried by a fire, and a needle being armed with it, the base of the tumor is transfixed with the needle, and the thread quietly drawn through the part. This is repeated in different parts of the tumor. Dr. S. states that he has now under care a case treated by this plan, and the tumor is rapidly wasting, without any distressing symptoms having occurred. —*Maryland Med. and Surg. Journ.*

RESEARCHES
ON THE
DECOMPOSITION AND DISINTE-
GRATION OF PHOSPHATIC
VESICAL CALCULI;
AND ON THE INTRODUCTION OF CHEMICAL
DECOMPOSANTS INTO THE
LIVING BLADDER.
BY S. ELLIOT HOSKINS.

THE object of these researches was the discovery of some chemical agent, more energetic in its action on certain varieties of human calculi, and less irritating when injected into the bladder, than any of the fluids hitherto employed.

These indications not being fulfilled by dilute acids, or other solvents which act by the exertion of single elective affinity, the author investigated the effects of complex affinity in producing decomposition, and consequent disintegration of vesical calculi.

For this purpose an agent is required, the base of which should unite with the acid of the calculus, whilst the acid of the former should combine and form soluble salts with the base of the latter. The combined acids would thereby be set free in definite proportions, to be neutralized in their nascent state, and removed out of the sphere of action, before any stimulating effect could be executed on the animal tissue. These intentions the author considers as having been fulfilled by the employment of weak solutions of some of the vegetable super-salts of lead; such as the super-malate, saccharate, lactate, &c. The preparation, however, to which he gives the preference, is an acid-saccharate, or, as he calls it, a *nitro-saccharate of lead*.

This salt, whichever it may be, must be moistened with a few drops of acetic, or of its own proper acid, previous to solution in water, whereby alone perfect transparency and activity are secured. He further states, that the decomposing liquid should not

exceed in strength one grain of the salt to each fluid ounce of water, as the decomposing effect is in an inverse ratio to its strength.

Having by experiments, which are fully detailed, ascertained the chemical effects of the above class of decomponents on calculous concretion *out of the body*, the author briefly alludes to the cases of three patients, in each of whom from four to eight ounces of these solutions had been repeatedly, for weeks together, introduced into the bladder, and retained in that organ, without inconvenience, for the space of from ten to fifty minutes. — *Proceedings of the Royal Society*, No. 56.

INSULT TO THE MEDICAL PROFESSION.

To the Editor of the Medical Gazette.

SIR,

ALLOW me to request your public reprobation of the accompanying "private and confidential" gross insult to the medical profession; and at the same time to suggest, that the shameful bargaining for attendance on Poor-Law Unions may possibly have appeared to promise it success.—I am, sir,

Your obedient servant,

C.

London, Sept. 1843.

PRIVATE AND CONFIDENTIAL.

23d June, 1843.

SIR,—As you must professionally know how very frequently funeral expenses press heavily on the funds of families, I beg leave to submit to you my plans, which combine economy with perfect decency at the smallest expense.

The highest prices combine funeral respectability, and even elegance, at very reduced charges; whilst the system tends to, and is, gradually abolishing walking funerals, by having a carriage to convey six mourners to and from any Cemetery at less cost; thereby giving to the poorest of the population the advantage of Cemetery interment, and mitigating the evil and disgust naturally attending many of the present grave-yards.

Should you be of opinion that by influencing families, in the hour of distress, to adopt my system, you are rendering them pecuniary service, and preserving public health, it will of course promote the interests of the "Cemetery and General Funeral Company," with which my patent carriages are united; and upon my being informed of such recommendations, I will pay into the Medical Benevolent Society, or to any hospital fund, 5 per cent. of the cost of such funerals.

Should it be preferred that such remuneration

ration should be personal, the amount shall be privately and most confidentially paid on addressing a note that you have rendered this essential benefit to families, and to the public health of the metropolis.

I hope you will put the most favourable construction on the novelty of my plan, which is respectfully submitted to you; and apologizing for the intrusion,—I remain, sir,
Your most obedient servant,
GEORGE SHILLIBEE.

P.S. A visit to the principal establishments, at the City Road, adjoining Bunhill Fields Burial Ground, and at High Street, facing St. Marylebone Church, also one on a smaller scale, at 136, Union Street, Southwark, will no doubt convince you of the public usefulness of my project.

Should church-yards be preferred to cemeteries, the expense is the same, subject only, in many instances, to the higher church fees.

OVARIAN OPERATION.
(From a Correspondent.)

WE understand that Mr. Walne operated successfully, by the large abdominal section, in a third case of dropsical ovarium, on the 12th inst. The tumor, weighing twenty-eight pounds, was removed entire, and the patient, a lady under twenty years of age, is recovering rapidly and satisfactorily.
[We hope to be able to lay before our readers the full particulars of this case in our next number.—ED. GAZ.]

BOOKS RECEIVED FOR REVIEW.

Lectures on the Principles and Practice of Physic, delivered at King's College, London. By Thomas Watson, M.D. Fellow of the Royal College of Physicians, &c. &c. In two volumes.
Dr. MacLagan on the Bebeern Tree of British Guiana.
Pulmonary Consumption, successfully treated with Naphtha. By John Hastings, M.D. Senior Physician to the Blenheim Street Free Dispensary.
Lectures on Polarised Light, delivered before the Pharmaceutical Society of Great Britain, and in the Medical School of the London Hospital. Illustrated with Engravings.

Cheyne, Dr. on bronchial blennorrhœa, considered in connection with rheumatism, 866.

Child, Dr. C. G. on pseudo-eructation, 386.

Childs, Mr. on the treatment of gonorrhœa by superficial cauterization of the urethra, 646.

Christison, Dr. on the preparation of the fluid extract of senna, 877.

Churchill, Dr. Fleetwood on the theory and practice of midwifery, reviewed, 101; report by, of the Western Lying in Hospital, Dublin, 620.

Cirrhosis of the lung, Dr. Stokes on, 287.

Circulation in acardiac fœtuses, Mr. Jackson on the, 467.

Citrate of iron, Mr. G. M. Mowbray on, 836.

Clark, Sir James, on medical reform, 77.

Clark's, Mr. Willington, case of intra-thoracic tumor, 134.

Clendinning, Dr. on the medicinal properties of Indian hemp, 279.

Cold, Mr. T. W. King's reflections on the influence of, upon the living body, 453.

College of Surgeons, appointment of president and vice-president of the, for the ensuing year, 624.

College of Surgeons, correction of an error in the notice of the new charter, 842.

College of Surgeons, notice of the late alterations in the regulations of the, 779; copy of the regulations of the council, 810.

College of Surgeons, list of gentlemen who have received diplomas: 80, 112, 144, 176, 256, 288, 336, 368, 400, 432, 480, 512, 544, 576, 624, 656, 688, 720, 752, 784, 816, 848, 880, 912, 944.

Colmer, Mr. on paralysis in teething children, 143.

- Collambell, Mr. on the reduction of hernia, 317.
- College of Physicians, list of gentlemen who have passed their examination, 112; names of gentlemen who received their degrees on the 28th April, 224; names of physicians appointed fellows of the, 624.
- Collegiate system, editorial observations on the, 426.
- Combination, editorial remarks on the prevailing tendency to, 26.
- Copeman, Mr. on the nature and treatment of apoplexy, 223.
- Corrosive sublimate, Dr. A. Frampton on a new test for, 384.
- Corrosive sublimate, observations by Forensis upon the new process proposed for the detection of, by means of metallic silver, 677, 709.
- Cornea, on the death of the, from chemosis, with remarks on the advantage of mercury in iritis, 708.
- Cough, nervous, M. Diday on a simple means of preventing or stopping, 844.
- Croup, Dr. West on a peculiar form of, which occurs as a complication of measles, 796.
- Cusack's, Mr. case of popliteal aneurism cured by pressure, 398.
- Cyclopædia of anatomy, complaint of the delay in the publication of the, 719.

D.

- Dalrymple, Mr. on the nature of the ossification of encysted tumors, 476.
- Dauverger's, M. cases of varus mentagra and gutta rosea, treated with sulphate of iron externally, 911.
- Deafness, M. Jobert on electro-puncture in the treatment of, depending on paralysis of the acoustic nerve, 367.
- Deafness, Mr. Toynbee's practical researches into the local causes of, 542.
- Death, sudden, Mr. Hand's remarks on the post-mortem examination in a case of, 71.
- Death, Dr. Deschamps on the signs of, 224.
- Deazeley's, Mr. case of tumor of the pharynx, 868.
- Deformity, congenital, of the head and neck of the femur. Dr. Knox on a, 860.
- Delirium tremens, Mr. Tapson's report of a case of, complicated with, and somewhat masked by, pneumonia, 683.
- Dendy's Mr. Walter C. case of closure of the vagina, 317.
- Deschamps, Dr. on the signs of death, 224.
- Diabetes, Dr. Bence Jones on the sugar in the blood in, 280.
- , notice by Mr. Markwick of an error in his translation of Dr. Bell's essay on, 253.
- mellitus, Dr. John Percy's case of, with numerous observations, and a review

- of the pathology and treatment of this disease, 44, 88, 119, 591, 640.
- Diabetes mellitus, Dr. J. F. Hodges' case of, 525.
- Diday, M. on a simple means of preventing or stopping nervous cough, 844.
- Diseases of children, Dr. Stöber on the, 510, 543.
- Dislocation, compound, of the first upon the second phalanx of the thumb, Dr. Norris's case of, 333.
- Domville's, Serjeant, remarks on a case in which symptoms like croup came on after scarlet-fever, and for which tracheotomy was performed, 204.
- Donné, M. on the composition of milk, 717.
- Douglas, Mr. note from, respecting the delay in the publication of the Cyclopædia of Anatomy, 719.
- Douglas, Mr. on the treatment of seminal discharges, 929.
- Dropsical ovaris, Mr. Camplin on the removal of, 805.
- Druggist, narrow escape of a, 912.
- Ducros, M. on the treatment of hemicrania and tic douloureux by cauterising the palate, 878.
- Dundee Royal Lunatic Asylum, extract from report of the, 781.
- Durant's, M. case of reduction of prolapsus uteri, after sixteen years' continuance, 31.
- Durrant, Dr. C. M. on the nature, diagnosis, and treatment of incipient phthisis, 324, 354.

E.

- Echometer, Dr. Aldis's, described, 249.
- EDITORIAL ARTICLES:—Combination, 26; population of England, 73; medical education, 102, 168; lunatic asylums in England and Ireland, 135; quack medicines, 210; legislation in medicine, 249; lunatic asylums, 276; gratuitous practice, 330; the revenue in jeopardy from spurious chemistry, 362; society for relief of widows and orphans of medical men, 388; the collegiate system, 426; professional success, 473; employment of women and children in agriculture, 506, 569; remuneration in general practice, 536; private tuition, 615; the last news from Gräfenberg, 651; private tuition, 680; women and children as agricultural labourers, 710; bathing, 743; the plea of monomania in criminal cases, 776; vital statistics of Sheffield, 807, 839; a late inquest in the north, 868; what is quackery? 902; Carlisle controversy, 905, 934.
- Education, medical, 102, 168.
- Emplastrum cerati saponis, form for, in prescriptions, 575.
- Empyema, case of, terminating favourably by spontaneous opening, 335.
- Emphysema of the internal organs, Mr. D. R. M'Nab on a case of, found in a

- child after having lived ten years with general emphysema, 314.
 Endocarditis in childhood, Dr. Charles West on, 738.
 Enteritis, Mr. Tapson on a case of, ushered in by copious discharges of blood from the bowels, 618.
 Erichsen's, Mr. practical remarks on the employment of arsenic in the treatment of diseases of the skin, 196, 238; circumstances that contra-indicate the employment of the arsenical preparations, *ib.*; temperament and habit of body of the patient, *ib.*; complication of the cutaneous affection with other diseases, 240; nature, stage, and condition of the diseases of the skin itself, 241, 263.
 Erichsen, Mr. on the sensibility of the glottis after the performance of tracheotomy, with the description of a new instrument, 556.
 Erysipelas of the face, case of, reported by Mr. Tapson, followed by scarlatina, and an abundant minute vesicular eruption, cured by aperients, antimonials, &c. 104.
 Ewen's, Mr. case of abscess in the inguinal canal, 836.
 Eye, Professor Rosas' operations on the, 511.
 Eye, Dr. J. C. Hall's remarks on certain diseases of the, 98.
 Eye, Dr. Hocken on the application of the nitrate of silver in diseases of the, 771.

F.

- Farre, Dr. T. J. on Indian hemp, 209.
 Farr's, Mr. W. notice relative to return of "causes of death," 252.
 Fawdington, the late T. Esq. biographical notice of, 280.
 Femur, Dr. Knox on a congenital deformity of the head and neck of the, 860.
 Fenwick, Mr. on the functions of the lacteals, 605.
 Ferri citras, Mr. G. M. Mowbray on, 836.
 Fever, rheumatico-catarrhal, case of, with metastasis to the toes, 432.
 Fever, note by Dr. Knox on the statistics of, 770.
 Fissure of the soft and hard palate, Dr. J. Mason Warren's operations for, 876.
 Fœtal circulation, Dr. Thomas Williams on the homology of the, 17, 80.
 Fœtuses, acardiac, Mr. Jackson on the circulation in, 467.
 Fractures, Mr. Norman on the treatment of, by means of the starched bandage, 704.
 France, Mr. on ophthalmic surgery, and remarks on the Royal Westminster ophthalmic report, 527.
 Frampton, Dr. Algernon, on a new test for corrosive sublimate, 384.

- Frogley, Mr. on two remarkably similar cases of osteo sarcoma of the thigh bone, requiring amputation in both instances, 75.

G.

- Gangrene of the face, and its treatment, Mr. Obre's remarks on, 75.
 Gavin, Mr. on feigned and fictitious diseases, chiefly of soldiers and seamen, &c. reviewed, 775.
 Gazsan's, Dr. P. case of luxation of the patella on its axis, 845.
 Gloucester Lunatic Asylum, extract from report of the, 110.
 Glover, Dr. R. M. on medical reform, 285.
 Glottis, Mr. Erichsen on the sensibility of the, after the performance of tracheotomy, with a description of a new instrument, 556; remarks on the paper, by "E.," 720; reply to, by Mr. Erichsen, 751.
 Gold medal, presentation of a, to Sir B. Brodie, 714.
 Gonorrhœa, Mr. Childs on the treatment of, by superficial cauterization of the urethra, 646, 816.
 Götz, Professor, account of the obstetrical Clinique at the University of Grätz, during 1837—8, 623.
 Gout, Mr. Parkin on the efficacy of carbonic acid gas in, 131.
 Gräfenberg, the last news from, 651.
 Gratuitous practice, editorial observations on the extent of, in England, 330.
 Greece, Dr. John Bouros on the mineral waters of, 917.
 Griffith, Dr. J. W. on molecules and molecular motion, 502.
 Guerin, M. Jules, on strabismus, 254.
 Gulliver's, Mr. pathological notes, 937.
 Guthrie, G. J. on the payment of medical officers of unions, 111.
 ———, on medical reform, 687.
 ———'s, Mr. Charles, reply to some remarks on the Westminster Hospital report, 624.
 Guy, Dr. on the influence of the seasons, 874.

H.

- Hæmorrhoids, Mr. R. A. Stafford on the treatment of, 62.
 Hahnemann, Dr. notice of the decease of, 688.
 Hall's Dr. J. C. remarks on certain diseases of the eye, 98.
 ———, note from, respecting the claim to priority in the use of mercury in iritis, 655.
 Hands, Mr. B. A. remarks by, on a post-mortem examination in a case of sudden death, 71.

- Handysides, Mr. notice respecting the trichina spiralis, 805.
- Harris, Dr. S. on the treatment of puerperal convulsions before the full term of uterogestation, 892.
- Harrison's, Mr. J. G. remarks on the medico-legal evidence in a case of sudden poisoning, 286.
- Head, clinical lecture by Mr. Solly on injuries of the:—Inflammation of the membranes of the brain, caused by fracture of the skull, arrested by antiphlogistic measures and aconite, 235; laceration of brain, from a blow, without fracture of the skull, 237; sequel and fatal termination of the case of John Wingrove, admitted with compound fracture of the skull, 344; on the use of the trephine, 347.
- Heart, Dr. Willis on the diseases of the:—Malformations of the heart, 125; cyanosis, 125; inflammation of the heart, and of its internal and external investing membranes, 128; carditis, myocarditis, *ib.*
- Heart, Mr. W. King on a peculiar sound of the, independent of valvular disease, 774.
- Heat, Dr. T. W. King on the influences of, on the living body, 595.
- Hedley's, Mr. remarks on the case of the late Sir. C. Nightingale, 806.
- Hemiplegia, case of, from tying the common carotid artery, 255.
- , from tying the common carotid artery, 400.
- Hemiplegia, Dr. Inman on a case of, consequent on syphilis, 608.
- Hemicrania and tic douloureux, M. Ducros on the treatment of, by cauterizing the palate, 878.
- Hernia, Mr. T. W. King on the causes of strangulation and death in cases of, or the signs of constitutional or humoral disorder in such cases, 192.
- , strangulated femoral, Mr. Toynbee's case of, in which the sac was distended with fluid blood, 209.
- , Mr. Collanbell on the reduction of, 317.
- , Dr. T. C. Stewart on a new knife for operating in cases of, 878.
- Heumann, M. on the preparation of muriatic acid, 334.
- Hocken, Dr. on the varieties, causes, pathology, and treatment, of diseases of the retina, 476.
- , on the application of the nitrate of silver to the outside of the eyelids, in superficial diseases of the eye, 771.
- Hodges', Dr. J. F. case of diabetes mellitus, 525.
- Hodgkin, Dr. on the characters and structural peculiarities of a group of morbid growths in which cancerous aff. ctions are included, 475.
- Hoffmann, Dr. on the doctrine of metamorphosis, 532.
- Holland's, Mr. case of perforation of the stomach, and consequent peritonitis, 97.
- Holland, Mr. on the medico-legal evidence in a case of suspected poisoning, 171.
- Holmes's, Dr. case of presentation of the belly, 648.
- Holst's, Dr. account of a child which was born in the twenty-fifth week of pregnancy, and lived three days, 623.
- Homœopathy, fatal effects of, 79.
- Hooper's Dr. Physician's vade-mecum, reviewed, 101.
- Horse, Mr. Webb on roaring in the, 877.
- Horner's, Professor, case of luxation of the cervical vertebræ, 367.
- Hospitals and hospital schools, changes in the, 428.
- Houlton, Dr. on collecting and preserving roots for medicinal purposes, 719.
- Hudson, Mr. on the efficacy of warm injections in stricture, 930.
- Hughes's Dr. H. M. illustrations of the alleged fallacies of auscultation. 418, 447.
- Hull, Dr. Robert, on vivisection, 862.
- Humerus, Dr. Knox on the structure of the, 529.
- Human structure, Dr. Knox on some varieties in, 502.
- Hunt, Dr. on cancrum oris, and phagedena of the cheek, and on the effect of chlorate of potash on those diseases, 76.
- Hutton's, Dr. case of popliteal aneurism, cured by compression of the femoral artery, 396.
- Hydrocele, encysted, Mr. Liston's observations on, 366.
- Hydriodic acid, on the preparation of, 875.
- Hydrostatic bed, Dr. Ogden on a modification of Dr. Arnott's, 707.
- Hysteric monomania, Dr. A. Lopez's case of, 855.
- Hydrosulphuret of ammonia, Mr. Randall on a process for, 622.

I.

- Ileus, Messrs. M'Nab's case of, 166; continuation of the case, 275.
- Indian hemp, Dr. T. J. Farre on, 209.
- Indian hemp, Dr. Clendinning on the medicinal properties of, 279.
- Inquest, a late, in the North, editorial observations on, 868.
- Inman's, Dr. case of hemiplegia consequent on syphilis, 608.
- Insanity, Dr. A. J. Sutherland's lectures on the theory and medical treatment of:—
- LECT. 1.—Introduction, 297; different theories of the nature and seat of insanity, 298; reasons for considering the seat of the disease to be in the brain, *ib.*; of disorders of the mental faculties, 299; of fatuity, *ib.*; incoherence, *ib.*; delusion, *ib.*; of disorders of emotion, 300; hallu-

cination, 301; illusion, 302; examples of each, *ib.*; alterations of the sensitive nerves, 303; alterations of the motor nerves, 304; general paralysis, *ib.*; Foville's theory, 305.

LECT. 2.—Alterations in the blood—pulse, 379; diagnosis between phrenitis and insanity, 380; signs of acute inflammation seldom met with in insanity, *ib.*; congestion, active, passive, or mechanical, generally accompanies the disease, 381; hyperæmia—Anæmia, 382; alterations in the quality of the blood, 383; M. Couerbe's theory refuted by M. Frémy, 383; post-mortem examination, 407.

LECT. 3.—The medical treatment, 443; the faculty of attention a good test of the amount of insanity, 444; caution necessary in estimating the value of a medicine in the treatment of madness, *ib.*; of purgatives, *ib.*; hellebore, *ib.*; opinions of Alex. Trallianus and Oribasius, 445; the preparations of mercury, *ib.*; taraxacum, croton oil, &c., 446; emetics: potassio-tartrate of antimony, 447; of narcotics—use and abuse of opium, 487; hydrocyanic acid, 488; digitalis, *ib.*; diuretics, *ib.*; tonics—mineral tonics, 489; blood-letting—leeches—cupping, *ib.*; counter-irritants, 490; setons, *ib.*; baths, *ib.*; antispasmodics, *ib.*; conclusion, *ib.*

Insanity, editorial observations on the treatment of, 276.

Insanity, Dr. Webster on, 541.

Insanity, report on the treatment of, at the Gloucester Lunatic Asylum, 110.

Insanity in France, announcement on the subject of, 752.

Insult to the medical profession, 943.

Irritation, Mr. T. W. King's rudimentary considerations on the nature of, 307.

Irrigation and water-dressing in the treatment of stumps after amputation, Mr. Jesse Leach on, 802.

J.

Jackson, Mr. on the circulation in acardiac fetuses, 467.

Jobert, M. on electro-puncture in the treatment of deafness depending on a paralysis of the acoustic nerve, 367.

Johnson's, Dr. Samuel, remarks on the subject of vivisection, 941.

Jones, Dr. Bence, on the sugar in the blood, in diabetes, 280.

K.

Kemp, Dr. on the difference of the bile as it flows from the liver, and the cystic bile, 207.

Knox's, Dr. Robert, contributions to anatomy and physiology, 463, 499, 529, 554, 586, 637, 860.

Knox, Dr. on the statistics of the vibrio humana, 305; note by, on the statistics of fever, 770.

Knox's, Dr. reply to a memoir, by M. Maligne, entitled, *recherches sur la fréquence des hernies selon les sexes, les âges, et relativement à la population*, 901.

King, Mr. T. W. on the causes of strangulation and death in cases of hernia, or the signs of constitutional or humoral disorder in such cases, 192; on the causes of death after operations in the London hospitals, 287; rudimentary considerations on the nature of irritation, 307; reflections on the influences of cold upon the living body, 453, 595.

King, Mr. W. on a peculiar sound of the heart, independent of valvular disease, 774.

L.

Lacteals, Mr. Fenwick on the functions of the, 605.

Lambert's, Mr. Edmund, account of the symptoms attending the illness of the late Sir Charles Nightingale, with the post-mortem examination, 675, 743.

Latham, Dr. John, notice of the decease of, 176; biographical sketch, 212.

Leach, Mr. on irrigation and water-dressing in the treatment of stumps after amputation, 802.

Lead, Professor Otto's two cases of poisoning by, in Maccuba snuff, 138.

Lee's, Dr. Robert, lectures on the principles and practice of midwifery—see "Midwifery, Dr. Robert Lee's lectures on the principles and practice of."

Lee, Mr. Edwin, on Belgian medical institutions, 898, 930.

Leeches, how to make them bite, 480.

Legislation in medicine, editorial observations on, 249.

Lizars', Mr. Alexander S. notice respecting the trichina spiralis, 805.

Lloyd, Mr. E. A. on the presence of spermatozoa in the fluid of common hydrocele, 476, 541.

London Hospital, statistical account of the accidents brought to the, during the year 1842, 143.

Lopez's, Dr. A. case of hysteric monomania, 855.

Lunatic Asylum Reports.—Belfast Asylum, 781; Dundee Royal Asylum, *ib.*; Montrose Lunatic Asylum, *ib.*; Retreat, near York, 783.

Lunatic asylums in England and Scotland, editorial observations on the management of, 135, 276.

Lang, Dr. Stokes on cirrhosis of the, 287.
Luxation of cervical vertebræ, case of, 367.

M.

Macilwain, Mr. on vivisection, 897.
M'William's, Dr. medical history of the expedition to the Niger, reviewed, 506.
M'Pherson's, Mr. case of fatal wound of the chest, accompanied with diarrhœa and excessive vomiting, 322.
M'Nab's, Messrs. case of ileus, 166; continuation of the case, 275.
M'Nab's Mr. D. R. case of emphysema of the internal organs, found in a child after having lived ten years with general emphysema, 314.
M'Cash, Mr. on the evil consequences of the too early application of the starched bandage in a case of simple fracture of the fore-arm, 602.
Macwilliam's, Dr. scenes on the Niger, 878.
Maclachlan, Dr. on primary cancerous degeneration and ulceration of the lung, 23.
Malcolm's, Mr. case of artificial anus successfully treated by incision of its divided edges, 361.
Maudl, M. on the tartar on the teeth, 843.
Markwick, Mr. Alfred, notice by, of an error in his translation of Dr. Bell's Essay on diabetes, 253.
Marriages, early, in oriental countries shewn by Mr. Robertson to be no proof of early puberty, 609, 666.
Materia Medica, notice of the re-opening of Mr. Battley's Museum of, 176.
Measles in an adult, Mr. Tapson's report of a case of, 477.
Medical reform, Sir James Clark on, 77.
Medical reform, remarks on, by Nemo, 109.
Medical reform, remarks on, by Philomathes, 139, 281.
Medical reform, resolutions passed at the North of England Medical Association, 144.
Medical reform, proceedings respecting, in the House of Commons, 170.
Medical reform, annual general meeting of the North of England Medical Association, 217, 285.
Medical reform, Mr. W. H. O. Sankey on, 394, 429.
Medical reform, letter on the subject of, by Mr. G. J. Guthrie, 687.
Medical attendance on the poor, alteration in the order of the Commissioners of 12th March, 1842, 880.
Medical education, editorial observations on, 102, 168.
Medical meeting in Surrey, with copy of petition to parliament, 31.
Medical meeting in Worcestershire, copy of petition to parliament, 76.

Medical officers to unions, Mr. G. J. Guthrie on the payment of, 112.

Medical and Chirurgical Society, note from "Justitia," respecting the election of officers to the, 32.
Medicine, editorial remarks on legislation in, 249.
Mesmerism, Mr. George Southam on the injurious effects of, 352, 459.
Mesmerism, Mr. Beddow's remarks on, 649.
Melancholia coming on during pregnancy, Mr. Tapson's report of a case of, 394.
Meningitis, Mr. C. Vines' case of, 422.
Menstruation, Dr. Raciborski's pathological studies on, 718.
Meteorological Journal, 32, 80, 144, 256, 288, 366, 368, 400, 432, 480, 512, 576, 624, 656, 688, 720, 784, 816, 848, 864, 944.
Metamorphosis, Dr. Hoffman on the doctrine of, 532.
Midwifery, Dr. Robert Lee's lectures on the principles and practices of:—
LECT. 21.—On the symptoms and treatment of natural labour, 1.
LECT. 22.—On protracted and difficult labours, 33.
LECT. 23.—Protracted and difficult labours, from rigidity and premature rupture of the foetal membranes, over-distension of the uterus, and unusual size and presentation of the head of the child, 81; from oblique position of the os uteri, 83; from rigidity of the foetal membranes, their premature rupture, imperfect discharge of the liquor amnii, over-distension of the uterus by dropsy of the amnion and a plurality of children, 84; from shortness of the umbilical cord, in consequence of being twisted once or several times around the neck and trunk of the child, *ib.*; from unusual size and ossification of the head of the child, hydrocephalus, the forehead situated under the arch of the pubes, presentation of the face, one of the arms with the head, death of the child and distension of its abdomen with air or fluid, 85.
LECT. 24.—Protracted and difficult labours, from the forehead of the child being inclined to the symphysis pubis, 113; from presentation of the face, 115; from one of the extremities descending along with the head, 118.
LECT. 25.—Protracted and difficult labours from original smallness of the pelvis, distortion, exostoses, and other morbid conditions, the most frequent causes of difficult labour, 177.
LECT. 26.—On protracted and difficult labours from anchylosis of the coccyx and tumors within the pelvis, 225.
LECT. 27.—On the invention and use of

the forceps in protracted and difficult labour, 259.

LECT. 28.—On the application of the forceps, 337.

LECT. 29.—On the operation of craniotomy, 369; on the induction of premature labour, 372; on the Cæsarean section, 374; a tabular view of 127 cases of difficult labour in which delivery was effected by the operation of craniotomy, 375.

LECT. 30.—On the causes, symptoms, and treatment of preternatural labours, 401; treatment of presentations of the nates and inferior extremities, 403.

LECT. 31.—On preternatural labours, 433; presentations of the shoulders and superior extremities, 433; a tabular view of sixty-six cases of shoulder and arm presentations, 438.

LECT. 32.—Preternatural labours, continued, 481; presentations of umbilical cord, *ib.*; labours with two or more children, 485.

LECT. 33.—On labours complicated with uterine hæmorrhage from placental presentation, 513; a tabular view of thirty-eight cases of uterine hæmorrhage from placental presentation, 520.

LECT. 34.—On labours complicated with uterine hæmorrhage occasioned by detachment of the placenta from the superior part of the uterus, 545; a tabular view of thirty-seven cases of severe uterine hæmorrhage, occasioned by detachment of the placenta from the superior part of the uterus, 546.

LECT. 35.—On labours complicated with uterine hæmorrhage after delivery of child and retention of the placenta, 577; on uterine hæmorrhage between the delivery of the child and expulsion of the placenta, 578; on uterine hæmorrhage after the expulsion or extraction of the placenta, 578; on retention of the placenta, 582; a tabular view of thirty-one cases of retention of the placenta, 583.

LECT. 36.—On labours complicated with convulsions, 625; treatment of puerperal convulsions, 627; a tabular view of fifty-two cases of puerperal convulsions, 629.

LECT. 37.—On labours complicated with inversion of the uterus, 657; on rupture of the uterus, 561; on extravasation of blood into the labia, 664.

LECT. 38.—Inflammation of the uterine system in puerperal women, 689; tabular view (No. 1) of 100 cases of severe inflammation of the uterus and its appendages, which occurred in London from March 1827 to the end of December 1830, 691, 726; inflammation of the uterine appendages, ovaria, fallopian tubes, and broad ligaments, 697; inflammation and

softening of the muscular coat of the uterus, 698.

LECT. 39.—On inflammation of the veins and absorbent vessels of the uterus in puerperal women, 721.

LECT. 40.—On the causes and nature of inflammation of the uterus and its appendages in puerperal women, 753; tabular view (No. 1) of 100 cases of severe inflammation of the uterus and its appendages, which occurred in London from March 1827 to the end of December 1830 (continued) 757.

LECT. 41.—Acute bronchitis, with vesicular emphysema and cretaceous concretions in the lungs—dilated hypertrophy of the heart, and disease of the aortic valves—disease of the liver, kidneys, &c.—fatal termination—*sectio cadaveris*, 811.

LECT. 42.—On the treatment of uterine inflammation in puerperal women, 817; tabular view (No. 2) of 62 additional cases of inflammation of the uterus and its appendages, observed from January 1831 to the end of April 1835 (continued) 823.

LECT. 43.—On crural phlebitis, 849.

LECT. 44.—On the origin, symptoms, and treatment of crural phlebitis, 881.

LECT. 45.—On diseases of the brain and mammae in puerperal women, 913.

Milk, M. Donné on the composition of, 717.

Mogford, Mr. on the removal of calculi from the bladder of the horse, 399.

Molecules, and molecular motion, Dr. J. W. Griffith on, 502.

Monomania, editorial observations on the plea of, in criminal cases, 776.

Monomania, hysteric, Dr. A. Lopez's case of 855.

Montrose Lunatic Asylum, extract from the report of the, 781.

Moon's rays, Mr. Berncastle on the influence of the 22.

Mortality, weekly tables of the in the metropolis, 32, 80, 112, 144, 176, 288, 336, 368, 400, 432, 512, 544, 576, 624, 656, 688, 720, 752, 784, 816, 848, 880, 912.

Mowbray, Mr. G. M. on citrate of iron, 836.

Muriatic acid, M. Henmann on the preparation of, 334.

Mineral waters of Greece, Dr. John Bouros' account of the, 917.

N.

Narcotic extracts, notice respecting the preparation of, by Mr. Battley, 288.

Needle, extraction of a, from the leg, supposed to have been accidentally swallowed, 362.

Nemo's remarks on medical reform, 109.

Niger, scenes on the, 878.

Nixon's, Mr. case in which severe after pains following labour were successfully treated by belladonna plasters, 133.

Nitrate of silver, Dr. Hocken on the application of the, to the outside of the eyelids in superficial diseases of the eye, 771.

Nitric acid, caution respecting, 877.

Norman, Mr. on the treatment of fractures by means of the starched bandage, 704.

Norris's, Dr. W. G. of Pennsylvania, case of compound dislocation of the first upon the second phalanx of the thumb, 333.

North of England Medical Association, account of the proceedings at the annual meeting of the, 217, 285.

Nott's, Dr. case of closure of the vagina in infants after death, 255.

News from Antigua, 910.

Notices, physiological, 940.

O.

Obre's, Mr. remarks on gangrene of the face, and its treatment, 75.

Oculists in Austria, 512.

Ogden, Dr. on a modification of Dr. Arnott's hydrostatic bed, 707.

Operations on the eye, by Professor Rosas, 511.

Operations in the London hospitals, Dr. Norman Chevers on the causes of death after, 252; Mr. King in reply, 287.

Ophthalmic surgery, Mr. France on, and remarks on the Royal Westminster ophthalmic report, 527.

Ophthalmic surgery at Vienna, 622.

Osteo-sarcoma of the thigh-bone, Mr. Frogley on two remarkably similar cases of, requiring amputation in both instances, 75.

Otto's, Professor, two cases of poisoning by lead, in Maccuba snuff, 133.

Ovarium, dropsical, Mr. Walne's second case of removal of, entire, by the large abdominal section, 544, 699; third case 944.

Ovarium, Dr. Frederick Bird's case of removal of an, which had been diseased for seventeen years, and in which paracentesis had been ten times performed, 732.

Ovaria, dropsical, Mr. Camplin on the removal of, 806.

Ovaria, dropsical, Dr. Frederick Bird on the removal of, in reply to Mr. Camplin, 846.

Owen's, Professor, Hunterian lectures for 1843, reviewed, 775.

P.

Parker's, Mr. case of abdominal presentation, 771.

Paralysis Dr. West on some forms of, incidental to infancy and childhood, 829.

Patella, Dr. P. Gazzan's case of luxation of the, on its axis, 845.

Painlessness of a mortal wound, 719; Dr. Alluatt's case, 727.

Paris milk, M. Donn  on the bad quality of, 717.

Paralysis in teething children, Mr. G. Colmer on, 143.

Parkin, Mr. on the efficacy of carbonic acid gas in gout, 131.

Peace's, Dr. case of ligature of the common iliac artery, 431.

Pelvis, Dr. Knox on the variety in form of the, 554.

Perforation of the stomach, Dr. Holland's case of, and consequent peritonitis, 97.

Percy's, Dr. John, case of diabetes mellitus, with numerous observations, and a review of the pathology and treatment of this disease, 44, 88, 119, 591, 640.

Pereira's, Dr. treatise on food and diet, reviewed, 506.

Pereira, Dr. on the varieties of sugar, 573.

Pessary, description of a new kind, invented by Mr. Snow, 400.

Pharynx, Mr. Deazeley's case of tumor of the, 868.

Philomathes, remarks by, on medical reform, 139, 281.

Phillips, Mr. Benjamin, on seminal and other discharges from the urethra, 215.

Phosphates in potatoes, 79.

Phthisis, Dr. C. M. Durrant on the nature, treatment, and diagnosis of, 324, 354.

Physicians of Dantzic, character of, sixty years since, 142.

Pilula ferri compositum, form for the preparation of the, 719.

Poisons, Dr. Watts on the tissue upon which their remote action is exerted, 468, 491.

Poisoning, suspected, Mr. Holland on the medico-legal evidence in a case of, 171.

Poisoning by lead, in Maccuba snuff, Professor Otto's two cases of, 138.

Poisoning, suspected, Mr. J. G. Harrison on the medico-legal evidence in a case of, 286.

Population of England, editorial remarks on the, 73.

Potatoes, proportion of the phosphates in, 80.

Potatoes, Dr. Golding Bird on the phosphates in, 110.

Presentation of the belly, Dr. Holmes's case of, 648; Mr. Parker's case of, 771.

Pretty's, Mr. case of loss of irritability in the glottis following a wound in the throat, 742.

Private tuition, editorial observations on, 615, 681.
 Professional success, editorial remarks on the most likely means for the attainment of, 472.
 Prolapsus uteri, Mr. Durant's case of reduction of, after sixteen years' continuance, 31.
 Pseudo-eructation, Dr. C. G. Child on, 386.
 Public health, Dr. Leonard Stewart's oration on, delivered on the 70th anniversary of the London Medical Society, 38.
 Pathology, Mr. Gulliver's notes on, 937.
 Phlebitis, Dr. R. Chapman's cases of, with some preliminary remarks on its pathology and treatment, 921.
 Physiological notes, 937.
 Poor-law Unions, legal opinion as to the qualifications required for holding offices under the, 910.
 Puerperal convulsions, Dr. S. Harrison on the treatment of, before the full term of utero-gestation, 892.

Q.

Quack medicines, editorial remarks on the sale of, 210.
 Queen's College, Birmingham, charter of incorporation conferred on the, with the appointments under it, 656.
 Quinine, sulphate of, Mr. Ranking on the occasional poisonous properties of, 72.
 Quinine, death from a large dose of the sulphate of, 430.
 Qualifications of medical officers of the poor-law unions, legal opinion as to the, 910.
 Quackery, editorial observations on, 902.

R.

Raciborski's, Dr. A. pathological studies on menstruation, 718.
 Randall, Mr. on a process for hydro-sulphuret of ammonia, 622.
 Ranking, Dr. on the occasional poisonous properties of sulphate of quinine, 72.
 Regulations of the College of Surgeons, with remarks upon them, by the editor, 779.
 Remuneration in general practice, editorial remarks on, 536.
 Respiration and food, M. Virey's objections to Liebig's theory of the use of, 254.
 Retina, Dr. Hocken on the varieties, causes, pathology, and treatment of the inflammatory affections of the, 476.
 Retreat, near York, extract from Mr. Thurnam's report of the, 783.
 Rheumatico-catarthal fever, case of, with metastasis to the toes, 432.

Rickets, Mr. Alexander Shaw on the influence of, upon the growth of the skull, 539.
 Rickets, Dr. L. R. Smyth on:—question of the ancient or modern origin of the disease, 562; opinions of Glisson, Bate, some Italian physicians, and others on this point, 562; history, description, and morbid appearances of the disease, 563; observations on the pulse and circulation, 566.
 Robertson's, Mr. John, observations shewing early marriages, so common in oriental countries, to be no proof of puberty, 609, 666.
 Robinson's British Quarterly Journal of Dental Surgery, reviewed, 425.
 Robinson, Mr. G. on the mechanism of absorption, 318.
 Roots, Dr. Houlton on the collection and preservation of, for medicinal purposes, 719.
 Rosas', Professor, operations on the eye, 511.
 Royal Medical and Chirurgical Society, papers read at the:—Mr. Frogley on two remarkably similar cases of osteo-sarcoma of the thigh-bone, requiring amputation in both instances, 75; Mr. Obre's remarks on gangrene of the face, and its treatment, *ib.*; Dr. Hunt on cancrum oris, and phagedena of the cheek, and on the effect of the chlorate of potash on those diseases, 76; Mr. Luke's cases of strangulated hernia reduced, *en masse* with observations, 212; Dr. Clendinning on the medicinal properties of Indian hemp, 279; Mr. Ure on the removal of blindness depending upon palsy of the iris, 280; Dr. Bence Jones on the sugar in the blood in diabetes, 278; Mr. Liston's observations on encysted hydrocele, 366; Dr. Bell's account of an epidemic which prevailed at Teheran in the months of January and February 1843, 367; Dr. Hodgkin on the characters and structural peculiarities of a group of morbid growths in which cancerous affections are included, 475; Mr. Dalrymple on the nature of the ossification of encysted tumors, 476; Dr. Hocken on the varieties, causes, pathology, and treatment of the inflammatory affections of the retina, *ib.*; Mr. Lloyd on the presence of spermatozoa in the fluid of common hydrocele, *ib.*; Mr. Alexander Shaw on the influence of rickets on the growth of the skull, 539; Sir Benjamin Brodie's account of a case in which a foreign body was lodged in the right bronchus, 540; Dr. Webster on the statistics of Bethlem Hospital, with some remarks on insanity, 541; Mr. Lloyd's account of a third case in which he had met with spermatozoa in the fluid of hydrocele, *ib.*; Mr. Toynbee's practical researches into the local causes of deafness, 542.

Rupture of the vagina, Mr. Sankey's case of, 837.

Regulations to be observed by students intending to qualify for practice in England and Wales, 1843, 907.

S.

St. Marylebone Infirmary, analytical table of the cases treated in the, for 1841, 878.

St. Peter's Hospital, Bristol, Dr. W. Budd and Dr. O'Brien elected physicians to, 688.

Sacral vertebræ, Dr. Knox on the form, &c. of the, 587.

Sankey's, Mr. W. H. O. remarks on medical reform, 394, 429.

Sankey's, Mr. W. H. O. case of rupture of the vagina, 837.

Salmon's, Mr. note on stricture of the rectum, 880.

Scarlet fever, Dr. J. H. Watts on a case of, in which symptoms like croup came on, for which tracheotomy was performed, 202; Sergeant Domville's remarks in continuation of the case, 204.

Scarlatina anginosa, Mr. Charles Vines' case of, 243.

Seasons, Dr. Guy on the influence of the, 874.

Sedillot's, M. case of hemiplegia from tying the common carotid artery, 400.

Seminal discharges, Mr. B. Phillips on, 315.

Senna, Dr. Christison on the preparation of the fluid extract of, 877.

Shaw, Mr. Alexander, on the influence of rickets upon the growth of the skull, 539.

Sherwin, Mr. H. C. on the treatment of calculi in the bladder, 800.

Skin, Dr. Willis on the special function of the, 107.

Skin, human, and its pathology, Dr. Otho Wuchurer on the, 54, 93.

Skin, Mr. John E. Erichsen on the employment of arsenic in certain diseases of the, 196, 238.

Skull, Mr. Alexander Shaw on the influence of rickets upon the growth of the, 539.

Smee, Mr. Alfred, on the inhalation of ammonia gas, as a remedial agent, 59.

Smyth's, Dr. James Richard, miscellaneous contributions to pathology and therapeutics:—rickets, 267; pathology and treatment of the affection, *ib.*; connection with enlargement of the liver and indigestion, 270; its affinity to scrofula, 272; scrofula—its pathology and treatment, *ib.*; gastrodynia—sometimes cured by a dietetical remedy, 273; chronic hydrocephalus—a cerebral murmur symptomatic of its first stage, 273.

Smyth's, Dr. J. R. miscellaneous contributions to pathology and therapeutics:—rickets, 562.

Snow's, Mr. description of a new pessary, 100.

Society for Relief of Widows and Orphans of Medical Men in London and its Vicinity, 336, 368; editorial remarks on the Society, 388.

Society for Relief of Widows and Orphans of Medical Men in London and its Vicinity, election of H. R. H. the Duke of Cambridge as President, 573.

Solly's, Mr. Samuel, clinical lecture on injuries of the head, 233, 334.

Southam, Mr. George, on the injurious effects of mesmerism, 352, 459.

Spermatozoa observed a second time within the ovum, by Dr. Martin Barry, 73.

Spermatozoa, Mr. E. A. Lloyd on the presence of, in the fluid of common hydrocele, 476, 541.

Spiders discharged from the eye, Dr. A. Lopez's case of, 835.

Spinal arachnoid, Dr. Knox on the structure and arrangement of the, 463.

Splenitis, Mr. Tapson's case of, coming on after intermittent fever; with rheumatism and signs of incipient phthisis, 214.

Stafford, Mr. R. A. on the treatment of hæmorrhoids or piles, 62.

Starched bandage, Mr. M'Cash on the evil consequences of the too early application of the, in a case of simple fracture of the fore-arm, 602.

Stallard's Mr. case of polypoid tumor in the trachea, 275.

Stewart's, Dr. Leonard, oration, on public health, delivered on the 70th anniversary of the London Medical Society, 38.

Stomach, Dr. Holland's case of perforation of the, and consequent peritonitis, 97.

Stöber, Dr. on the diseases of children, 510, 543.

Stokes, Dr. on cirrhosis of the lung, 287.

Strabismus, M. Jules Guerin on, 254.

Stricture of the rectum, melancholy case at Bath, erroneously treated as, 847.

Stricture of the rectum, Mr. Frederick Salmon's note on, 880.

Stumps, Mr. Leach on the treatment of, after amputation, by irrigation and water-dressing, 802.

Sugar, Dr. Pereira on the varieties of, 573.

Sunderland's, Dr. John, clinical lectures on the theory and medical treatment of insanity—see "Insanity, Dr. A. J. Sutherland's clinical lectures on the theory and medical treatment of."

Sulphate of quinine, death from a large dose of 430.

Sydenham's works, suggestion respecting the publication of, by a member of the Sydenham Society, 848.

Salt, adulteration of, at Paris, 912.

Society of Apothecaries, new regulations of the, 907.

Stricture, Mr. Hudson on the efficacy of warm injections in, 930.

T.

Tapson's, Mr. Alfred J. Fellowes' Clinical Prize Reports:—Erysipelas of the face, followed by scarlatina and an abundant minute vesicular eruption, cured by aperients, antimonials, &c. 104; splenitis, coming on after intermittent fever, with rheumatism, and signs of incipient phthisis, 214; melancholia coming on during pregnancy, without much, if any, derangement of the general health—considerably relieved by aperients, morphia, and tonics, 392; measles in an adult—treated by mercury, saline draughts, tartar emetic, &c. 477; enteritis, ushered in by copious discharges of blood from the bowels, and marked by the usual symptoms of a mild attack of enteritis, 618; delirium tremens, complicated with, and somewhat masked by, pneumonia; and when both these had been cured by the use of opium, calomel, tartar emetic, and leeches, an attack of hepatitis came on, which was successfully treated by cupping, blue pill, and taraxacum, 683; hemiplegia et tuberculæ pulmonum—the former treated by cupping, purging, cantharides, &c. with considerable benefit, 747.

Tartar on the teeth, M. Mandl on the, 843.

Taylor, Dr. on a new test for arsenic, 575.

Taylor, Dr. A. on the curative influence of the climate of Pau, reviewed, 776.

Tensor tarsi, Dr. Knox's observations on the muscle of the, 861.

Therapeutics, Dr. Venables on certain sources of fallacy in, their causes, consequences, and the means of preventing them, 414.

Thomson, Dr. R. D. on the proper method of studying chemistry as a branch of professional and general education, 763.

Thompson's, Dr. J. B. observations on the climate of the British Colonies of New Zealand, New South Wales, and Van Dieman's Land, as compared with that of the Brazils, Madeira, and the Continent of Europe, 766.

Thurnam's, Mr. report of the Retreat, near York, 783.

Tinea capitis, Dr. Wigan on the cure of, 864.

Tissues, animal, Mr. Toynbee's researches tending to prove the non-vascularity and the peculiar uniform mode of organization and nutrition of, 67.

Toynbee's, Mr. J. researches to prove the non-vascularity and the peculiar uniform

mode of organization and nutrition of certain animal tissues, 67.

Toynbee's, Mr. case of strangulated femoral hernia, in which the sac was distended with fluid blood, 209.

Toynbee's, Mr. practical researches into the local causes of deafness, 542.

Todd's, Dr. R. B. practical remarks on gout, rheumatic fever, and chronic rheumatism of the joints, reviewed, 424.

Toothache, cat's mint recommended as a remedy for, 480.

Transactions of the Provincial Medical and Surgical Association, Vol. II. reviewed, 567.

Tracheotomy, Mr. Erichsen on the sensibility of the glottis after the performance of, with the description of a new instrument, 566; remarks on this paper by "E," 720; reply to, by Mr. Erichsen, 751.

Trachea, Dr. Burridge on the removal of foreign bodies from the, with reference more particularly to the treatment of the recent case of Mr. Brunel, 323.

Trichina spiralis, Dr. Knox's notice respecting the, 805.

Tumor, polypoid, in the trachea, Mr. Stalard's case of, 275.

Tumors, encysted, Mr. Dalrymple on the nature of the ossification of, 476.

Tumor of the pharynx, Mr. Deazeley's case of, 868.

Tumor, non-malignant, of the breast, of four years' standing, successfully removed, 174.

Tunica vaginalis testis, Dr. Knox on obliteration of the cavity of the, in middle-aged and old persons, 860.

Turpentine, oil of, M. Bouchardat on a convenient mode for the administration of, 911.

Tyrrell, Mr. Frederick, notice of the sudden death of, 336; examination of the body, 365.

U.

University of London, examinations for bachelor of medicine:—anatomy and physiology, 715; chemistry, 716; materia medica and pharmacy, *ib.*; structural and physiological botany, *ib.*

University of London, examinations for honours:—anatomy and physiology, 780; chemistry, *ib.*; materia medica and pharmaceutical chemistry, *ib.*

Unions, Mr. G. J. Guthrie on the payment of medical officers to, 112.

Unlucky births, 752.

Urea and uric acid, Mr. Ancell on the production of, 385.

Urethra, Mr. B. Phillips on seminal and other discharges from the, 315.

Urethra, on superficial cauterization of the, for the cure of gonorrhœa, 816.

Ure, Mr. Alexander, on the removal of blindness depending upon palsy of the iris, 280.

Urinary deposits, Dr. Golding Bird on the physical and pathological characters of:—carbonate of lime, 10; cause of ammoniacal urine, *ib.*; phosphatic deposits, 11; solubility of phosphates in ammoniacal salts, 12; in carbonic acid, *ib.*; deposited by boiling, *ib.*; mistaken for mucus, *ib.*; crystalline forms of, 13; phosphate of lime, 14; varieties of phosphatic urine, *ib.*; sources of phosphates, 15; traced to vegetable ingesta, and destructive assimilation of nervous tissue, 16; pathology of deposits of triple phosphate and phosphate of lime, 153; foetid urine, 154; phosphates in old people, *ib.*; in irritable bladder, *ib.*; treatment, *ib.*; siliceous deposits, 155; organised deposits, 156; supposed filament in blood-discs, *ib.*; pus, *ib.*; mucus, 157; organic globules, *ib.*; ferment, 158; torula cervicis, *ib.*; epithelial debris, *ib.*

V.

Vaccine report to the Secretary of State for the Home Department, 29.

Vagina, Dr. Nott on closure of the, in infants after birth, 255.

Vagina, Mr. Walter C. Dendy's case of closure of the, 317.

Vagina, Mr. Sankey's case of rupture of the, 837.

Varus mentagra and gutta rosea, M. Daurverger's cases of, treated with sulphate of iron externally, 911.

Vascular nævus, treatment of, 943.

Venables, Dr. observations on certain sources of fallacy in therapeutics, their causes, consequences, and the means of preventing them, 414.

Vines', Mr. Charles, case of scarlatina anginosa, 243.

Vines', Mr. Charles, case of meningitis, 422.

Virey's, M. objections to Liebig's theory of the uses of respiration and of food, 254.

Vivisection, Dr. Hull on, 882.

Vivisection, Mr. Macilwain on, 897.

Vivisection, some remarks by Dr. Samuel Johnson on the subject of, 941.

W.

Walne, Mr. on the removal of dropsical

ovaria, entire, by the large abdominal section, second case, 544, 699; third case, 944.

Warren's, Dr. J. Mason, operations for fissure of the soft and hard palate, 876.

Watts, Dr. on the tissue upon which the remote actions of poisons is exerted, 468, 491.

Watts's, Dr. J. H. account of a case in which symptoms like croup came on after scarlet-fever, and in which tracheotomy was performed, 202; Sergeant Domville's remarks in continuation of the case, 204.

Webb, Mr. on roaring in the horse, 877.

Webster, Dr. on the statistics of Bethlem Hospital, with remarks on insanity, 541.

Western Lying-in Hospital, Dublin, medical report of the, 620.

West's, Dr. observations on some of the more important diseases of childhood:—on endocarditis, 738; on a peculiar form of croup which occurs as a complication of measles, 796; on some forms of paralysis incidental to infancy and childhood, 829.

Wharton's, Dr. case of artificial anus, 940.

Whitshed's, Mr. case of difficult parturition, 206.

Widows' and Orphans' Society, postponement of the annual dinner of the, 170.

Wigan, Dr. on the treatment of tinea capitis, 864.

Wilde's, Mr. work on the literary, scientific, and medical institutions of Austria, reviewed, 425.

Willis's, Dr. essays on diseases of the heart, great vessels, and circulating fluids—see "Heart, Dr. Willis on the diseases of the."

Willis, Dr. on the special function of the skin, 107.

Williams, Dr. Thomas, on the homology of the foetal circulation, 17, 80.

Women and children, editorial observations on the employment of, as agricultural labourers, 710.

Worcestershire, meeting of the profession in, with copy of petition to parliament, 76.

Wound of the chest, Mr. M'Pherson's case of, accompanied with diarrhœa and excessive vomiting, 322.

Wound of the aorta and pericardium, 880.

Wound, a mortal, painlessness of, 719; Dr. Allnatt's case, 727.

Wuchurer, Dr. Otho, on the human skin, and its pathology, 54, 93.

Y.

Yellow bark, Mr. Battley's pharmaceutical analysis of, 159.
